To create an index, call [Create Index \(preview\)](#):

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sharepoint-index",
    "fields": [
        { "name": "id", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "metadata_spo_item_name", "type": "Edm.String", "key": false, "searchable": true, "filterable": false,
"sortable": false, "facetable": false },
        { "name": "metadata_spo_item_path", "type": "Edm.String", "key": false, "searchable": false, "filterable": false,
"sortable": false, "facetable": false },
        { "name": "metadata_spo_item_content_type", "type": "Edm.String", "key": false, "searchable": false, "filterable": true,
"sortable": false, "facetable": true },
        { "name": "metadata_spo_item_last_modified", "type": "Edm.DateTimeOffset", "key": false, "searchable": false, "filterable": false,
"sortable": true, "facetable": false },
        { "name": "metadata_spo_item_size", "type": "Edm.Int64", "key": false, "searchable": false, "filterable": false,
"sortable": false, "facetable": false },
        { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false, "sortable": false, "facetable": false }
    ]
}
```

① Important

Only [metadata spo site library item id](#) may be used as the key field in an index populated by the SharePoint in Microsoft 365 indexer. If a key field doesn't exist in the data source, `metadata_spo_site_library_item_id` is automatically mapped to the key field.

If your indexer will use either [SharePoint ACL configuration \(preview\)](#) or will [preserve and honor Microsoft Purview sensitivity labels \(preview\)](#), review each article for index and skillset configuration before proceeding with indexer creation since those functionalities have specific configurations.

Step 6: Create an indexer

An indexer connects a data source with a target search index and provides a schedule to automate the data refresh. Once the index and data source are created, you can create the indexer.

If you're using delegated permissions, during this step, you're asked to sign in with organization credentials that have access to the SharePoint site. If possible, we recommend creating a new organizational user account and giving that new user the exact permissions that you want the indexer to have.

There are a few steps to creating the indexer:

1. Send a [Create Indexer \(preview\)](#) request:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sharepoint-indexer",
    "dataSourceName" : "sharepoint-datasource",
    "targetIndexName" : "sharepoint-index",
    "parameters": {
        "batchSize": null,
        "maxFailedItems": null,
        "base64EncodeKeys": null,
        "maxFailedItemsPerBatch": null,
        "configuration": {
            "indexedFileNameExtensions" : ".pdf, .docx",
            "excludedFileNameExtensions" : ".png, .jpg",
            "dataToExtract": "contentAndMetadata"
        }
    },
    "schedule" : { },
    "fieldMappings" : [
        {
            "sourceFieldName" : "metadata_spo_site_library_item_id",
            "targetFieldName" : "id",
            "mappingFunction" : {
                "name" : "base64Encode"
            }
        }
    ]
}
```

If you're using application permissions, it's necessary to wait until the initial run is complete before starting to query your index. The following instructions provided in this step pertain specifically to delegated permissions, and aren't applicable to application permissions.

2. When you create the indexer for the first time, the [Create Indexer \(preview\)](#) request waits until you complete the next step. You must call [Get Indexer Status](#) to get the link and enter your new device code.

HTTP

```
GET https://[service name].search.windows.net/indexers/sharepoint-indexer/status?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]
```

If you don't run the [Get Indexer Status](#) within 10 minutes, the code expires and you'll need to recreate the [data source](#).

3. Copy the device login code from the [Get Indexer Status](#) response. The device login can be found in the "errorMessage".

HTTP

```
{
    "lastResult": {
        "status": "transientFailure",
        "errorMessage": "To sign in, use a web browser to open the page https://microsoft.com/devicelogin and enter the code <CODE> to authenticate."
    }
}
```

4. Provide the code that was included in the error message.

5. The SharePoint in Microsoft 365 indexer will access the SharePoint content as the signed-in user. The user that logs in during this step will be that signed-in user. So, if you sign in with a user account that doesn't have access to a document in the Document Library that you want to index, the indexer won't have access to that document.

If possible, we recommend creating a new user account and giving that new user the exact permissions that you want the indexer to have.

6. Approve the permissions that are being requested.

7. The [Create Indexer \(preview\)](#) initial request completes if all the permissions provided above are correct and within the 10 minute timeframe.

Note

If the Microsoft Entra application requires admin approval and was not approved before logging in, you may see the following screen. [Admin approval](#) is required to continue. A screenshot of a web browser showing a consent screen from Microsoft Entra. It asks for permission to access the user's profile information. The user has selected 'Allow' and is prompted to 'Sign in with Microsoft'. Below the consent screen, there is a message: 'Admin approval is required to continue. Please sign in with your organization's administrator account.' There is also a link to 'Get help'.

Step 7: Check the indexer status

After the indexer has been created, you can call [Get Indexer Status](#):

HTTP

```
GET https://[service name].search.windows.net/indexers/sharepoint-indexer/status?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]
```

Updating the data source

If there are no updates to the data source object, the indexer runs on a schedule without any user interaction.

If you change the data source while the device code is expired, sign in again to run the indexer. For example, if you change the data source query, sign in again using the <https://microsoft.com/devicelogin> and get the new device code.

Here are the steps for updating a data source, assuming an expired device code:

1. Call [Run Indexer \(preview\)](#) to manually start [indexer execution](#).

HTTP

```
POST https://[service name].search.windows.net/indexers/sharepoint-indexer/run?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]
```

2. Check the [indexer status](#).

HTTP

```
GET https://[service name].search.windows.net/indexers/sharepoint-indexer/status?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]
```

3. If you get an error asking you to visit <https://microsoft.com/devicelogin>, open the page and copy the new code.

4. Paste the code into the dialog box.

5. Manually run the indexer again and check the indexer status. This time, the indexer run should successfully start.

Indexing document metadata

If you're indexing document metadata (`"dataToExtract": "contentAndMetadata"`), the following metadata is available to index.

Expand table

Identifier	Type	Description
metadata_spo_site_library_item_id	Edm.String	The combination key of site ID, library ID, and item ID, which uniquely identifies an item in a document library for a site.
metadata_spo_site_id	Edm.String	The ID of the SharePoint site.
metadata_spo_library_id	Edm.String	The ID of document library.
metadata_spo_item_id	Edm.String	The ID of the (document) item in the library.
metadata_spo_item_last_modified	Edm.DateTimeOffset	The last modified date/time (UTC) of the item.
metadata_spo_item_name	Edm.String	The name of the item.
metadata_spo_item_size	Edm.Int64	The size (in bytes) of the item.
metadata_spo_item_content_type	Edm.String	The content type of the item.
metadata_spo_item_extension	Edm.String	The extension of the item.
metadata_spo_item_weburi	Edm.String	The URI of the item.
metadata_spo_item_path	Edm.String	The combination of the parent path and item name.

The SharePoint in Microsoft 365 indexer also supports metadata specific to each document type. More information can be found in [Content metadata properties used in Azure AI Search](#).

① Note

To index custom metadata, "additionalColumns" must be specified in the [query parameter of the data source](#).

Include or exclude by file type

You can control which files are indexed by setting inclusion and exclusion criteria in the "parameters" section of the indexer definition.

Include specific file extensions by setting "`indexedFileNameExtensions`" to a comma-separated list of file extensions (with a leading dot). Exclude specific file extensions by setting "`excludedFileNameExtensions`" to the extensions that should be skipped. If the same extension is in both lists, it's excluded from indexing.

HTTP

```
PUT /indexers/[indexer name]?api-version=2025-11-01-preview
{
    "parameters" : {
        "configuration" : {
            "indexedFileNameExtensions" : ".pdf, .docx",
            "excludedFileNameExtensions" : ".png, .jpeg"
        }
    }
}
```

Controlling which documents are indexed

A single SharePoint in Microsoft 365 indexer can index content from one or more document libraries. To specify which sites and document libraries to index, use the "container" parameter in the data source definition.

The [data source "container" section](#) has two properties for this task: "name" and "query".

Name

The "name" property is required and must be one of three values:

 Expand table

Value	Description
defaultSiteLibrary	Index all content from the site's default document library.

Value	Description
allSiteLibraries	Index all content from all document libraries in a site. Document libraries from a subsite are out of scope/ If you need content from subsites, choose "useQuery" and specify "includeLibrariesInSite".
useQuery	Only index the content defined in the "query".

Query

The "query" parameter of the data source is made up of keyword/value pairs. The below are the keywords that can be used. The values are either site URLs or document library URLs.

① Note

To get the value for a particular keyword, we recommend navigating to the document library that you're trying to include/exclude and copying the URI from the browser. This is the easiest way to get the value to use with a keyword in the query.

[Expand table](#)

Keyword	Value description and examples
null	If null or empty, index either the default document library or all document libraries depending on the container name. Example: <pre>"container" : { "name" : "defaultSiteLibrary", "query" : null }</pre>
includeLibrariesInSite	Index content from all libraries under the specified site in the connection string. The value should be the URI of the site or subsite. Example 1: <pre>"container" : { "name" : "useQuery", "query" : "includeLibrariesInSite=https://mycompany.sharepoint.com/mysite" }</pre> Example 2 (include a few subsites only): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrariesInSite=https://mycompany.sharepoint.com/sites/TopSite/SubSite1;includeLibrariesInSite=https://mycompany.sharepoint.com/sites/TopSite/SubSite2" }</pre>
includeLibrary	Index all content from this library. The value is the fully qualified path to the library, which can be copied from your browser. Example 1 (fully qualified path): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrary=https://mycompany.sharepoint.com/mysite/MyDocumentLibrary" }</pre> Example 2 (URI copied from your browser): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrary=https://mycompany.sharepoint.com/teams/mysite/MyDocumentLibrary/Forms/AllI...</pre>
excludeLibrary	Don't index content from this library. The value is the fully qualified path to the library, which can be copied from your browser. Example 1 (fully qualified path): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrariesInSite=https://mysite.sharepoint.com/subsite1;excludeLibrary=https://mysite.sharepoint.com/subsite1/MyDocumentLibrary" }</pre> Example 2 (URI copied from your browser): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrariesInSite=https://mycompany.sharepoint.com/teams/mysite;excludeLibrary=https://mycompany.sharepoint.com/teams/mysite/MyDocumentLibrary/Forms/AllItems.aspx" }</pre>
additionalColumns	Index columns from the document library. The value is a comma-separated list of column names you want to index. Use a double backslash to escape commas in column names: Example 1 (additionalColumns=MyCustomColumn,MyCustomColumn2): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrary=https://mycompany.sharepoint.com/mysite/MyDocumentLibrary;additionalColumns=MyCustomColumn,MyCustomColumn2" }</pre> Example 2 (escape characters using double backslash): <pre>"container" : { "name" : "useQuery", "query" : "includeLibrary=https://mycompany.sharepoint.com/mysite/MyDocumentLibrary;additionalColumns=MyCustomColumn,MyCustomColumn2" }</pre>

Keyword	Value description and examples
	"includeLibrary=https://mycompany.sharepoint.com/teams/mysite/MyDocumentLibrary/Forms/AllItems.aspx;additionalColumns=MyCustomColumnWith\\n\\}

Handling errors

By default, the SharePoint in Microsoft 365 indexer stops as soon as it encounters a document with an unsupported content type (for example, an image). You can use the `excludedFileNameExtensions` parameter to skip certain content types. However, you might need to index documents without knowing all the possible content types in advance. To continue indexing when an unsupported content type is encountered, set the `failOnUnsupportedContentType` configuration parameter to false:

HTTP

```
PUT https://[service name].search.windows.net/indexers/[indexer name]?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]

{
    ... other parts of indexer definition
    "parameters" : { "configuration" : { "failOnUnsupportedContentType" : false } }
}
```

For some documents, Azure AI Search is unable to determine the content type, or unable to process a document of otherwise supported content type. To ignore this failure mode, set the `failOnUnprocessableDocument` configuration parameter to false:

HTTP

```
"parameters" : { "configuration" : { "failOnUnprocessableDocument" : false } }
```

Azure AI Search limits the size of documents that are indexed. These limits are documented in [Service Limits in Azure AI Search](#). Oversized documents are treated as errors by default. However, you can still index storage metadata of oversized documents if you set `indexStorageMetadataOnlyForOversizedDocuments` configuration parameter to true:

HTTP

```
"parameters" : { "configuration" : { "indexStorageMetadataOnlyForOversizedDocuments" : true } }
```

You can also continue indexing if errors happen at any point of processing, either while parsing documents or while adding documents to an index. To ignore a specific number of errors, set the `maxFailedItems` and `maxFailedItemsPerBatch` configuration parameters to the desired values. For example:

HTTP

```
{  
    ... other parts of indexer definition  
    "parameters" : { "maxFailedItems" : 10, "maxFailedItemsPerBatch" : 10 }  
}
```

If a file on the SharePoint site has encryption enabled, you might see the following error message:

Code: resourceModified Message: The resource has changed since the caller last read it; usually an eTag mismatch Inner error: Code: irmEncryptFailedToFindProtector

The error message will also include the SharePoint site ID, drive ID, and drive item ID in the following pattern: <sharepoint site id> :: <drive id> :: <drive item id>. This information can be used to identify which item is failing on the SharePoint end. The user can then remove the encryption from the item to resolve the issue.

Skillset concepts in Azure AI Search

07/11/2025

This article is for developers who need a deeper understanding of skillset composition, and assumes familiarity with the high-level concepts of [AI enrichment](#), or applied AI, in Azure AI Search.

A skillset is a reusable object in Azure AI Search that's attached to [an indexer](#). It contains one or more skills that call built-in AI or external custom processing over documents retrieved from an external data source.

The following diagram illustrates the basic data flow of skillset execution.

From the onset of skillset processing to its conclusion, skills read from and write to an [enriched document tree](#) that exists in memory. Initially, an enriched document is just the raw content extracted from a data source (articulated as the `"/document"` root node). With each skill execution, the enriched document gains structure and substance as each skill writes its output as nodes in the graph.

After skillset execution is done, the output of an enriched document is routed to an index through user-defined *output field mappings*. Any raw content that you want transferred intact, from source to an index, is defined through *field mappings*. In contrast, *output field mappings* transfer in-memory content (nodes) to the index.

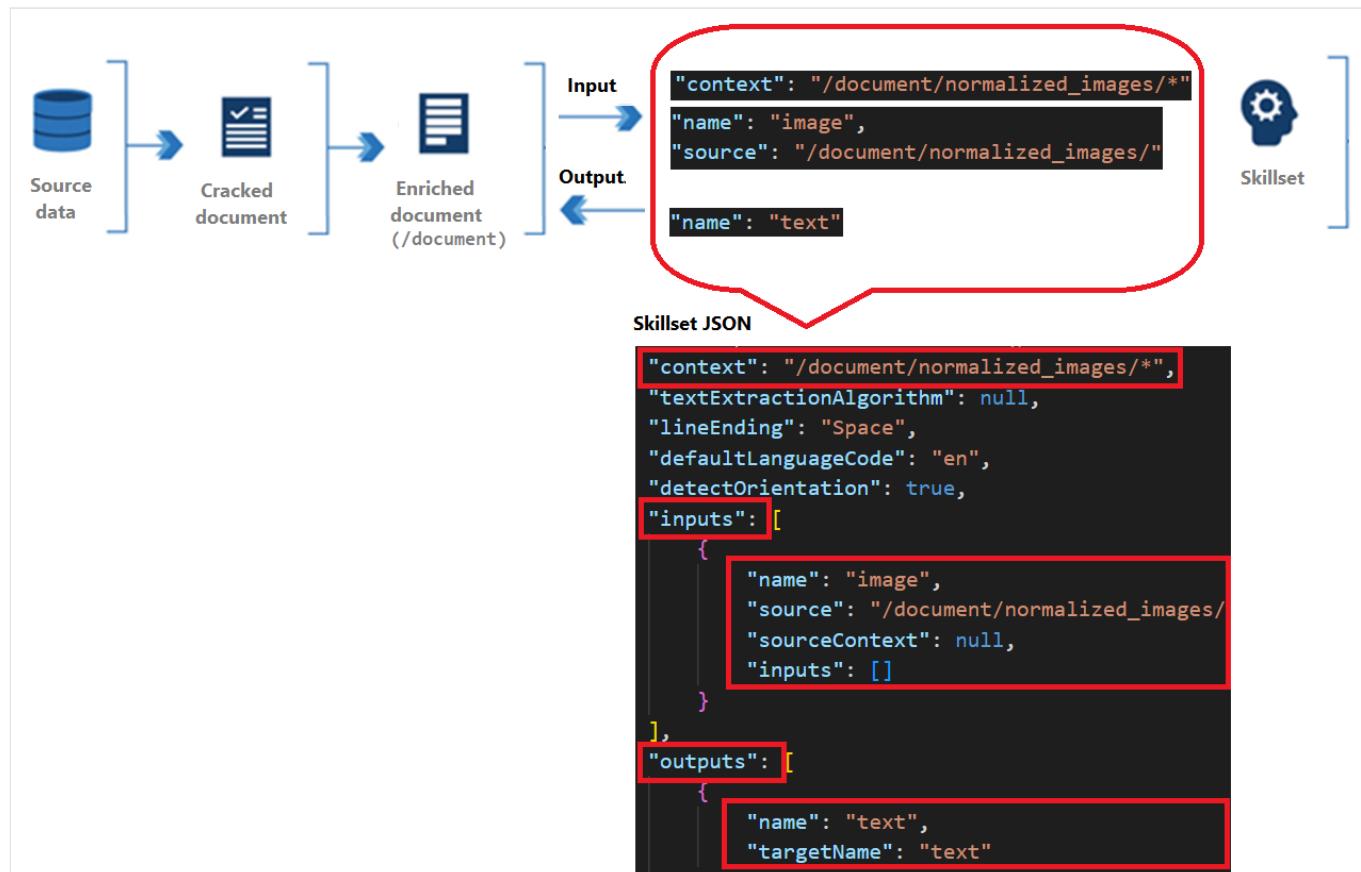

To configure applied AI, specify settings in a skillset and indexer.

Skillset definition

A skillset is an array of one or more *skills* that perform an enrichment, such as translating text or optical character recognition (OCR) on an image file. Skills can be the [built-in skills](#) from Microsoft, or [custom](#)

skills for processing logic that you host externally. A skillset produces enriched documents that are either consumed during indexing or projected to a knowledge store.

Skills have a context, inputs, and outputs:

- **Context** refers to the scope of the operation, which could be once per document or once for each item in a collection.
- Inputs originate from nodes in an enriched document, where a "source" and "name" identify a given node.
- Output is sent back to the enriched document as a new node. Values are the node "name" and node content. If a node name is duplicated, you can set a target name for disambiguation.

Skill context

Each skill has a context, which can be the entire document (`/document`) or a node lower in the tree (`/document/countries/*`).

A context determines:

- The number of times the skill executes, over a single value (once per field, per document), or for a collection, where adding an `/*` results in skill invocation for each instance in the collection.
- Output declaration, or where in the enrichment tree the skill outputs are added. Outputs are always added to the tree as children of the context node.

- Shape of the inputs. For multi-level collections, setting the context to the parent collection affects the shape of the input for the skill. For example if you have an enrichment tree with a list of countries/regions, each enriched with a list of states containing a list of ZIP codes, how you set the context determines how the input is interpreted.

[\[+\] Expand table](#)

Context	Input	Shape of Input	Skill Invocation
/document/countries/*	/document/countries/*/states/*/zipcodes/*	A list of all ZIP codes in the country/region	Once per country/region
/document/countries/*/states/*	/document/countries/*/states/*/zipcodes/*	A list of ZIP codes in the state	Once per combination of country/region and state

Skill dependencies

Skills can execute independently and in parallel, or sequentially in a dependent relationship if you feed the output of one skill into another skill. The following example demonstrates two [built-in skills](#) that execute in sequence:

- Skill #1 is a [Text Split skill](#) that accepts the contents of the "reviews_text" source field as input, and splits that content into "pages" of 5,000 characters as output. Splitting large text into smaller chunks can produce better outcomes for skills like sentiment detection.
- Skill #2 is a [Sentiment Detection skill](#) depends on the split skill output. It accepts "pages" as input, and produces a new field called "Sentiment" as output that contains the results of sentiment analysis.

Notice how the output of the first skill ("pages") is used in sentiment analysis, where "/document/reviews_text/pages/*" is both the context and input. For more information about path formulation, see [How to reference enrichments](#).

```
JSON
{
  "skills": [
    {
      "@odata.type": "#Microsoft.Skills.Text.SplitSkill",
      "name": "#1",
      "description": null,
      "context": "/document/reviews_text",
      "defaultLanguageCode": "en",
      "textSplitMode": "pages",
      "maximumPageLength": 5000,
      "inputs": [
        {
          "id": "#1"
        }
      ]
    },
    {
      "@odata.type": "#Microsoft.Skills.Text.SentimentSkill",
      "name": "#2",
      "description": null,
      "context": "/document/reviews_text/pages/*",
      "defaultLanguageCode": "en",
      "sentimentType": "TextClassification"
    }
  ]
}
```

```

        {
            "name": "text",
            "source": "/document/reviews_text"
        }
    ],
    "outputs": [
        {

            "targetName": "sentences"
        }
    ]
}
...
]
}

```

Enrichment tree

An enriched document is a temporary, tree-like data structure created during skillset execution that collects all of the changes introduced through skills. Collectively, enrichments are represented as a hierarchy of addressable nodes. Nodes also include any unenriched fields that are passed in verbatim from the external data source. The best approach for examining the structure and content of an enrichment tree is through a [debug session](#) in the Azure portal.

An enriched document exists for the duration of skillset execution, but can be [cached](#) or sent to a [knowledge store](#).

Initially, an enriched document is simply the content extracted from a data source during [document cracking](#), where text and images are extracted from the source and made available for language or image analysis.

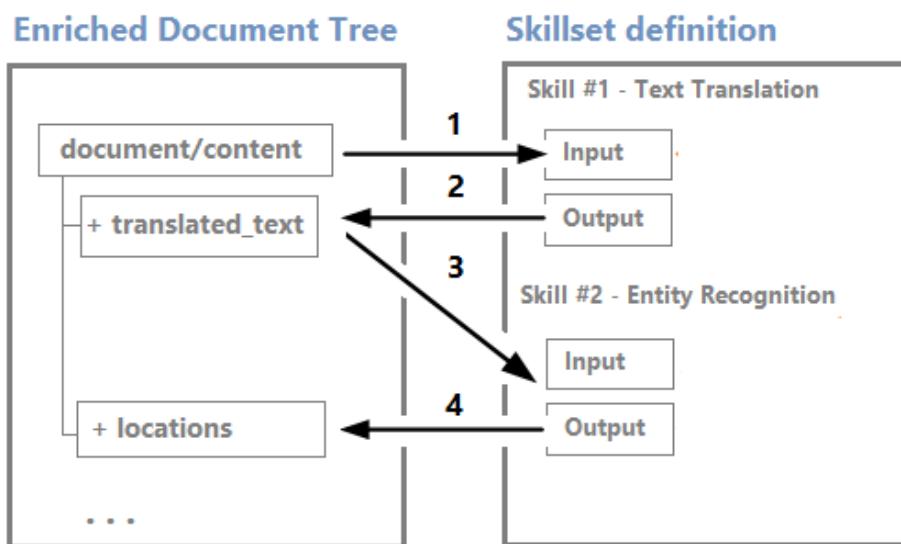

The initial content is metadata and the *root node* (`document/content`). The root node is usually a whole document or a normalized image that is extracted from a data source during document cracking. How it's articulated in an enrichment tree varies for each data source type. The following table shows the state of a document entering into the enrichment pipeline for several supported data sources:

[\[\] Expand table](#)

Data Source\Parsing Mode	Default	JSON, JSON Lines & CSV
Blob Storage	/document/content /document/normalized_images/* ...	/document/{key1} /document/{key2} ...
Azure SQL	/document/{column1} /document/{column2} ...	N/A
Azure Cosmos DB	/document/{key1} /document/{key2} ...	N/A

As skills execute, output is added to the enrichment tree as new nodes. If skill execution is over the entire document, nodes are added at the first level under the root.

Nodes can be used as inputs for downstream skills. For example, skills that create content, such as translated strings, could become input for skills that recognize entities or extract key phrases.

Although you can visualize and work with an enrichment tree through the [Debug Sessions visual editor](#), it's mostly an internal structure.

Enrichments are immutable: once created, nodes can't be edited. As your skillsets get more complex, so will your enrichment tree, but not all nodes in the enrichment tree need to make it to the index or the knowledge store.

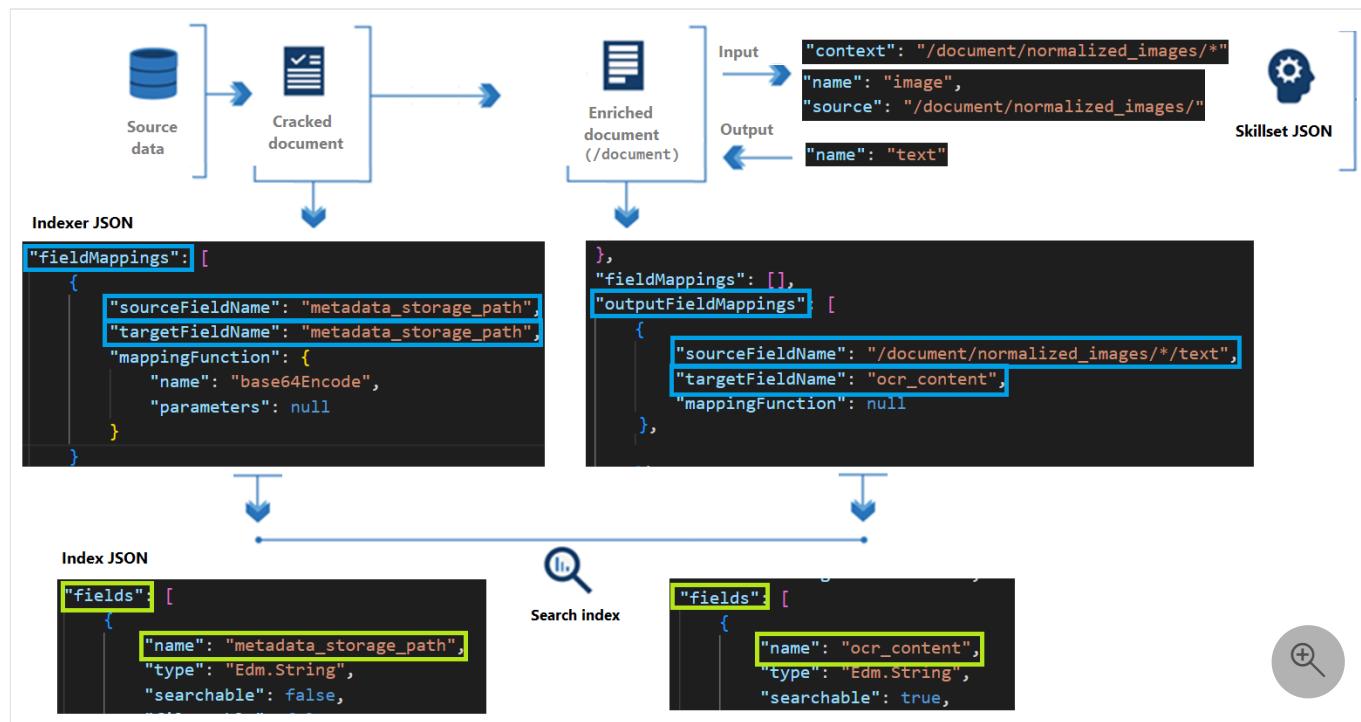

You can selectively persist just a subset of the enrichment outputs so that you're only keeping what you intend to use. The [output field mappings](#) in your indexer definition determines what content actually gets ingested in the search index. Likewise, if you're creating a knowledge store, you can map outputs into [shapes](#) that are assigned to projections.

ⓘ Note

The enrichment tree format enables the enrichment pipeline to attach metadata to even primitive data types. The metadata won't be a valid JSON object, but can be projected into a valid JSON format in projection definitions in a knowledge store. For more information, see [Shaper skill](#).

Indexer definition

An indexer has properties and parameters used to configure indexer execution. Among those properties are mappings that set the data path to fields in a search index.

There are two sets of mappings:

- "["fieldMappings"](#)" map a source field to a search field.
- "["outputFieldMappings"](#)" map a node in an enriched document to a search field.

The "sourceFieldName" property specifies either a field in your data source or a node in an enrichment tree. The "targetFieldName" property specifies the search field in an index that receives the content.

Enrichment example

Using the [hotel reviews skillset](#) as a reference point, this example explains how an [enrichment tree](#) evolves through skill execution using conceptual diagrams.

This example also shows:

- How a skill's context and inputs work to determine how many times a skill executes
- What the shape of the input is based on the context

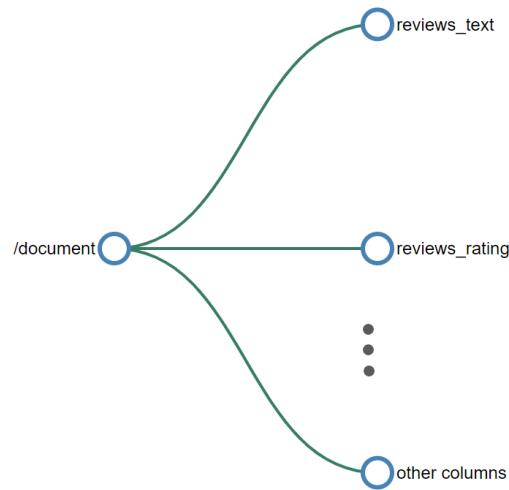

In this example, source fields from a CSV file include customer reviews about hotels ("reviews_text") and ratings ("reviews_rating"). The indexer adds metadata fields from Blob storage, and skills add translated text, sentiment scores, and key phrase detection.

In the hotel reviews example, a "document" within the enrichment process represents a single hotel review.

Tip

You can create a search index and knowledge store for this data in [Azure portal](#) or [REST APIs](#). You can also use [Debug Sessions](#) for insights into skillset composition, dependencies, and effects on an enrichment tree. Images in this article are pulled from Debug Sessions.

Conceptually, the initial enrichment tree looks as follows:

The root node for all enrichments is `"/document"`. When you're working with blob indexers, the `"/document"` node has child nodes of `"/document/content"` and `"/document/normalized_images"`. When the data is CSV, as in this example, the column names map to nodes beneath `"/document"`.

Skill #1: Split skill

When source content consists of large chunks of text, it's helpful to break it into smaller components for [integrated vectorization](#), or for greater accuracy of language, sentiment, and key phrase detection. There are two grains available: pages and sentences. A page consists of approximately 5,000 characters.

An alternative to chunking with the Split skill is through the [Document Layout skill](#), but that skill is out of scope for this article.

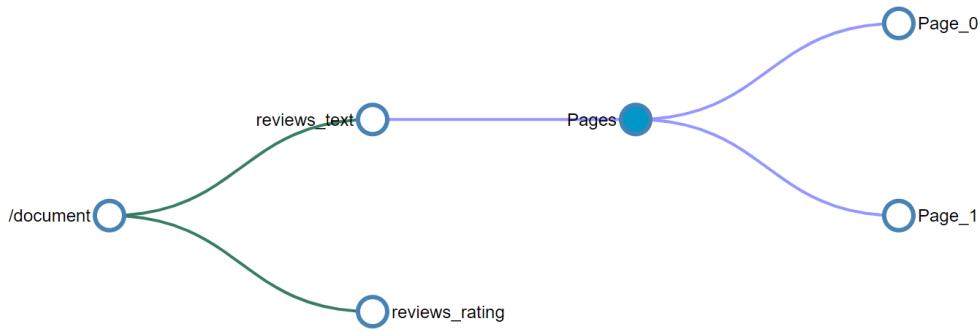

When chunking is required, the Split skill is typically first in a skillset.

```
JSON

{@odata.type": "#Microsoft.Skills.Text.SplitSkill",
"name": "#1",
"description": null,
"context": "/document/reviews_text",
"defaultLanguageCode": "en",
"textSplitMode": "pages",
"maximumPageLength": 5000,
"inputs": [
  {
    "name": "text",
    "source": "/document/reviews_text"
  }
],
"outputs": [
  {
    "name": "textItems",
    "targetName": "pages"
  }
]
```

With the skill context of `"/document/reviews_text"`, the split skill executes once for the `reviews_text`. The skill output is a list where the `reviews_text` is chunked into 5,000 character segments. The output from the split skill is named `pages` and it's added to the enrichment tree. The `targetName` feature allows you to rename a skill output before being added to the enrichment tree.

The enrichment tree now has a new node placed under the context of the skill. This node is available to any skill, projection, or output field mapping.

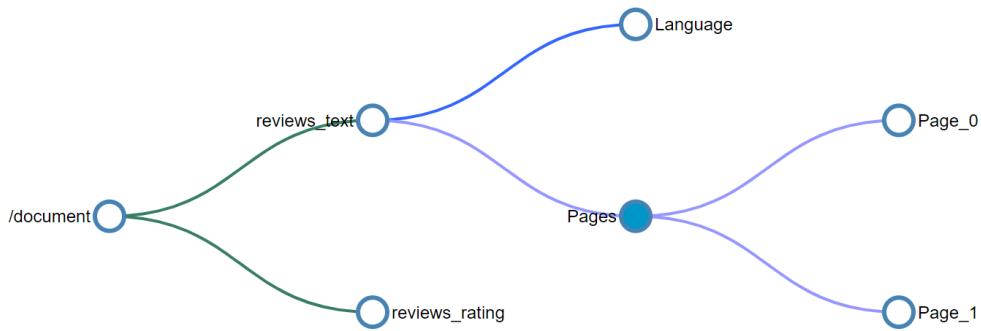

To access any of the enrichments added to a node by a skill, the full path for the enrichment is needed. For example, if you want to use the text from the `pages` node as an input to another skill, specify it as `"/document/reviews_text/pages/*"`. For more information about paths, see [Reference enrichments](#).

Skill #2 Language detection

Hotel review documents include customer feedback expressed in multiple languages. The language detection skill determines which language is used. The result will then be passed to key phrase extraction and sentiment detection (not shown), taking language into consideration when detecting sentiment and phrases.

While the language detection skill is the third (skill #3) skill defined in the skillset, it's the next skill to execute. It doesn't require any inputs so it executes in parallel with the previous skill. Like the split skill that preceded it, the language detection skill is also invoked once for each document. The enrichment tree now has a new node for language.

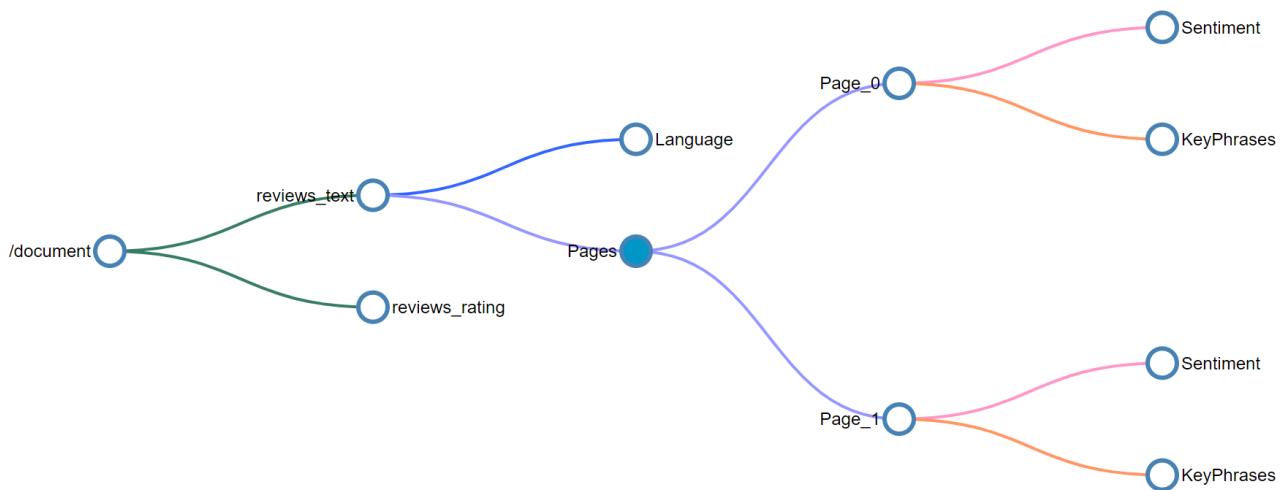

Skills #3 and #4 (sentiment analysis and key phrase detection)

Customer feedback reflects a range of positive and negative experiences. The sentiment analysis skill analyzes the feedback and assigns a score along a continuum of negative to positive numbers, or neutral if sentiment is undetermined. Parallel to sentiment analysis, key phrase detection identifies and extracts words and short phrases that appear consequential.

Given the context of `/document/reviews_text/pages/*`, both sentiment analysis and key phrase skills are invoked once for each of the items in the `pages` collection. The output from the skill will be a node under the associated page element.

You should now be able to look at the rest of the skills in the skillset and visualize how the enrichment tree grows with the execution of each skill. Some skills, such as the merge skill and the shaper skill, also create new nodes but only use data from existing nodes and don't create net new enrichments.

The colors of the connectors in the tree above indicate that the enrichments were created by different skills and the nodes need to be addressed individually and won't be part of the object returned when selecting the parent node.

Skill #5 Shaper skill

If output includes a [knowledge store](#), add a [Shaper skill](#) as a last step. The Shaper skill creates data shapes out of nodes in an enrichment tree. For example, you might want to consolidate multiple nodes into a single shape. You can then project this shape as a table (nodes become the columns in a table), passing the shape by name to a table projection.

The Shaper skill is easy to work with because it focuses shaping under one skill. Alternatively, you can opt for in-line shaping within individual projections. The Shaper Skill doesn't add or detract from an enrichment tree, so it's not visualized. Instead, you can think of a Shaper skill as the means by which you rearticulate the enrichment tree you already have. Conceptually, this is similar to creating views out of tables in a database.

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",  
  "name": "#5",  
  "description": null,  
  "context": "/document",  
  "inputs": [  
    {  
      "name": "name",  
      "source": "/document/name"  
    },  
    {  
      "name": "reviews_date",  
      "source": "/document/reviews_date"  
    },

            "targetName": "tableprojection"
        }
    ]
}
```

Next steps

With an introduction and example behind you, try creating your first skillset using [built-in skills](#).

[Create your first skillset](#)

Create a skillset in Azure AI Search

10/03/2025

A skillset defines operations that generate vector and textual content and structure from documents that contain images or raw content. Examples are chunking skills, embedding (vectorization) skills, image verbalization, and other processes like optical character recognition (OCR) for images, entity recognition for undifferentiated text, and text translation. A skillset executes after raw content is extracted from an external data source, and after [field mappings](#) are processed.

This article explains how to create a skillset using [REST APIs](#), but the same concepts and steps apply to other programming languages.

Rules for skillset definition include:

- Must have a unique name within the skillset collection. A skillset is a top-level resource that can be used by any indexer.
- Must have at least one skill. Three to five skills are typical. The maximum is 30.
- A skillset can repeat skills of the same type. For example, a skillset can have multiple Shaper skills.
- A skillset supports chained operations, looping, and branching.

A skillset is attached to an indexer. To use the skillset, reference it in an [indexer](#) and then run the indexer to import data, invoke skills processing, and send output to an [index](#). A skillset is a high-level resource, but it's operational only within indexer processing. As a high-level resource, you can reference it in multiple indexers.

💡 Tip

Enable [enrichment caching](#) to reuse the content you've already processed and lower the cost of development.

Add a skillset definition

Creating a skillset adds it to your search service. Updating a skillset fully overwrites an existing skillset with the contents of the request payload. A best practice for updates is to retrieve the

skillset definition with a GET, modify it, and then update with PUT.

Start with the basic structure. In the [Create Skillset REST API](#), the body of the request is authored in JSON and has the following sections:

JSON

```
{  
    "name": "skillset-template",  
    "description": "A description makes the skillset self-documenting (comments  
aren't allowed in JSON itself)",  
    "skills": [  
        ],  
    "cognitiveServices": {  
        "@odata.type": "#Microsoft.Azure.Search.CognitiveServicesByKey",  
        "description": "An Azure AI services resource in the same region as Azure AI  
Search",  
        "key": "<Your-Cognitive-Services-Multi-Service-Key>"  
    },  
    "knowledgeStore": {  
        "storageConnectionString": "<Your-Azure-Storage-Connection-String>",  
        "projections": [  
            {  
                "tables": [ ],  
                "objects": [ ],  
                "files": [ ]  
            }  
        ]  
    },  
    "encryptionKey": { }  
}
```

After the name and description, a skillset has four main properties:

- `skills` array, an unordered [collection of skills](#). Skills are either standalone or chained together through input-output associations, where the output of one transform becomes input to another. Skills can be utilitarian (like splitting text), transformational (based on AI from Azure OpenAI or Azure AI services), or custom skills that you provide. An example of a skills array is provided in the next section.
- `cognitiveServices` is used for [billable skills](#) that call Azure AI services APIs. Remove this section if you aren't using billable skills or Custom Entity Lookup. If you are, attach [an Azure AI services multi-service resource](#).
- `knowledgeStore` (optional) specifies an Azure Storage account and settings for projecting skillset output into tables, blobs, and files in Azure Storage. Remove this section if you don't need it, otherwise [specify a knowledge store](#).

- `encryptionKey` (optional) specifies an Azure Key Vault and [customer-managed keys](#) used to encrypt sensitive content (descriptions, connection strings, keys) in a skillset definition. Remove this property if you aren't using customer-managed encryption.

Add skills

Inside the skillset definition, the `skills` array specifies which skills to execute. Three to five skills are common, but you can add as many skills as necessary, subject to [service limits](#).

The end result of an enrichment pipeline is textual content in either a search index or a knowledge store. For this reason, most skills either create text from images (OCR text, captions, tags), or analyze existing text to create new information (entities, key phrases, sentiment). Skills that operate independently are processed in parallel. Skills that depend on each other specify the output of one skill (such as key phrases) as the input of a second skill (such as text translation). The search service determines the order of skill execution and the [execution environment](#).

All skills have a type, context, inputs, and outputs. A skill might optionally have a name and description. The following example shows two unrelated [built-in skills](#) so that you can compare the basic structure.

JSON

```
"skills": [
  {
    "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
    "name": "#1",
    "description": "This skill detects organizations in the source content",
    "context": "/document",
    "categories": [
      "Organization"
    ],
    "inputs": [
      {
        "name": "text",
        "source": "/document/content"
      }
    ],
    "outputs": [
      {
        "name": "organizations",
        "targetName": "orgs"
      }
    ]
  },
  {
    "name": "#2",
    "description": "This skill detects corporate logos in the source files",
  }
]
```

```
 "@odata.type": "#Microsoft.Skills.Vision.ImageAnalysisSkill",
 "context": "/document/normalized_images/*",
 "visualFeatures": [
     "brands"
 ],
 "inputs": [
     {
         "name": "image",
         "source": "/document/normalized_images/*"
     }
 ],
 "outputs": [
     {
         "name": "brands"
     }
 ]
}
```

Each skill is unique in terms of its input values and the parameters that it takes. [Skill reference documentation](#) describes all of the parameters and properties of a given skill. Although there are differences, most skills share a common set and are similarly patterned.

➊ Note

You can build complex skillsets with looping and branching using the [Conditional cognitive skill](#) to create the expressions. The syntax is based on the [JSON Pointer](#) path notation, with a few modifications to identify nodes in the enrichment tree. A `"/"` traverses a level lower in the tree and `"*"` acts as a for-each operator in the context. Numerous examples in this article illustrate [the syntax](#).

Set skill context

Each skill has a [context property](#) that determines the level at which operations take place. If the `context` property isn't explicitly set, the default is `"/document"`, where the context is the whole document (the skill is called once per document).

JSON

```
"skills": [
    {
        "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
        "context": "/document",
        "inputs": [],
        "outputs": []
    },
}
```

```
{
  "@odata.type": "#Microsoft.Skills.Vision.ImageAnalysisSkill",
  "context": "/document/normalized_images/*",
  "visualFeatures": [],
  "inputs": [],
  "outputs": []
}
```

The `context` property is usually set to one of the following examples:

[] [Expand table](#)

Context example	Description
<code>context: /document</code>	(Default) Inputs and outputs are at the document level.
<code>context: /document/pages/*</code>	Some skills like sentiment analysis perform better over smaller chunks of text. If you're splitting a large content field into pages or sentences, the context should be over each component part.
<code>context: /document/normalized_images/*</code>	For image content, inputs and outputs are one per image in the parent document.

Context also determines where outputs are produced in the [enrichment tree](#). For example, the Entity Recognition skill returns a property called `organizations`, captured as `orgs`. If the context is `"/document"`, then an `organizations` node is added as a child of `"/document"`. If you then want to reference this node in downstream skills, the path is `"/document/orgs"`.

Define inputs

Skills read from and write to an enriched document. Skill inputs specify the origin of the incoming data. It's often the root node of the enriched document. For blobs, a typical skill input is the document's content property.

[Skill reference documentation](#) for each skill describes the inputs it can consume. Each input has a `name` that identifies a specific input, and a `source` that specifies the location of the data in the enriched document. The following example is from the Entity Recognition skill:

JSON

```
"inputs": [
  {
    "name": "text",
    "source": "/document/content"
  },
  {
    "name": "language",
    "source": "/document/language"
  }
]
```

```
{
  "name": "languageCode",
  "source": "/document/language"
}
]
```

- Skills can have multiple inputs. The `name` is the specific input. For Entity Recognition, the specific inputs are `text` and `languageCode`.
- The `source` property specifies which field or row provides the content to be processed. For text-based skills, the source is a field in the document or row that provides text. For image-based skills, the node providing the input is normalized images.

 Expand table

Source example	Description
<code>source: /document</code>	For a tabular data set, a document corresponds to a row.
<code>source: /document/content</code>	For blobs, the source is usually the blob's content property.
<code>source: /document/some-named-field</code>	For text-based skills, such as entity recognition or key phrase extraction, the origin should be a field that contains sufficient text to be analyzed, such as a <i>description</i> or <i>summary</i> .
<code>source: /document/normalized_images/*</code>	For image content, the source is image that's been normalized during document cracking.

If the skill iterates over an array, both context and input source should include `/*` in the correct positions. For more information about the complete syntax, see [Skill context and input annotation language](#).

Define outputs

Each skill is designed to emit specific kinds of output, which are referenced by name in the skillset. A skill output has a `name` and an optional `targetName`.

[Skill reference documentation](#) for each skill describes the outputs it can produce. The following example is from the Entity Recognition skill:

JSON

```
"outputs": [
  {
    "name": "persons",
    "targetName": "people"
```

```
        },
        {
            "name": "organizations",
            "targetName": "orgs"
        },
        {
            "name": "locations",
            "targetName": "places"
        }
    ]
}
```

- Skills can have multiple outputs. The `name` property identifies a specific output. For example, for Entity Recognition, output can be *persons*, *locations*, *organizations*, among others.
- The `targetName` property specifies the name you would like this node to have in the enriched document. This is useful if skill outputs have the same name. If you have multiple skills that return the same output, use `targetName` for name disambiguation in enrichment node paths. If the target name is unspecified, the name property is used for both.

Some situations call for referencing each element of an array separately. For example, suppose you want to pass *each element* of `"/document/orgs"` separately to another skill. To do so, add an asterisk to the path: `"/document/orgs/*"`.

Skill output is written to the enriched document as a new node in the enrichment tree. It might be a simple value, such as a sentiment score or language code. It could also be a collection, such as a list of organizations, people, or locations. Skill output can also be a complex structure, as is the case with the Shaper skill. The inputs of the skill determine the composition of the shape, but the output is the named object, which can be referenced in a search index, a knowledge store projection, or another skill by its name.

Add a custom skill

This section includes an example of a [custom skill](#). The URI points to an Azure Function, which in turn invokes the model or transformation that you provide. For more information, see [Add a custom skill to an Azure AI Search enrichment pipeline](#).

Although the custom skill executes code that is external to the pipeline, in a skills array, it's just another skill. Like the built-in skills, it has a type, context, inputs, and outputs. It also reads and writes to an enrichment tree, just as the built-in skills do. Notice that the `context` field is set to `"/document/orgs/*"` with an asterisk, meaning the enrichment step is called *for each* organization under `"/document/orgs"`.

Output, such as the company description in this example, is generated for each organization that's identified. When referring to the node in a downstream step (for example, in key phrase extraction), you would use the path `"/document/orgs/*/companyDescription"` to do so.

```
JSON

{
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",
    "description": "This skill calls an Azure function, which in turn calls custom code",
    "uri": "https://indexer-e2e-webskill.azurewebsites.net/api/InvokeCode?code=foo",
    "httpHeaders": {
        "Ocp-Apim-Subscription-Key": "foobar"
    },
    "context": "/document/orgs/*",
    "inputs": [
        {
            "name": "query",
            "source": "/document/orgs/*"
        }
    ],
    "outputs": [
        {
            "name": "description",
            "targetName": "companyDescription"
        }
    ]
}
```

Send output to a destination

Although skill output can be optionally cached for reuse purposes, it's usually temporary and exists only while skill execution is in progress.

- To send output to a field in a search index, [create an output field mapping](#) in an indexer.
- To send output to a knowledge store, [create a projection](#).
- To send output to a downstream skill, reference the output by its node name, such as `"/document/organization"`, in the downstream skill's input source property. See [Reference an annotation](#) for examples.

Tips for a first skillset

- Try the [Import data wizard](#) or [Import data \(new\) wizard](#).

The wizards automate several steps that can be challenging the first time around. It defines the skillset, index, and indexer, including field mappings and output field mappings. It also defines projections in a knowledge store if you're using one. For some skills, such as OCR or image analysis, the wizard adds utility skills that merge the image and text content that was separated during document cracking.

After the wizard runs, you can open each object in the Azure portal to view its JSON definition.

- Try [Debug Sessions](#) to invoke skillset execution over a target document and inspect the enriched document that the skillset creates. You can view and modify input and output settings and values. This tutorial is a good place to start: [Tutorial: Debug a skillset using Debug Sessions](#).

Next step

Context and input source fields are paths to nodes in an enrichment tree. As a next step, learn more about the path syntax for nodes in an enrichment tree.

[Referencing annotations in a skillset](#)

Tips for AI enrichment in Azure AI Search

05/08/2025

This article contains tips to help you get started with AI enrichment and skillsets used during indexing.

Tip 1: Start simple and start small

Both the [Import data wizard](#) and [Import and vectorize data wizard](#) in the Azure portal support AI enrichment. Without writing any code, you can create and examine all of the objects used in an enrichment pipeline: an index, indexer, data source, and skillset.

Another way to start simply is by creating a data source with just a handful of documents or rows in a table that are representative of the documents that will be indexed. A small data set is the best way to increase the speed of finding and fixing issues. Run your sample through the end-to-end pipeline and check that the results meet your needs. Once you're satisfied with the results, you're ready to add more files to your data source.

Tip 2: See what works even if there are some failures

Sometimes a small failure stops an indexer in its tracks. That is fine if you plan to fix issues one by one. However, you might want to ignore a particular type of error, allowing the indexer to continue so that you can see what flows are actually working.

To ignore errors during development, set `maxFailedItems` and `maxFailedItemsPerBatch` as -1 as part of the indexer definition.

JSON

```
{  
  // rest of your indexer definition  
  "parameters":  
  {  
    "maxFailedItems": -1,  
    "maxFailedItemsPerBatch": -1  
  }  
}
```

 Note

As a best practice, set the `maxFailedItems` and `maxFailedItemsPerBatch` to 0 for production workloads

Tip 3: Use Debug session to troubleshoot issues

Debug session is a visual editor that shows a skillset's dependency graph, inputs and outputs, and definitions. It works by loading a single document from your search index, with the current indexer and skillset configuration. You can then run the entire skillset, scoped to a single document. Within a debug session, you can identify and resolve errors, validate changes, and commit changes to a parent skillset. For a walkthrough, see [Tutorial: debug sessions](#).

Tip 4: Expected content fails to appear

If you're missing content, check for dropped documents in the Azure portal. In the search service page, open **Indexers** and look at the **Docs succeeded** column. Click through to indexer execution history to review specific errors.

If the problem is related to file size, you might see an error like this: "The blob <file-name>" has the size of <file-size> bytes, which exceed the maximum size for document extraction for your current service tier." For more information on indexer limits, see [Service limits](#).

A second reason for content failing to appear might be related input/output mapping errors. For example, an output target name is "People" but the index field name is lower-case "people". The system could return 201 success messages for the entire pipeline so you think indexing succeeded, when in fact a field is empty.

Tip 5: Extend processing beyond maximum run time

Image analysis is computationally intensive for even simple cases, so when images are especially large or complex, processing times can exceed the maximum time allowed.

For indexers that have skillsets, skillset execution is [capped at 2 hours for most tiers](#). If skillset processing fails to complete within that period, you can put your indexer on a 2-hour recurring schedule to have the indexer pick up processing where it left off.

Scheduled indexing resumes at the last known good document. On a recurring schedule, the indexer can work its way through the image backlog over a series of hours or days, until all unprocessed images are processed. For more information on schedule syntax, see [Schedule an indexer](#).

Note

If an indexer is set to a certain schedule but repeatedly fails on the same document over and over again each time it runs, the indexer will begin running on a less frequent interval (up to the maximum of at least once every 24 hours) until it successfully makes progress again. = If you believe you have fixed whatever the issue that was causing the indexer to be stuck at a certain point, you can perform an on-demand run of the indexer, and if that successfully makes progress, the indexer will return to its set schedule interval again.

Tip 6: Increase indexing throughput

For [parallel indexing](#), distribute your data into multiple containers or multiple virtual folders inside the same container. Then create multiple data source and indexer pairs. All indexers can use the same skillset and write into the same target search index, so your search app doesn't need to be aware of this partitioning.

- [Quickstart: Create an AI enrichment pipeline in the Azure portal](#)
- [Tutorial: Learn AI enrichment REST APIs](#)
- [How to configure blob indexers](#)
- [How to define a skillset](#)
- [How to map enriched fields to an index](#)

Attach a billable resource to a skillset in Azure AI Search

If you're using built-in skills for [AI enrichment](#) in Azure AI Search, you can enrich a small number of documents for free, up to 20 transactions per index per day. For larger or more frequent workloads, you should attach a billable Microsoft Foundry resource to your [skillset](#).

Azure AI Search uses dedicated, internally hosted resources to execute built-in skills backed by Foundry Tools and requires a Foundry resource solely for billing purposes. The exception is the [Azure Content Understanding skill](#), which uses your resource for both billing and processing.

A Foundry resource provides access to multiple services within Foundry Tools. When you specify it in a skillset, Microsoft is able to charge you for using the following services:

- [Azure Vision in Foundry Tools](#) for image analysis, optical character recognition (OCR), and multimodal embeddings.
- [Azure Language in Foundry Tools](#) for language detection, entity recognition, sentiment analysis, and key phrase extraction.
- [Azure Translator in Foundry Tools](#) for machine text translation.

Skillset processing is billed to the underlying service of each skill. Azure AI Search consolidates charges for Foundry Tools into a single Foundry resource. For example, if you use the [Image Analysis](#) and [Language Detection](#) skills, charges for Azure Vision and Azure Language appear on the same bill for your Foundry resource. All other resources are billed independently.

To attach a Foundry resource, provide connection information in the skillset. You can use a key-based approach or keyless approach, which is currently in preview.

Prerequisites

- Connectivity over a public endpoint, unless your search service meets the creation date, tier, and region requirements for [private connections](#) to a Foundry resource.
- A [Foundry resource](#) with the `AI Services` API kind. You can verify the API kind on the resource's [Overview](#) page in the Azure portal:

Endpoints	: Click here to view endpoints
API Kind	: AI Services
Location	:
Status	: Succeeded 

(!) Note

- If your Foundry resource is configured to use a private endpoint, Azure AI Search can [connect using a shared private link](#). For more information, see [Shared private link resource limits](#).
- The 2025-11-01-preview introduces support for the `AI Services` API kind. The previous `CognitiveServices` and classic Azure AI multi-service accounts continue to work, but for new skillsets, we recommend that you use `AI Services` and Foundry resources.

Bill through a keyless connection

(!) Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

You can use a managed identity and permissions to attach a Foundry resource. The advantage of this approach is that billing is keyless and doesn't have region requirements.

As with keys, the details you provide about the resource are used for billing, not connections. All API requests made by Azure AI Search to Foundry Tools for built-in skills processing remain internal and managed by Microsoft.

To bill through a keyless connection:

1. On your Azure AI Search service, [configure a managed identity](#). Both system-assigned and user-assigned identities are supported.

2. On your Foundry resource, assign the [Cognitive Services User role](#) to the managed identity of your search service.
3. Configure a skillset to use the managed identity. You can use the Azure portal, the latest preview version of [Skillsets - Create Or Update \(REST API\)](#), or an Azure SDK beta package that provides the syntax.
 - `@odata.type` is always `#Microsoft.Azure.Search.AIServicesByIdentity`.
 - `subdomainUrl` is the endpoint of your Foundry resource. You can use the `https://<resource-name>.services.ai.azure.com` or `https://<resource-name>.cognitiveservices.azure.com` format, both of which are available on the [Keys and Endpoint](#) page in the Azure portal.
 - Other properties are specific to the type of managed identity, as shown in the following REST API examples.

System-assigned managed identity

Here's a sample skillset configuration for a system-assigned managed identity. In this scenario, you must set `identity` to `null`.

HTTP

```
POST https://[service-name].search.windows.net/skillsets/[skillset-name]?api-version=2025-11-01-preview
api-key: [admin-key]
Content-Type: application/json

{
    "name": "my-skillset",
    "skills": [
        // Skills definition goes here
    ],
    "cognitiveServices": {
        "@odata.type": "#Microsoft.Azure.Search.AIServicesByIdentity",
        "description": "A sample configuration for a system-assigned managed identity.",
        "subdomainUrl": "https://[resource-name].services.ai.azure.com",
        "identity": null
    }
}
```

Bill through a resource key

By default, Azure AI Search charges for transactions using the key of a Foundry resource. This approach is generally available. You can use the Azure portal, a stable REST API version, or an equivalent Azure SDK to add the key to a skillset.

There are two supported key types:

- `#Microsoft.Azure.Search.CognitiveServicesByKey` calls the regional endpoint.
- `#Microsoft.Azure.Search.AIPropertiesByKey` calls the subdomain. We recommend this type because it supports shared private links and doesn't have regional requirements relative to the search service.

Your Foundry resource must be in the same region as your search service. Choose an [Azure AI Search region that provides Foundry Tools integration](#), which is indicated by the **AI enrichment** column. For more information about the same-region requirement, see [How the key is used](#).

If you don't specify the `cognitiveServices` property, your search service attempts to use the free enrichments available to your indexer each day. Execution of billable skills stops at 20 transactions per indexer invocation, and a "Time Out" message appears in the indexer execution history.

Azure portal

1. Sign in to the [Azure portal](#).
2. Create a Foundry resource in the same region as your search service.
3. From the left pane, select **Resource Management > Keys and Endpoint**.
4. Copy one of the keys.
 - If you're using an [import wizard](#), select the Foundry resource. The wizard adds the resource key to your skillset definition.
 - For a new or existing skillset, provide the key in skillset definition.
5. Add the key to a skillset definition.

The screenshot shows the Microsoft Azure portal interface. On the left, there's a navigation bar with 'Microsoft Azure' at the top, followed by 'Home > contoso-search-eastus | Skillsets > py-rag-tutorial-ss ...'. Below this is a toolbar with 'Save', 'Refresh', 'Delete', and 'Connect AI service' (which is highlighted with a red box). The main area is titled 'Skillset Definition (JSON)' and shows a code editor with JSON code. A specific section of the code, which defines 'cognitiveServices', is also highlighted with a red box. On the right, a modal window titled 'Connect AI service' is open. It contains a table where an AI services resource named 'contosoazureaimultiservice' is listed under the 'Free (Limited enrichments)' plan in the 'eastus' region. There are 'Save' and 'Cancel' buttons at the bottom of the modal.

➊ Note

The portal automatically attaches the key of type
#Microsoft.Azure.Search.CognitiveServicesByKey .

Remove the key

Enrichments are billable operations. If you no longer need to call Foundry Tools, follow these instructions to remove the key and prevent use of the Foundry resource.

Without the key, the skillset reverts to the default allocation of 20 free transactions per indexer per day. Execution of billable skills stops at 20 transactions, and a "Time Out" message appears in the indexer execution history when the allocation is used.

Azure portal

1. Sign in to the [Azure portal](#).
2. Under **Search management > Skillsets**, select a skillset from the list.

How the key is used

Billing goes into effect when API calls to a Foundry resource exceed 20 API calls per indexer per day. You can [reset the indexer](#) to reset the API count.

Keyless and key-based connections are used for billing, but not for connections related to enrichment operations.

For key-based connections, a search service [connects over the internal network](#) to a Foundry resource located in the [same physical region](#). Most regions that offer Azure AI Search also offer other Azure services. If you attempt AI enrichment in a region that doesn't have both services, you see this message: "Provided key isn't a valid CognitiveServices type key for the region of your search service."

For keyless connections, a search service authenticates using its identity and role assignment and targets a Foundry resource. The resource is specified as a fully qualified URI, and the URI includes a unique subdomain.

Indexers can be configured to run in a [private execution environment](#) for dedicated processing using just the search nodes of your own search service. Even if you're using a private execution environment, Azure AI Search still uses its internally provisioned resources to perform all skill enrichments.

 **Note**

Some built-in skills, such as the [Text Translation skill](#), are based on non-regional Foundry Tools services. If you use a non-regional skill, your request might be serviced in a different region than the Azure AI Search region. For more information about non-regional services, see the [product availability by region](#) ↗ page.

Public connection requirements

Depending on when your search service was created, its pricing tier, and its region, billing for [built-in skills](#) can require a public connection from Azure AI Search to your Foundry resource. Disabling public network access breaks billing in some scenarios. Review the requirements for [connections through a shared private link](#) to determine whether your search service requires a public connection.

If you can't use the public network, you can configure a [Custom Web API skill](#) implemented with an [Azure Function](#) that supports [private endpoints](#) and add your [Foundry resource to the same VNET](#). In this scenario, you can call your Foundry resource directly from the custom skill using private endpoints.

Key requirements special cases

[Custom Entity Lookup](#) is metered by Azure AI Search, but it requires a Foundry resource key to unlock transactions beyond 20 per indexer per day. For this skill only, the resource key unblocks the number of transactions but is unrelated to billing.

Free enrichments

AI enrichment offers a small quantity of free processing of billable enrichments so that you can complete short exercises without having to attach an external resource. Free enrichments are 20 documents per indexer per day. You can [reset the indexer](#) to reset the counter if you want to repeat an exercise.

Some enrichments are always free:

- Utility skills that don't call Foundry Tools (namely the [Conditional](#), [Document Extraction](#), [Shaper](#), [Text Merge](#), and [Text Split](#) skills) aren't billable.
- Text extraction from PDF documents and other application files is nonbillable. Text extraction, which occurs during [document cracking](#), isn't an AI enrichment, but it occurs during AI enrichment and is thus noted here.

Billable enrichments

During AI enrichment, Azure AI Search calls APIs for [built-in skills](#) that are based on Azure Vision, Azure Language, and Azure Translator.

Billable built-in skills that make backend calls to external services include:

- [Entity Linking](#)
- [Entity Recognition](#)
- [Image Analysis](#)
- [Key Phrase Extraction](#)
- [Language Detection](#)
- [OCR](#)
- [Personally Identifiable Information \(PII\) Detection](#)
- [Sentiment](#)
- [Text Translation](#)
- [Azure Vision multimodal embeddings](#)

A [query-time vectorizer](#) backed by the Azure Vision multimodal embedding model is also a billable enrichment.

Image extraction is an Azure AI Search operation that occurs when documents are cracked prior to enrichment. Image extraction is billable on all pricing tiers, except for 20 free daily extractions on the free tier. Image extraction costs apply to image files inside blobs, embedded images in other files (PDF and other app files), and images extracted using [Document Extraction](#). For image extraction pricing, see the [Azure AI Search pricing page](#).

Tip

To lower the cost of skillset processing, enable [incremental enrichment](#) to cache and reuse any enrichments that are unaffected by changes made to a skillset. Caching requires Azure Storage (see [pricing ↗](#)), but the cumulative cost of skillset execution is lower if existing enrichments can be reused, especially for skillsets that use image extraction and analysis.

Example: Estimate costs

The prices shown in this section are hypothetical and used to illustrate the estimation process. Your costs could be lower. For the actual price of transactions, see [Foundry Tools pricing ↗](#).

To estimate the costs associated with Azure AI Search indexing, start with an idea of what an average document looks like so you can run some numbers. For example, you might approximate:

- 1,000 PDFs
- Six pages each
- One image per page (6,000 images)
- 3,000 characters per page

Assume a pipeline that consists of document cracking of each PDF, image and text extraction, OCR of images, and entity recognition of organizations.

1. For document cracking with text and image content, text extraction is currently free. For 6,000 images, assume \$1 for every 1,000 images extracted. That's a cost of \$6.00 for this step.
2. For OCR of 6,000 images in English, the OCR cognitive skill uses the best algorithm (`DescribeText`). Assuming a cost of \$2.50 per 1,000 images to be analyzed, you would pay \$15.00 for this step.
3. For entity extraction, you'd have a total of three text records per page. Each record is 1,000 characters. Three text records per page multiplied by 6,000 pages equal 18,000 text records. Assuming \$2.00 per 1,000 text records, this step would cost \$36.00.

Putting it all together, you'd pay about \$57.00 to ingest 1,000 PDF documents of this type with the described skillset.

Define an index projection for parent-child indexing

05/08/2025

For indexes containing chunked documents, an *index projection* specifies how parent-child content is mapped to fields in a search index for one-to-many indexing. Through an index projection, you can send content to:

- A single index, where the parent fields repeat for each chunk, but the grain of the index is at the chunk level. The [RAG tutorial](#) is an example of this approach.
- Two or more indexes, where the parent index has fields related to the parent document, and the child index is organized around chunks. The child index is the primary search corpus, but the parent index could be used for [lookup queries](#) when you want to retrieve the parent fields of a particular chunk, or for independent queries.

Most implementations are a single index organized around chunks with parent fields, such as the document filename, repeating for each chunk. However, the system is designed to support separate and multiple child indexes if that's your requirement. Azure AI Search doesn't support index joins so your application code must handle which index to use.

An index projection is defined in a [skillset](#). It's responsible for coordinating the indexing process that sends chunks of content to a search index, along with the parent content associated with each chunk. It improves how native data chunking works by giving you more options for controlling how parent-child content is indexed.

This article explains how to create the index schema and indexer projection patterns for one-to-many indexing.

Prerequisites

- An [indexer-based indexing pipeline](#).
- An index (one or more) that accepts the output of the indexer pipeline.
- A [supported data source](#) having content that you want to chunk. It can be vector or nonvector content.
- A skill that splits content into chunks, either the [Text Split skill](#) or a custom skill that provides equivalent functionality.

The skillset contains the indexer projection that shapes the data for one-to-many indexing. A skillset could also have other skills, such as an embedding skill like [AzureOpenAIEmbedding](#) if your scenario includes integrated vectorization.

Dependency on indexer processing

One-to-many indexing takes a dependency on skillsets and indexer-based indexing that includes the following four components:

- A data source
- One or more indexes for your searchable content
- A skillset that contains an index projection*
- An indexer

Your data can originate from any supported data source, but the assumption is that the content is large enough that you want to chunk it, and the reason for chunking it is that you're implementing a RAG pattern that provides grounding data to a chat model. Or, you're implementing vector search and need to meet the smaller input size requirements of embedding models.

Indexers load indexed data into a predefined index. How you define the schema and whether to use one or more indexes is the first decision to make in a one-to-many indexing scenario. The next section covers index design.

Create an index for one-to-many indexing

Whether you create one index for chunks that repeat parent values, or separate indexes for parent-child field placement, the primary index used for searching is designed around data chunks. It must have the following fields:

- A document key field uniquely identifying each document. It must be defined as type `Edm.String` with the `keyword` analyzer.
- A field associating each chunk with its parent. It must be of type `Edm.String`. It can't be the document key field, and must have `filterable` set to true. It's referred to as `parent_id` in the examples and as a [projected key value](#) in this article.
- Other fields for content, such as text or vectorized chunk fields.

An index must exist on the search service before you create the skillset or run the indexer.

Single index schema inclusive of parent and child fields

A single index designed around chunks with parent content repeating for each chunk is the predominant pattern for RAG and vector search scenarios. The ability to associate the correct parent content with each chunk is enabled through index projections.

The following schema is an example that meets the requirements for index projections. In this example, parent fields are the parent_id and the title. Child fields are the vector and nonvector vector chunks. The chunk_id is the document ID of this index. The parent_id and title repeat for every chunk in the index.

You can use the Azure portal, REST APIs, or an Azure SDK to [create an index](#).

REST

JSON

```
{  
    "name": "my_consolidated_index",  
    "fields": [  
        {"name": "chunk_id", "type": "Edm.String", "key": true, "filterable": true, "analyzer": "keyword"},  
        {"name": "parent_id", "type": "Edm.String", "filterable": true},  
        {"name": "title", "type": "Edm.String", "searchable": true, "filterable": true, "sortable": true, "retrievable": true},  
        {"name": "chunk", "type": "Edm.String", "searchable": true, "retrievable": true},  
        {"name": "chunk_vector", "type": "Collection(Edm.Single)", "searchable": true, "retrievable": false, "stored": false, "dimensions": 1536, "vectorSearchProfile": "hnsw"}  
    ],  
    "vectorSearch": {  
        "algorithms": [{"name": "hnsw", "kind": "hnsw", "hnswParameters": {}}],  
        "profiles": [{"name": "hnsw", "algorithm": "hnsw"}]  
    }  
}
```

Add index projections to a skillset

Index projections are defined inside a skillset definition and are primarily defined as an array of `selectors`, where each selector corresponds to a different target index on the search service. This section starts with syntax and examples for context, followed by [parameter reference](#).

Choose a tab for the various API syntax. There's currently no portal support for setting up projections, other than editing the skillset JSON definition. Refer to the REST example for JSON.

Index projections are generally available. We recommend the most recent stable API:

- [Create Skillset \(api-version=2024-07-01\)](#)

Here's an example payload for an index projections definition that you might use to project individual pages output by the [Text Split skill](#) as their own documents in the search index.

JSON

```
"indexProjections": {  
    "selectors": [  
        {  
            "targetIndexName": "my_consolidated_index",  
            "parentKeyFieldName": "parent_id",  
            "sourceContext": "/document/pages/*",  
            "mappings": [  
                {  
                    "name": "chunk",  
                    "source": "/document/pages/*",  
                    "sourceContext": null,  
                    "inputs": []  
                },  
                {  
                    "name": "chunk_vector",  
                    "source": "/document/pages/*/chunk_vector",  
                    "sourceContext": null,  
                    "inputs": []  
                },  
                {  
                    "name": "title",  
                    "source": "/document/title",  
                    "sourceContext": null,  
                    "inputs": []  
                }  
            ]  
        },  
        {  
            "parameters": {  
                "projectionMode": "skipIndexingParentDocuments"  
            }  
        }  
    ]  
}
```

Parameter reference

 [Expand table](#)

Index	Definition
projection parameters	
<code>selectors</code>	Parameters for the main search corpus, usually the one designed around chunks.
<code>projectionMode</code>	An optional parameter providing instructions to the indexer. The only valid value for this parameter is <code>skipIndexingParentDocuments</code> , and it's used when the chunk index is the primary search corpus and you need to specify whether parent fields are indexed as extra search documents within the chunked index. If you don't set <code>skipIndexingParentDocuments</code> , you get extra search documents in your index that are null for chunks, but populated with parent fields only. For example, if five documents contribute 100 chunks to the index, then the number of documents in the index is 105. The five documents created or parent fields have nulls for chunk (child) fields, making them substantially different from the bulk of the documents in the index. We recommend <code>projectionMode</code> set to <code>skipIndexingParentDocument</code> .

Selectors have the following parameters as part of their definition.

[] [Expand table](#)

Selector parameters	Definition
<code>targetIndexName</code>	The name of the index into which index data is projected. It's either the single chunked index with repeating parent fields, or it's the child index if you're using separate indexes for parent-child content.
<code>parentKeyFieldName</code>	The name of the field providing the key for the parent document.
<code>sourceContext</code>	The enrichment annotation that defines the granularity at which to map data into individual search documents. For more information, see Skill context and input annotation language .
<code>mappings</code>	<p>An array of mappings of enriched data to fields in the search index. Each mapping consists of:</p> <ul style="list-style-type: none"> <code>name</code>: The name of the field in the search index that the data should be indexed into. <code>source</code>: The enrichment annotation path that the data should be pulled from. <p>Each <code>mapping</code> can also recursively define data with an optional <code>sourceContext</code> and <code>inputs</code> field, similar to the knowledge store or Shaper Skill. Depending on your application, these parameters allow you to shape data into fields of type <code>Edm.ComplexType</code> in the search index. Some LLMs don't accept a complex type in search results, so the LLM you're using determines whether a complex type mapping is helpful or not.</p>

The `mappings` parameter is important. You must explicitly map every field in the child index, except for the ID fields such as document key and the parent ID.

This requirement is in contrast with other field mapping conventions in Azure AI Search. For some data source types, the indexer can implicitly map fields based on similar names, or known characteristics (for example, blob indexers use the unique metadata storage path as the default document key). However, for indexer projections, you must explicitly specify every field mapping on the "many" side of the relationship.

Do not create a field mapping for the parent key field. Doing so disrupts change tracking and synchronized data refresh.

Handling parent documents

Now that you've seen several patterns for one-to-many indexings, let's compare key differences about each option. Index projections effectively generate "child" documents for each "parent" document that runs through a skillset. You have several choices for handling the "parent" documents.

- To send parent and child documents to separate indexes, set the `targetIndexName` for your indexer definition to the parent index, and set the `targetIndexName` in the index projection selector to the child index.
- To keep parent and child documents in the same index, set the indexer `targetIndexName` and the index projection `targetIndexName` to the same index.
- To avoid creating parent search documents and ensuring the index contains only child documents of a uniform grain, set the `targetIndexName` for both the indexer definition and the selector to the same index, but add an extra `parameters` object after `selectors`, with a `projectionMode` key set to `skipIndexingParentDocuments`, as shown here:

JSON

```
"indexProjections": {
    "selectors": [
        ...
    ],
    "parameters": {
        "projectionMode": "skipIndexingParentDocuments"
    }
}
```

Review field mappings

Indexers are affiliated with three different types of field mappings. Before you run the indexer, check your field mappings and know when to use each type.

[Field mappings](#) are defined in an indexer and used to map a source field to an index field. Field mappings are used for data paths that lift data from the source and pass it in for indexing, with no intermediate skills processing step. Typically, an indexer can automatically map fields that have the same name and type. Explicit field mappings are only required when there's discrepancies. In one-to-many indexing and the patterns discussed thus far, you might not need field mappings.

[Output field mappings](#) are defined in an indexer and used to map enriched content generated by a skillset to a field into the main index. In the one-to-many patterns covered in this article, this is the parent index in a [two-index solution](#). In the examples shown in this article, the parent index is sparse, with just a title field, and that field isn't populated with content from the skillset processing, so we don't an output field mapping.

Indexer projection field mappings are used to map skillset-generated content to fields in the child index. In cases where the child index also includes parent fields (as in the [consolidated index solution](#)), you should set up field mappings for every field that has content, including the parent-level title field, assuming you want the title to show up in each chunked document. If you're using [separate parent and child indexes](#), the indexer projections should have field mappings for just the child-level fields.

Note

Both output field mappings and indexer projection field mappings accept enriched document tree nodes as source inputs. Knowing how to specify a path to each node is essential to setting up the data path. To learn more about path syntax, see [Reference a path to enriched nodes](#) and [skillset definition](#) for examples.

Run the indexer

Once you have created a data source, indexes, and skillset, you're ready to [create and run the indexer](#). This step puts the pipeline into execution.

You can query your search index after processing concludes to test your solution.

Content lifecycle

Depending on the underlying data source, an indexer can usually provide ongoing change tracking and deletion detection. This section explains the content lifecycle of one-to-many

indexing as it relates to data refresh.

For data sources that provide change tracking and deletion detection, an indexer process can pick up changes in your source data. Each time you run the indexer and skillset, the index projections are updated if the skillset or underlying source data has changed. Any changes picked up by the indexer are propagated through the enrichment process to the projections in the index, ensuring that your projected data is a current representation of content in the originating data source. Data refresh activity is captured in a projected key value for each chunk. This value gets updated when the underlying data changes.

 **Note**

While you can manually edit the data in the projected documents using the [index push API](#), you should avoid doing so. Manual updates to an index are overwritten on the next pipeline invocation, assuming the document in source data is updated and the data source has change tracking or deletion detection enabled.

Updated content

If you add new content to your data source, new chunks or child documents are added to the index on the next indexer run.

If you modify existing content in the data source, chunks are updated incrementally in the search index if the data source you're using supports change tracking and deletion detection. For example, if a word or sentence changes in a document, the chunk in the target index that contains that word or sentence is updated on the next indexer run. Other types of updates, such as changing a field type and some attributions, aren't supported for existing fields. For more information about allowed updates, see [Update an index schema](#).

Some data sources like [Azure Storage](#) support change and deletion tracking by default, based on the timestamp. Other data sources such as [OneLake](#), [Azure SQL](#), or [Azure Cosmos DB](#) must be configured for change tracking.

Deleted content

If the source content no longer exists (for example, if text is shortened to have fewer chunks), the corresponding child document in the search index is deleted. The remaining child documents also get their key updated to include a new hash value, even if their content didn't otherwise change.

If a parent document is completely deleted from the datasource, the corresponding child documents only get deleted if the deletion is detected by a `dataDeletionDetectionPolicy` defined on the datasource definition. If you don't have a `dataDeletionDetectionPolicy` configured and need to delete a parent document from the datasource, then you should manually delete the child documents if they're no longer wanted.

Projected key value

To ensure data integrity for updated and deleted content, data refresh in one-to-many indexing relies on a *projected key value* on the "many" side. If you're using integrated vectorization or the [Import and vectorize data wizard](#), the projected key value is the `parent_id` field in a chunked or "many" side of the index.

A projected key value is a unique identifier that the indexer generates for each document. It ensures uniqueness and allows for change and deletion tracking to work correctly. This key contains the following segments:

- A random hash to guarantee uniqueness. This hash changes if the parent document is updated on subsequent indexer runs.
- The parent document's key.
- The enrichment annotation path that identifies the context that that document was generated from.

For example, if you split a parent document with key value "aa1b22c33" into four pages, and then each of those pages is projected as its own document via index projections:

- aa1b22c33
- aa1b22c33_pages_0
- aa1b22c33_pages_1
- aa1b22c33_pages_2

If the parent document is updated in the source data, perhaps resulting in more chunked pages, the random hash changes, more pages are added, and the content of each chunk is updated to match whatever is in the source document.

Example of separate parent-child indexes

This section shows examples for separate parent and child indexes. It's an uncommon pattern, but it's possible you might have application requirements that are best met using this approach. In this scenario, you're projecting parent-child content into two separate indexes.

Each schema has the fields for its particular grain, with the parent ID field common to both indexes for use in a [lookup query](#). The primary search corpus is the child index, but then issue a lookup query to retrieve the parent fields for each match in the result. Azure AI Search doesn't support joins at query time, so your application code or orchestration layer would need to merge or collate results that can be passed to an app or process.

The parent index has a parent_id field and title. The parent_id is the document key. You don't need vector search configuration unless you want to vectorize fields at the parent document level.

JSON

```
{  
    "name": "my-parent-index",  
    "fields": [  
  
        {"name": "parent_id", "type": "Edm.String", "filterable": true},  
        {"name": "title", "type": "Edm.String", "searchable": true, "filterable":  
true, "sortable": true, "retrievable": true},  
    ]  
}
```

The child index has the chunked fields, plus the parent_id field. If you're using integrated vectorization, scoring profiles, semantic ranker, or analyzers you would set these in the child index.

JSON

```
{  
    "name": "my-child-index",  
    "fields": [  
        {"name": "chunk_id", "type": "Edm.String", "key": true, "filterable":  
true, "analyzer": "keyword"},  
        {"name": "parent_id", "type": "Edm.String", "filterable": true},  
        {"name": "chunk", "type": "Edm.String", "searchable": true, "retrievable":  
true},  
        {"name": "chunk_vector", "type": "Collection(Edm.Single)", "searchable":

    ],  
    "vectorSearch": {  
        "algorithms": [{"name": "hnsw", "kind": "hnsw", "hnswParameters": {}}],  
        "profiles": [{"name": "hnsw", "algorithm": "hnsw"}]  
    },  
    "scoringProfiles": [],  
    "semanticConfiguration": [],  
    "analyzers": []  
}
```

Here's an example of an index projection definition that specifies the data path the indexer should use to index content. It specifies the child index name in the index projection definition, and it specifies the mappings of every child or chunk-level field. This is the only place the child index name is specified.

JSON

```
"indexProjections": {  
    "selectors": [  
        {  
            "targetIndexName": "my-child-index",  
            "parentKeyFieldName": "parent_id",  
            "sourceContext": "/document/pages/*",  
            "mappings": [  
                {  
                    "name": "chunk",  
                    "source": "/document/pages/*",  
                    "sourceContext": null,  
                    "inputs": []  
                },  
                {  
                    "name": "chunk_vector",  
                    "source": "/document/pages/*/chunk_vector",  
                    "sourceContext": null,  
                    "inputs": []  
                }  
            ]  
        }  
    ]  
}
```

The indexer definition specifies the components of the pipeline. In the indexer definition, the index name to provide is the parent index. If you need field mappings for the parent-level fields, define them in outputFieldMappings. For one-to-many indexing that uses separate indexes, the indexer definition might look like the following example.

JSON

```
{  
    "name": "my-indexer",  
    "dataSourceName": "my-ds",  
    "targetIndexName": "my-parent-index",  
    "skillsetName" : "my-skillset"  
    "parameters": { },  
    "fieldMappings": (optional) Maps fields in the underlying data source to fields  
in an index,  
    "outputFieldMappings" : (required) Maps skill outputs to fields in an index,  
}
```

Next step

Data chunking and one-to-many indexing are part of the RAG pattern in Azure AI Search. Continue on to the following tutorial and code sample to learn more about it.

[How to build a RAG solution using Azure AI Search](#)

Debug Sessions in Azure AI Search

Debug Sessions is a visual editor that works with an existing skillset in the Azure portal, exposing the structure and content of a single enriched document as it's produced by an indexer and skillset for the duration of the session. Because you're working with a live document, the session is interactive - you can identify errors, modify and invoke skill execution, and validate the results in real time. If your changes resolve the problem, you can commit them to a published skillset to apply the fixes globally.

This article explains supported scenarios and how the editor is organized. Tabs and sections of the editor unpack different layers of the skillset so that you can examine skillset structure, flow, and the content it generates at run time.

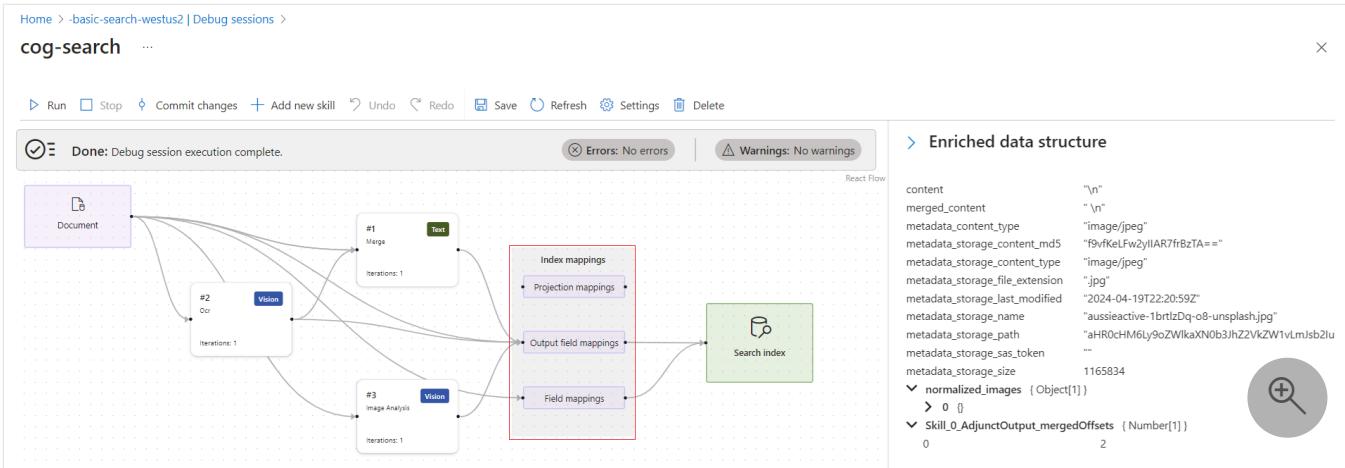

Supported scenarios

Use Debug Sessions to investigate and resolve problems with:

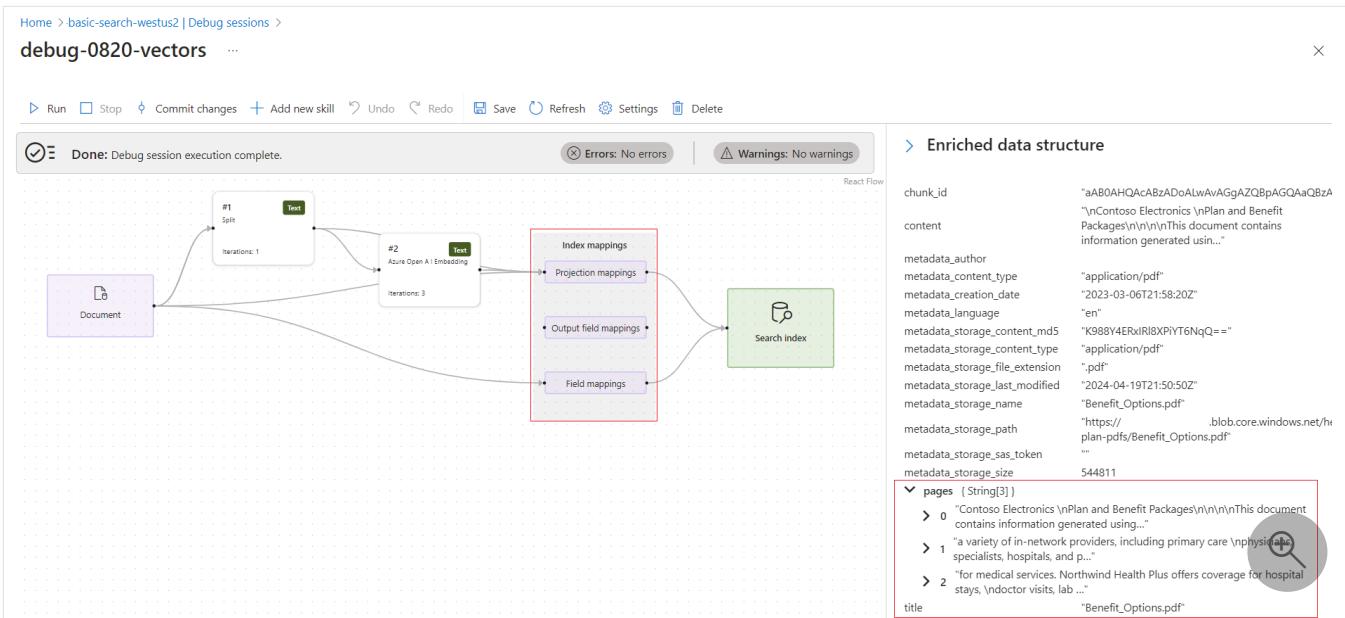

- Built-in skills used for [AI enrichment](#), such as OCR, image analysis, entity recognition, and keyword extraction.
- Built-in skills used for [integrated vectorization](#), with data chunking through Text Split, and vectorization through an embedding skill.
- Custom skills used to integrate external processing that you provide.

Compare the following debug session images for the first two scenarios. For both scenarios, the surface area shows the progression of skills that generate or transform content en route from the source document to the search index. The flow includes index mapping options, and you can trace the arrows to follow the processing trail. The details pane to the right is context-sensitive. It shows a representation of the enriched document that's created by the pipeline, or the details of a skill or mapping.

The first image shows a pattern for applied AI enrichment (no vectors). Skills can run sequentially or in parallel if there are no dependencies. Index mappings show how enriched or generated content travels from in-memory data structures to fields in an index. Enriched document shows the data structure that the skillset creates.

The second image shows a typical pattern for integrated vectorization. Skills for integrated vectorization usually include a Text Split skill and an embedding skill. A Text Split skill divides a document into chunks. An embedding skill calls an embedding API to vectorize those chunks. This particular skillset chunks content into an array of "pages". For integrated vectorization, projection mappings control how chunks are mapped to fields in the index.

Limitations

Debug Sessions work with all generally available [indexer data sources](#) and most preview data sources, with the following exceptions:

- SharePoint indexer.
- Azure Cosmos DB for MongoDB indexer.
- For the Azure Cosmos DB for NoSQL, if a row fails during index and there's no corresponding metadata, the debug session might not pick the correct row.

- For the SQL API of Azure Cosmos DB, if a partitioned collection was previously non-partitioned, the debug session won't find the document.
- For custom skills, a user-assigned managed identity isn't supported for a debug session connection to Azure Storage. As stated in the prerequisites, you can use a system managed identity, or specify a full access connection string that includes a key. For more information, see [Connect a search service to other Azure resources using a managed identity](#).
- Data sources with encryption enabled via [customer managed keys \(CMK\)](#).
- Currently, the ability to select which document to debug is unavailable. This limitation isn't permanent and should be lifted soon. At this time, Debug Sessions selects the first document in the source data container or folder.

How a debug session works

When you start a session, the search service creates a copy of the skillset, indexer, and a data source containing a single document used to test the skillset. All session state is saved to a new blob container created by the Azure AI Search service in an Azure Storage account that you provide. The name of the generated container has a prefix of `ms-az-cognitive-search-debugsession`. The prefix is required because it mitigates the chance of accidentally exporting session data to another container in your account.

A cached copy of the enriched document and skillset is loaded into the visual editor so that you can inspect the content and metadata of the enriched document, with the ability to check each document node and edit any aspect of the skillset definition. Any changes made within the session are cached. Those changes won't affect the published skillset unless you commit them. Committing changes will overwrite the production skillset.

If the enrichment pipeline doesn't have any errors, a debug session can be used to incrementally enrich a document, test and validate each change before committing the changes.

Debug sessions help identify the root cause of errors or warnings by analyzing the data, skill inputs and outputs, and field mappings. If the indexer encounters configuration issues, such as incorrect network setup, permission-related access errors, or similar, please review the specific error message along with the linked documentation provided. For troubleshooting guidance, refer to the [common indexer errors and warnings](#).

Debug Sessions with private connectivity

If your AI enrichment pipeline uses shared private links to access Azure resources, additional configuration is required to ensure indexer and debug sessions work correctly. This includes permissions, trusted access, and network setup.

- If you're using [managed identity](#), assign the necessary roles to your search service identity, including `Storage Blob Data Contributor`, so debug sessions can write session data to your storage account.
- Ensure the search service has access to all resources referenced in the [skillset definition](#), including any used in the debug session.
- In your storage account, [enable trusted services](#) to allow access from Azure AI Search.
- Set `"executionEnvironment" = "private"` property in the indexer definition to ensure the indexer runs in a private context.
- Create a [shared private link](#) for each resource accessed by the search service, including: your data source, if configured to indexer AI enrichment cache and knowledge store, and any other resources configured in your skillset.
- For other troubleshooting guidance, refer to the [common indexer errors and warnings](#).

Debug session layout

The visual editor is organized into a surface area showing a progression of operations, starting with document cracking, followed by skills, mappings, and an index.

Select any skill or mapping, and a pane opens to side showing relevant information.

Home > -basic-search-westus2 | Debug sessions >
debug-0820-vectors ...

Run Stop Commit changes Add new skill Undo Redo Save

Done: Debug session execution complete. Errors: No errors Warnings:

Skill: #2

Iterations (3) Skill Settings Errors/Warnings (0)

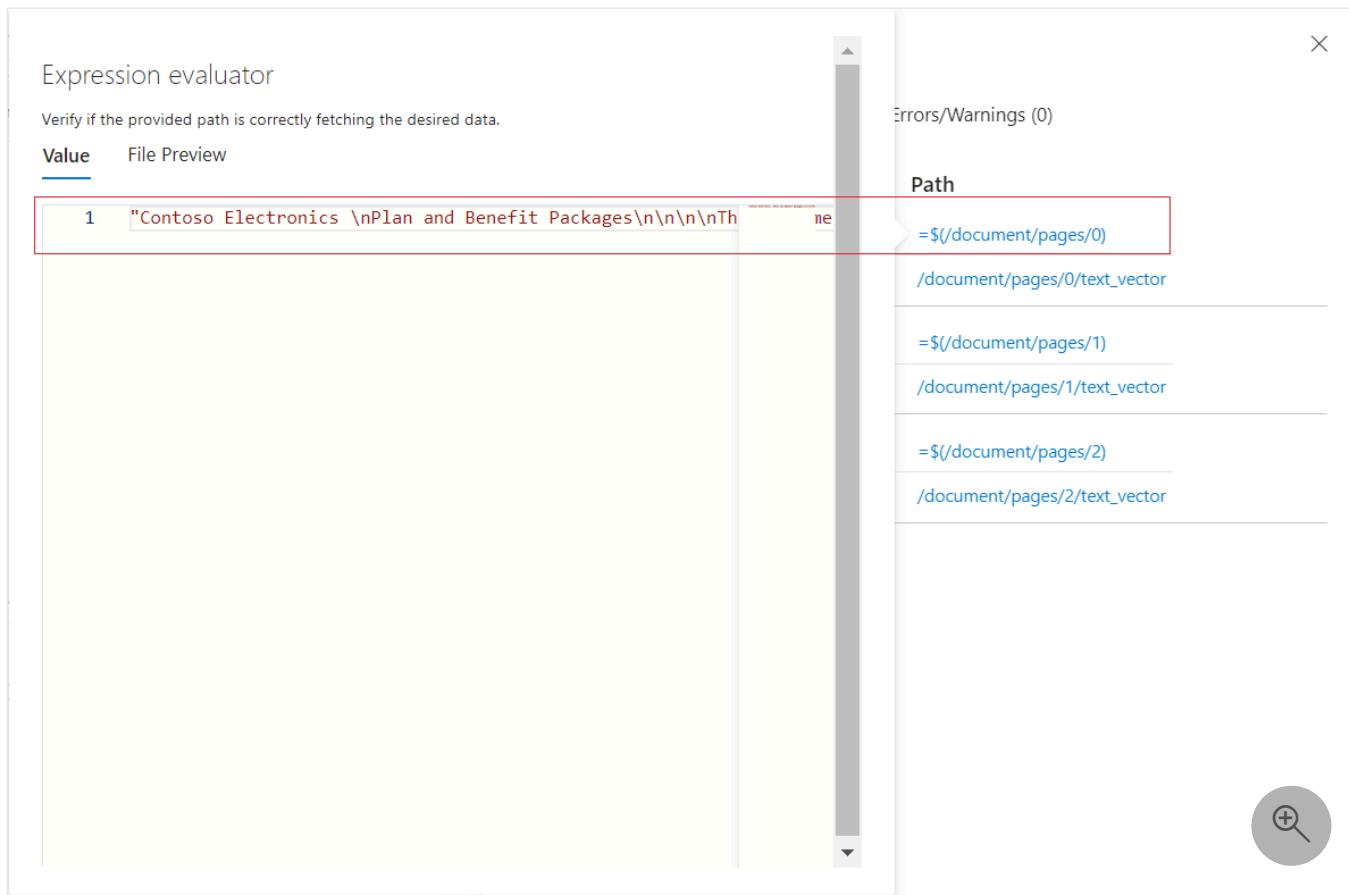

Iteration	Property	Name	Path
0	Inputs	text	=\${/document/pages/0}
	Outputs	embedding	/document/pages/0/text_vector
1	Inputs	text	=\${/document/pages/1}
	Outputs	embedding	/document/pages/1/text_vector
2	Inputs	text	=\${/document/pages/2}
	Outputs	embedding	/document/pages/2/text_vector

Document

#1 Split
Iterations: 1

#2 Azure Open AI Embedding
Iterations: 3

Follow the links to drill further into skills processing. For example, the following screenshot shows the output of the first iteration of the Text Split skill.

Skill details pane

The **Skill details** pane has the following sections:

- **Iterations:** Shows you how many times a skill executes. You can check the inputs and outputs of each one.
- **Skill Settings:** View or edit the JSON skillset definition.
- **Errors and warnings:** Shows the errors or warnings specific to this skill.

Enriched data structure pane

The **Enriched Data Structure** pane slides out to the side when you select the blue show or hide arrow symbol. It's a human readable representation of what the enriched document contains. Previous screenshots in this article show examples of the enriched data structure.

Next steps

Now that you understand the elements of debug sessions, start your first debug session on an existing skillset.

[How to debug a skillset](#)

Last updated on 10/21/2025

Debug an Azure AI Search skillset in Azure portal

05/08/2025

Start a portal-based debug session to identify and resolve errors, validate changes, and push changes to an existing skillset in your Azure AI Search service.

A debug session is a cached indexer and skillset execution, scoped to a single document, that you can use to edit and test skillset changes interactively. When you're finished debugging, you can save your changes to the skillset.

For background on how a debug session works, see [Debug sessions in Azure AI Search](#). To practice a debug workflow with a sample document, see [Tutorial: Debug sessions](#).

Prerequisites

- An Azure AI Search service, any region or tier.
- An Azure Storage account, used to save session state.
- An existing enrichment pipeline, including a data source, a skillset, an indexer, and an index.

Security and permissions

- To save a debug session to Azure storage, the search service identity must have **Storage Blob Data Contributor** permissions on Azure Storage. Otherwise, plan on choosing a full access connection string for the debug session connection to Azure Storage.
- If the Azure Storage account is behind a firewall, configure it to [allow search service access](#).

Limitations

Debug sessions work with all generally available [indexer data sources](#) and most preview data sources, with the following exceptions:

- SharePoint Online indexer.
- Azure Cosmos DB for MongoDB indexer.

- For the Azure Cosmos DB for NoSQL, if a row fails during index and there's no corresponding metadata, the debug session might not pick the correct row.
- For the SQL API of Azure Cosmos DB, if a partitioned collection was previously non-partitioned, the debug session won't find the document.
- For custom skills, a user-assigned managed identity isn't supported for a debug session connection to Azure Storage. As stated in the prerequisites, you can use a system managed identity, or specify a full access connection string that includes a key. For more information, see [Connect a search service to other Azure resources using a managed identity](#).

Create a debug session

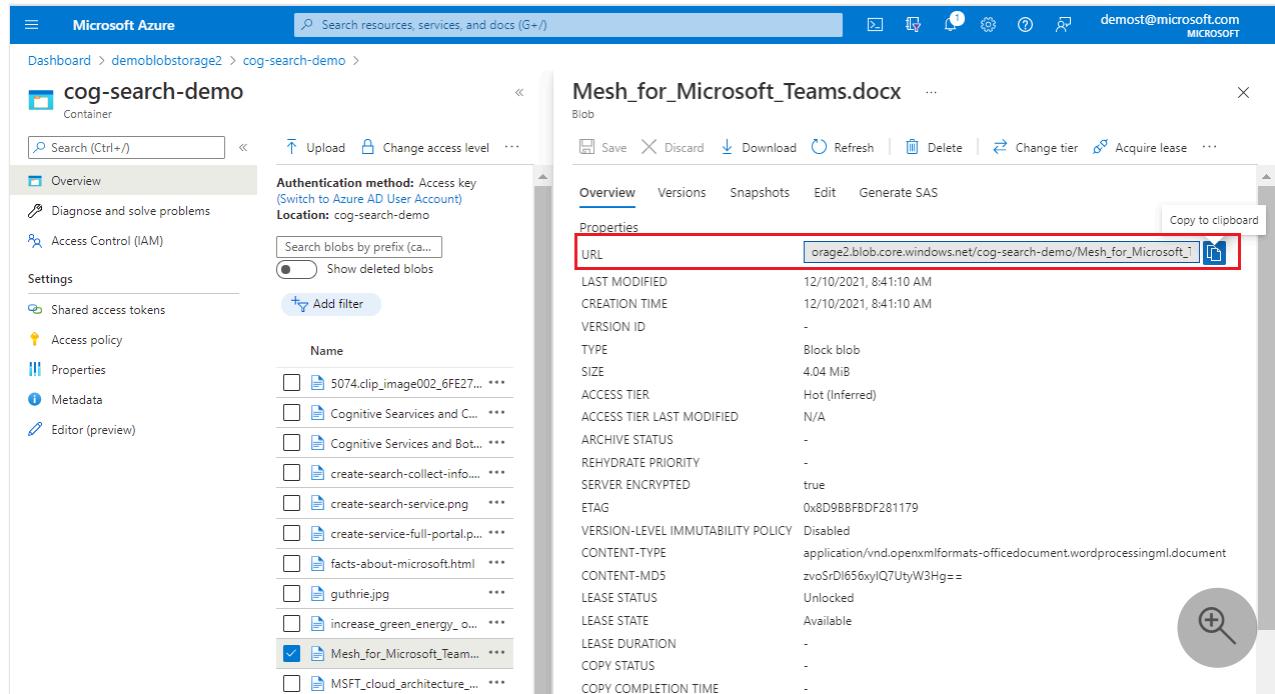

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. On the left menu, select **Search management > Debug sessions**.
3. On the action bar at the top, select **Add debug session**.

The screenshot shows the Azure portal interface for managing a search service named 'demo-srch'. The main area displays a table for 'Debug sessions' with one entry: 'No debug sessions were found'. The top navigation bar includes a 'Search' bar, a 'Filter by name...' bar, and buttons for 'Add debug session', 'Refresh', and 'Delete'. The left sidebar lists various management sections: Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Search management (with sub-options like Indexes, Indexers, Data sources, Aliases, Skillsets, and the currently selected 'Debug sessions'), Settings, and Semantic ranker. A large circular button with a plus sign and a magnifying glass icon is located in the bottom right corner of the main content area.

4. In **Debug session name**, provide a name that will help you remember which skillset, indexer, and data source the debug session is about.
5. In **Indexer template**, select the indexer that drives the skillset you want to debug. Copies of both the indexer and skillset are used to initialize the session.

6. In **Document to debug**, choose the first document in the index or select a specific document. If you select a specific document, depending on the data source, you're asked for a URI or a row ID.

If your specific document is a blob, provide the blob URI. You can find the URI in the blob property page in the Azure portal.

The screenshot shows the Microsoft Azure Storage Blob properties page. On the left, there's a sidebar with options like Overview, Diagnose and solve problems, Access Control (IAM), Settings, Shared access tokens, Access policy, Properties, Metadata, and Editor (preview). The main area shows a list of blobs with their names and preview icons. One blob, "Mesh_for_Microsoft_Teams.docx", is selected and highlighted with a blue border. On the right, there's a detailed properties pane with tabs for Overview, Versions, Snapshots, Edit, and Generate SAS. The "Overview" tab is selected. Under the "Properties" section, the "URL" field is highlighted with a red box and contains the value "https://cog-search-demo.cognitiveservices.azure.com/blobs/cog-search-demo/Mesh_for_Microsoft_Teams.docx?sv=2021-07-01&st=2021-10-12T08%3A41%3A10Z&se=2021-10-12T08%3A41%3A10Z&srt=b&sp=r&sr=b&sig=0wD9BBFBDF281179&api-version=2021-07-01". There are also "Save", "Discard", "Download", "Refresh", "Delete", "Change tier", "Acquire lease", and "Copy to clipboard" buttons at the top of the properties pane.

7. In **Storage account**, choose a general-purpose storage account for caching the debug session.

8. Select **Authenticate using managed identity** if you previously assigned **Storage Blob Data Contributor** permissions to the search service system-managed identity. If you don't check this box, the search service connects using a full access connection string.

9. Select **Save**.

- Azure AI Search creates a blob container on Azure Storage named *ms-az-cognitive-search-debugsession*.
- Within that container, it creates a folder using the name you provided for the session name.
- It starts your debug session.

The debug session begins by executing the indexer and skillset on the selected document. The document's content and metadata are visible and available in the session.

A debug session can be canceled while it's executing. If you hit the **Cancel** button you should be able to analyze partial results.

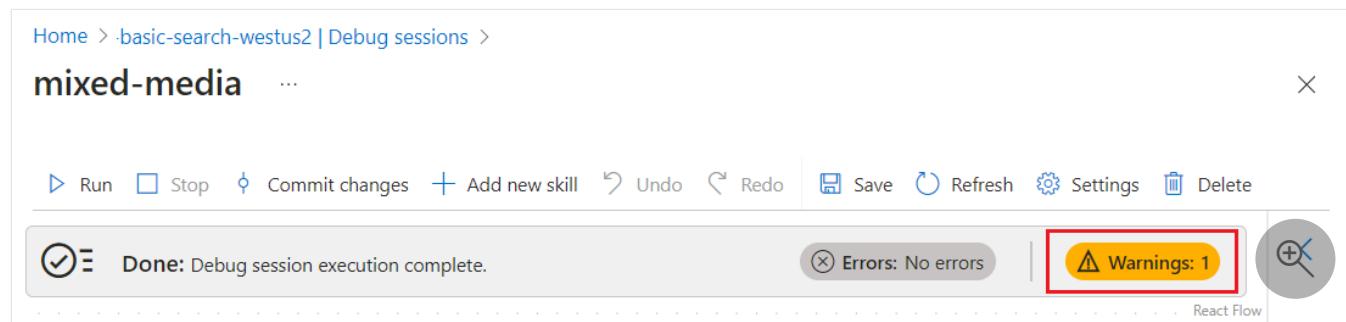

It's expected for a debug session to take longer to execute than the indexer since it goes through extra processing.

Start with errors and warnings

Indexer execution history in the Azure portal gives you the full error and warning list for all documents. In a debug session, the errors and warnings are limited to one document. You can work through this list, make your changes, and then return to the list to verify whether issues are resolved.

Remember that a debug session is based on one document from the entire index. If an input or output looks wrong, the problem could be specific to that document. You can choose a different document to confirm whether errors and warnings are pervasive or specific to a single document.

Select **Errors** or **Warnings** for a list of issues.

As a best practice, resolve problems with inputs before moving on to outputs.

To prove whether a modification resolves an error, follow these steps:

1. Select **Save** in the skill details pane to preserve your changes.
2. Select **Run** in the session window to invoke skillset execution using the modified definition.
3. Return to **Errors** or **Warnings** to see if the count is reduced.

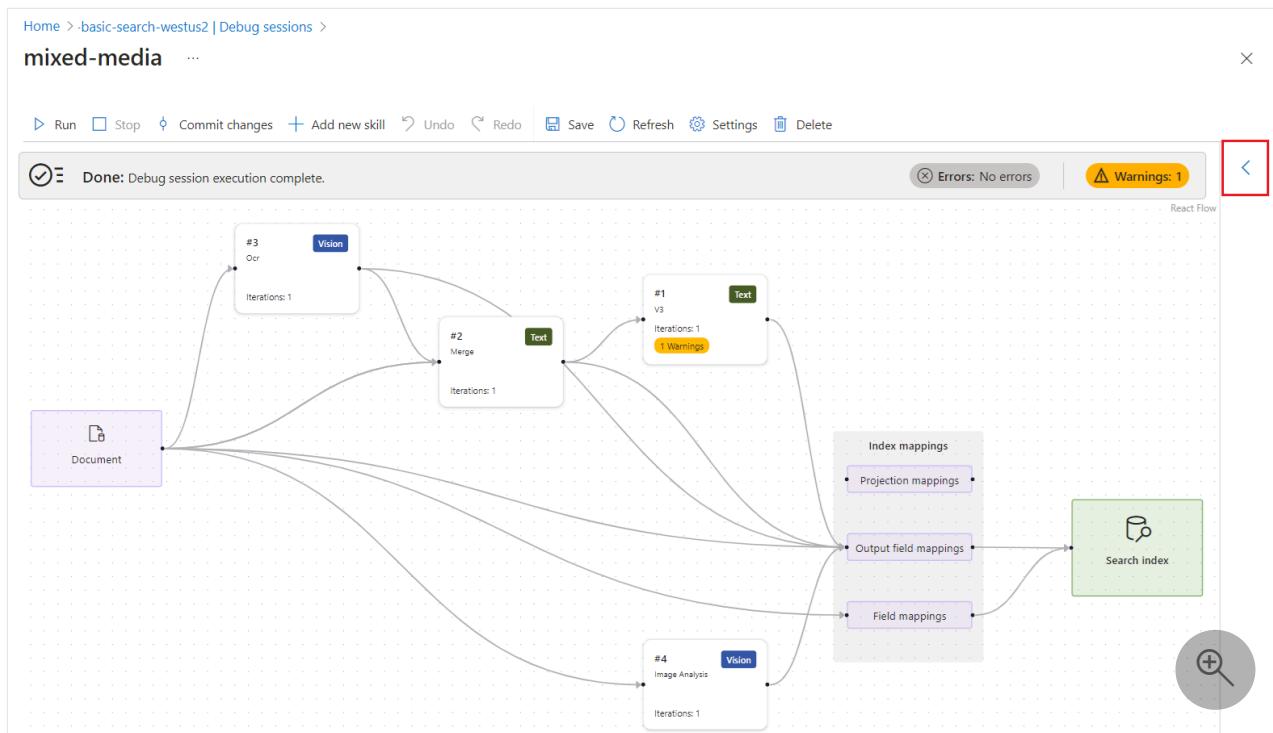

View enriched or generated content

AI enrichment pipelines extract or infer information and structure from source documents, creating an enriched document in the process. An enriched document is first created during document cracking and populated with a root node (`/document`), plus nodes for any content that is lifted directly from the data source, such as metadata and the document key. More

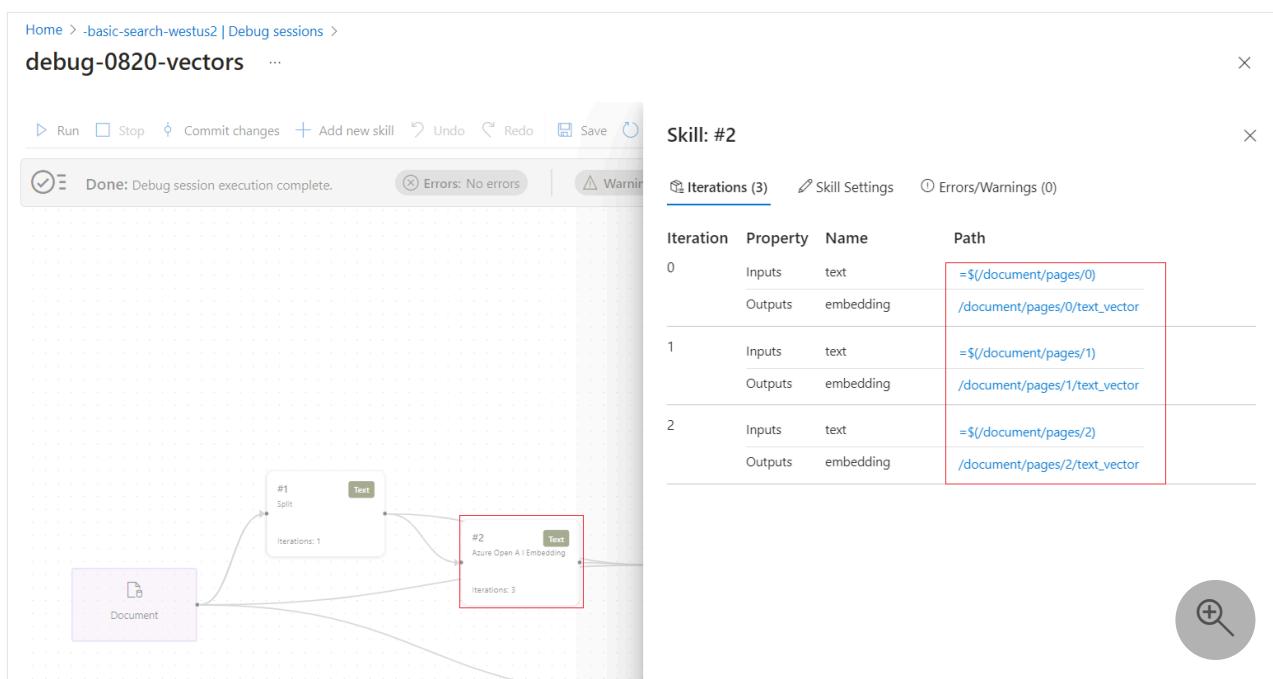

nodes are created by skills during skill execution, where each skill output adds a new node to the enrichment tree.

All content created or used by a skillset appears in the Expression Evaluator. You can hover over the links to view each input or output value in the enriched document tree. To view the input or output of each skill, follow these steps:

1. In a debug session, expand the blue arrow to view context-sensitive details. By default, the detail is the enriched document data structure. However, if you select a skill or a mapping, the detail is about that object.

2. Select a skill.

3. Follow the links to drill further into skills processing. For example, the following screenshot shows the output of the first iteration of the Text Split skill.

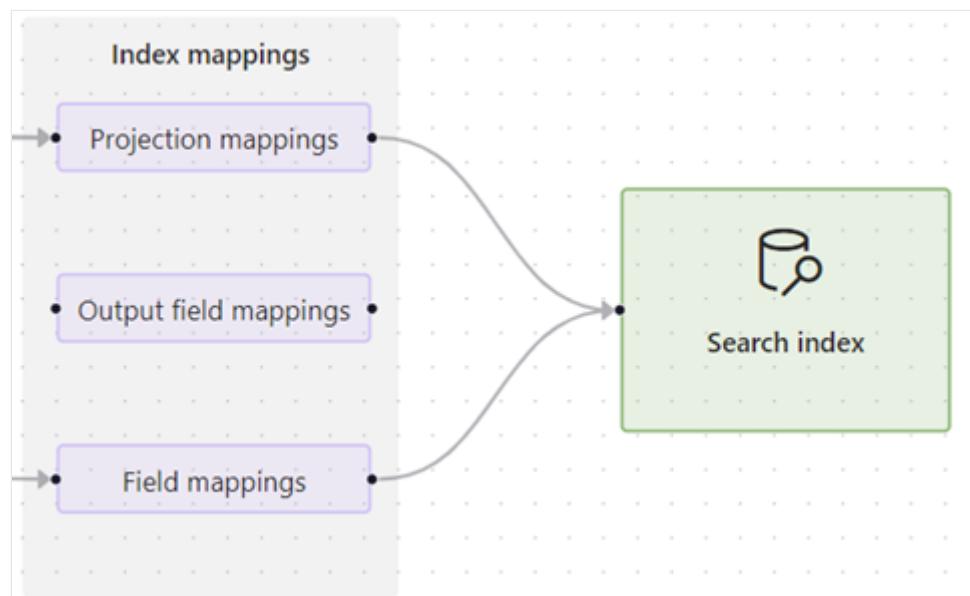

The screenshot shows the 'Expression evaluator' interface. On the left, under 'Value', the output is displayed as a red-bordered box containing the string: "Contoso Electronics \nPlan and Benefit Packages\n\n\n\n\nTh". Below this, under 'File Preview', there is a small preview icon. On the right, the 'Path' section lists several paths:

- =\${/document/pages/0}
- /document/pages/0/text_vector
- =\${/document/pages/1}
- /document/pages/1/text_vector
- =\${/document/pages/2}
- /document/pages/2/text_vector

A magnifying glass icon is located at the bottom right of the panel.

Check index mappings

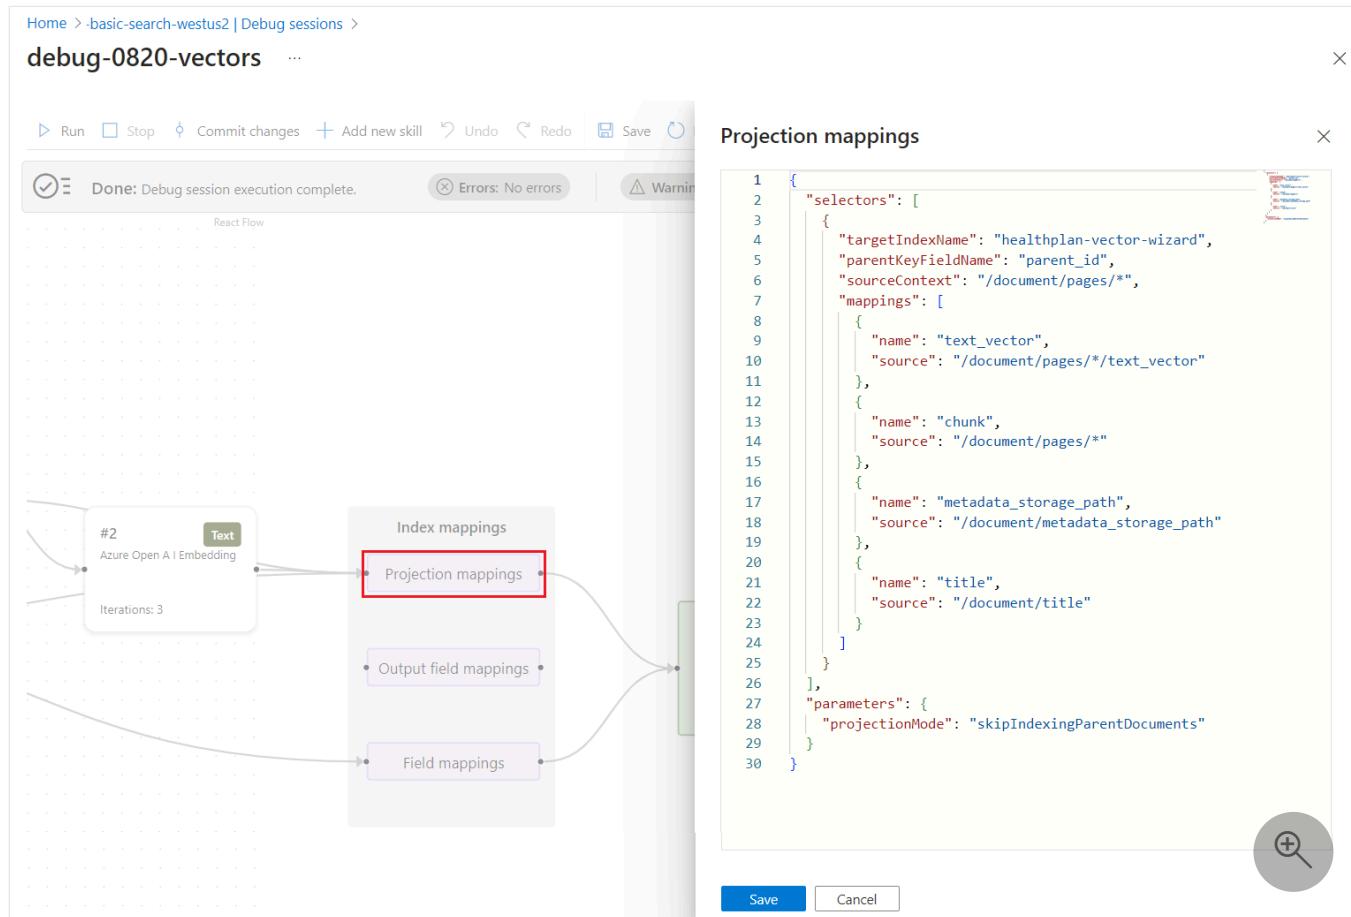

If skills produce output but the search index is empty, check the field mappings. Field mappings specify how content moves out of the pipeline and into a search index.

Select one of the mapping options and expand the details view to review source and target definitions.

- **Projection Mappings** are found in skillsets that provide integrated vectorization, such as the skills created by the [Import and vectorize data wizard](#). These mappings determine parent-child (chunk) field mappings and whether a secondary index is created for just the chunked content
- **Output Field Mappings** are found in indexers and are used when skillsets invoke built-in or custom skills. These mappings are used to set the data path from a node in the enrichment tree to a field in the search index. For more information about paths, see [enrichment node path syntax](#).
- **Field Mappings** are found in indexer definitions and they establish the data path from raw content in the data source and a field in the index. You can use field mappings to add encoding and decoding steps as well.

This example shows the details for a projection mapping. You can edit the JSON to fix any mapping issues.

The screenshot shows the Azure AI Search interface for editing a skill definition named "debug-0820-vectors". The top navigation bar includes "Home", ".basic-search-westus2 | Debug sessions", and "debug-0820-vectors". Below the navigation is a toolbar with "Run", "Stop", "Commit changes", "Add new skill", "Undo", "Redo", "Save", and a refresh icon. A message bar indicates "Done: Debug session execution complete." with "Errors: No errors" and "Warnings".

The main area displays a "React Flow" diagram. On the left, a node labeled "#2 Azure Open AI Embedding" with "Text" type and "Iterations: 3" is connected to a central "Index mappings" node. From "Index mappings", arrows point to three boxes: "Projection mappings" (which is highlighted with a red border), "Output field mappings", and "Field mappings".

To the right of the diagram is a code editor titled "Projection mappings" showing the following JSON code:

```

1  {
2    "selectors": [
3      {
4        "targetIndexName": "healthplan-vector-wizard",
5        "parentKeyFieldName": "parent_id",
6        "sourceContext": "/document/pages/*",
7        "mappings": [
8          {
9            "name": "text_vector",
10           "source": "/document/pages/*/text_vector"
11         },
12         {
13           "name": "chunk",
14           "source": "/document/pages/*"
15         },
16         {
17           "name": "metadata_storage_path",
18           "source": "/document/metadata_storage_path"
19         },
20         {
21           "name": "title",
22           "source": "/document/title"
23         }
24       ],
25     },
26   ],
27   "parameters": {
28     "projectionMode": "skipIndexingParentDocuments"
29   }
30 }

```

At the bottom of the code editor are "Save" and "Cancel" buttons, and a magnifying glass icon for search.

Edit skill definitions

If the field mappings are correct, check individual skills for configuration and content. If a skill fails to produce output, it might be missing a property or parameter, which can be determined through error and validation messages.

Other issues, such as an invalid context or input expression, can be harder to resolve because the error will tell you what is wrong, but not how to fix it. For help with context and input syntax, see [Reference enrichments in an Azure AI Search skillset](#). For help with individual messages, see [Troubleshooting common indexer errors and warnings](#).

The following steps show you how to get information about a skill.

1. Select a skill on the work surface. The Skill details pane opens to the right.
2. Edit a skill definition using **Skill Settings**. You can edit the JSON directly.
3. Check the [path syntax for referencing nodes](#) in an enrichment tree. Following are some of the most common input paths:
 - `/document/content` for chunks of text. This node is populated from the blob's content property.
 - `/document/merged_content` for chunks of text in skillets that include Text Merge skill.
 - `/document/normalized_images/*` for text that is recognized or inferred from images.

Debug a custom skill locally

Custom skills can be more challenging to debug because the code runs externally, so the debug session can't be used to debug them. This section describes how to locally debug your Custom Web API skill, debug session, Visual Studio Code and [ngrok](#) or [Tunnelmole](#). This technique works with custom skills that execute in [Azure Functions](#) or any other Web Framework that runs locally (for example, [FastAPI](#)).

Get a public URL

This section describes two approaches for getting a public URL to a custom skill.

Use Tunnelmole

Tunnelmole is an open source tunneling tool that can create a public URL that forwards requests to your local machine through a tunnel.

1. Install Tunnelmole:

- npm: `npm install -g tunnelmole`
- Linux: `curl -s https://tunnelmole.com/sh/install-linux.sh | sudo bash`
- Mac: `curl -s https://tunnelmole.com/sh/install-mac.sh --output install-mac.sh`
`&& sudo bash install-mac.sh`

- Windows: Install by using npm. Or if you don't have Node.js installed, download the [precompiled .exe file for Windows](#) and put it somewhere in your PATH.

2. Run this command to create a new tunnel:

```
Console
```

```
tmole 7071
```

You should see a response that looks like this:

```
Console
```

```
http://m5hdpb-ip-49-183-170-144.tunnelmole.net is forwarding to  
localhost:7071  
https://m5hdpb-ip-49-183-170-144.tunnelmole.net is forwarding to  
localhost:7071
```

In the preceding example, `https://m5hdpb-ip-49-183-170-144.tunnelmole.net` forwards to port `7071` on your local machine, which is the default port where Azure functions are exposed.

Use ngrok

[ngrok](#) is a popular, closed source, cross-platform application that can create a tunneling or forwarding URL, so that internet requests reach your local machine. Use ngrok to forward requests from an enrichment pipeline in your search service to your machine to allow local debugging.

1. Install ngrok.
2. Open a terminal and go to the folder with the ngrok executable.
3. Run ngrok with the following command to create a new tunnel:

```
Console
```

```
ngrok http 7071
```

ⓘ Note

By default, Azure functions are exposed on 7071. Other tools and configurations might require that you provide a different port.

4. When ngrok starts, copy and save the public forwarding URL for the next step. The forwarding URL is randomly generated.

Session Status	online												
Account	[REDACTED]												
Version	2.3.40												
Region	United States (us)												
Web Interface	http://127.0.0.1:4040												
Forwarding	http://3b7e-2a0e-41b-8f8f-0-90c8-fd24-9bd7-22b6.ngrok.io -> http://localhost:7071												
Forwarding	https://3b7e-2a0e-41b-8f8f-0-90c8-fd24-9bd7-22b6.ngrok.io -> http://localhost:7071												
Connections	<table><thead><tr><th>ttl</th><th>opn</th><th>rt1</th><th>rt5</th><th>p50</th><th>p90</th></tr></thead><tbody><tr><td>0</td><td>0</td><td>0.00</td><td>0.00</td><td>0.00</td><td>0.00</td></tr></tbody></table>	ttl	opn	rt1	rt5	p50	p90	0	0	0.00	0.00	0.00	0.00
ttl	opn	rt1	rt5	p50	p90								
0	0	0.00	0.00	0.00	0.00								

Configure in Azure portal

Once you have a public URL for your custom skill, modify your Custom Web API Skill URI within a debug session to call the Tunnelmole or ngrok forwarding URL. Be sure to append "/api/FunctionName" when using Azure Function for executing the skillset code.

You can edit the skill definition in the **Skill settings** section of the **Skill details** pane.

Test your code

At this point, new requests from your debug session should now be sent to your local Azure Function. You can use breakpoints in your Visual Studio Code to debug your code or run step by step.

Next steps

Now that you understand the layout and capabilities of the Debug Sessions visual editor, try the tutorial for a hands-on experience.

[Tutorial: Explore Debug sessions](#)

Reference a path to enriched nodes using context and source properties an Azure AI Search skillset

05/27/2025

During skillset execution, the engine builds an in-memory [enrichment tree](#) that captures each enrichment, such as recognized entities or translated text. In this article, learn how to reference an enrichment node in the enrichment tree so that you can pass output to downstream skills or specify an output field mapping for a search index field.

This article uses examples to illustrate various scenarios. For the full syntax, see [Skill context and input annotation language](#).

Background concepts

Before reviewing the syntax, let's revisit a few important concepts to better understand the examples provided later in this article.

 [Expand table](#)

Term	Description
"enriched document"	An enriched document is an in-memory structure that collects skill output as it's created and it holds all enrichments related to a document. Think of an enriched document as a tree. Generally, the tree starts at the root document level, and each new enrichment is created from a previous node as its child.
"node"	Within an enriched document, a node (sometimes referred to as an "annotation") is specific output such as the "text" or "layoutText" of the OCR skill, or an original source field value such as the content of a product ID field, or metadata copied from the source such as <code>metadata_storage_path</code> from blobs in Azure Storage.
"context"	The scope of enrichment, which is either the entire document, a portion of a document (pages or sentences), or if you're working with images, the extracted images from a document. By default, the enrichment context is at the <code>"/document"</code> level, scoped to individual documents contained in the data source. When a skill runs, the outputs of that skill become properties of the defined context .

Paths for different scenarios

Paths are specified in the "context" and "source" properties of a skillset, and in the [output field mappings](#) in an indexer.

```
{  
    "@odata.type": "#Microsoft.Skills.Text.TranslationSkill",  
    "name": "#2",  
    "description": null,  
    "context": "/document/HotelId",  
    "defaultFromLanguageCode": null,  
    "defaultToLanguageCode": "es",  
    "suggestedFrom": "en",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/Description"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "translatedText",  
            "targetName": "translated_text"  
        }  
    ]  
}
```

The example in the screenshot illustrates the path for an item in an Azure Cosmos DB collection.

- `context` path is `/document/HotelId` because the collection is partitioned into documents by the `/HotelId` field.
- `source` path is `/document/Description` because the skill is a translation skill, and the field that you want to translate is the `Description` field in each document.

All paths start with `/document`. An enriched document is created in the "document cracking" stage of indexer execution, when the indexer opens a document or reads in a row from the data source. Initially, the only node in an enriched document is the [root node \(`/document`\)](#), and it's the node from which all other enrichments occur.

The following list includes several common examples:

- `/document` is the root node and indicates an entire blob in Azure Storage, or a row in a SQL table.
- `/document/{key}` is the syntax for a document or item in an Azure Cosmos DB collection, where `{key}` is the actual key, such as `/document/HotelId` in the previous example.
- `/document/content` specifies the "content" property of a JSON blob.

- `/document/{field}` is the syntax for an operation performed on a specific field, such as translating the `/document/Description` field, seen in the previous example.
- `/document/pages/*` or `/document/sentences/*` become the context if you're breaking a large document into smaller chunks for processing. If "context" is `/document/pages/*`, the skill executes once over each page in the document. Because there might be more than one page or sentence, you can append `/*` to catch them all.
- `/document/normalized_images/*` is created during document cracking if the document contains images. All paths to images start with normalized_images. Since there are often multiple images embedded in a document, append `/*`.

Examples in the remainder of this article are based on the "content" field generated automatically by [Azure blob indexers](#) as part of the [document cracking](#) phase. When referring to documents from a Blob container, use a format such as `"/document/content"`, where the "content" field is part of the "document".

Example 1: Simple annotation reference

In Azure Blob Storage, suppose you have various files containing references to people's names that you want to extract using entity recognition. In the following skill definition, `"/document/content"` is the textual representation of the entire document, and "people" is an extraction of full names for entities identified as persons.

Because the default context is `"/document"`, the list of people can now be referenced as `"/document/people"`. In this specific case `"/document/people"` is an annotation, which could now be mapped to a field in an index, or used in another skill in the same skillset.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
  "categories": [ "Person" ],
  "defaultLanguageCode": "en",
  "inputs": [
    {
      "name": "text",
      "source": "/document/content"
    }
  ],
  "outputs": [
    {
      "name": "persons",
      "targetName": "people"
    }
  ]
}
```

```
]  
}
```

Example 2: Reference an array within a document

This example builds on the previous one, showing you how to invoke an enrichment step multiple times over the same document. Assume the previous example generated an array of strings with 10 people names from a single document. A reasonable next step might be a second enrichment that extracts the last name from a full name. Because there are 10 names, you want this step to be called 10 times in this document, once for each person.

To invoke the right number of iterations, set the context as `"/document/people/*"`, where the asterisk (`"*"`) represents all the nodes in the enriched document as descendants of `"/document/people"`. Although this skill is only defined once in the skills array, it's called for each member within the document until all members are processed.

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",  
    "description": "Fictitious skill that gets the last name from a full name",  
    "uri": "http://names.azurewebsites.net/api/GetLastName",  
    "context" : "/document/people/*",  
    "defaultLanguageCode": "en",  
    "inputs": [  
        {  
            "name": "fullname",  
            "source": "/document/people/*"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "lastname",  
            "targetName": "last"  
        }  
    ]  
}
```

When annotations are arrays or collections of strings, you might want to target specific members rather than the array as a whole. The previous example generates an annotation called `"last"` under each node represented by the context. If you want to refer to this family of annotations, you could use the syntax `"/document/people/*/last"`. If you want to refer to a particular annotation, you could use an explicit index: `"/document/people/1/last"` to reference the last name of the first person identified in the document. Notice that in this syntax arrays are "0 indexed".

Example 3: Reference members within an array

Sometimes you need to group all annotations of a particular type to pass them to a particular skill. Consider a hypothetical custom skill that identifies the most common last name from all the last names extracted in Example 2. To provide just the last names to the custom skill, specify the context as `"/document"` and the input as `"/document/people/*/lastname"`.

Notice that the cardinality of `"/document/people/*/lastname"` is larger than that of document. There might be 10 lastname nodes while there's only one document node for this document. In that case, the system will automatically create an array of `"/document/people/*/lastname"` containing all of the elements in the document.

```
JSON

{
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",
    "description": "Fictitious skill that gets the most common string from an
array of strings",
    "uri": "http://names.azurewebsites.net/api/MostCommonString",
    "context" : "/document",
    "inputs": [
        {
            "name": "strings",
            "source": "/document/people/*/lastname"
        }
    ],
    "outputs": [
        {
            "name": "mostcommon",
            "targetName": "common-lastname"
        }
    ]
}
```

Tips for annotation path troubleshooting

If you're having trouble with specifying skill inputs, these tips might help you move forward:

- [Run the Import data wizard](#) over your data to review the skillset definitions and field mappings that the wizard generates.
- [Start a debug session](#) on a skillset to view the structure of an enriched document. You can edit the paths and other parts of the skill definition, and then run the skill to validate your changes.

Map enriched output to fields in a search index in Azure AI Search

Article • 04/14/2025

This article explains how to set up *output field mappings*, defining a data path between in-memory data generated during [skillset processing](#), and target fields in a search index. During indexer execution, skills-generated information exists in memory only. To persist this information in a search index, you need to tell the indexer where to send the data.

An output field mapping is defined in an [indexer](#) and has the following elements:

JSON

```
"outputFieldMappings": [
  {
    "sourceFieldName": "document/path-to-a-node-in-an-enriched-document",
    "targetFieldName": "some-search-field-in-an-index",
    "mappingFunction": null
  }
],
```

In contrast with a [fieldMappings](#) definition that maps a path between verbatim source fields and index fields, an [outputFieldMappings](#) definition maps in-memory enrichments to fields in a search index.

Prerequisites

- Indexer, index, data source, and skillset.
- Index fields must be simple or top-level fields. You can't output to a [complex type](#). However, if you have a complex type, you can use an output field definition to flatten parts of the complex type and send them to a collection in a search index.

When to use an output field mapping

Output field mappings are required if your indexer has an attached [skillset](#) that creates new information that you want in your index. Examples include:

- Vectors from embedding skills
- Optical character recognition (OCR) text from image skills
- Locations, organizations, or people from entity recognition skills

Output field mappings can also be used to:

- Create multiple copies of your generated content (one-to-many output field mappings).
- Flatten a source document's complex type. For example, assume source documents have a complex type, such as a multipart address, and you want just the city. You can use an output field mapping to [flatten a nested data structure](#), and then use an output field mapping to send the output to a string collection in your search index.

Output field mappings apply to search indexes only. If you're populating a [knowledge store](#), use [projections](#) for data path configuration.

Define an output field mapping

Output field mappings are added to the `outputFieldMappings` array in an indexer definition, typically placed after the `fieldMappings` array. An output field mapping consists of three parts.

You can use the REST API or an Azure SDK to define output field mappings.

Tip

Indexers created by the [Import data wizard](#) include output field mappings generated by the wizard. If you need examples, run the wizard over your data source to see the output field mappings in the indexer.

REST APIs

1. Use [Create Indexer](#) or [Create or Update Indexer](#) or an equivalent method in an Azure SDK. Here's an example of an indexer definition.

JSON

```
{  
  "name": "myindexer",  
  "description": null,  
  "dataSourceName": "mydatasource",  
  "targetIndexName": "myindex",  
  "schedule": { },  
  "parameters": { },
```

```

    "fieldMappings": [],
    "outputFieldMappings": [],
    "disabled": false,
    "encryptionKey": { }
}

```

2. Fill out the `outputFieldMappings` array to specify the mappings. A field mapping consists of three parts.

JSON

```

"outputFieldMappings": [
{
  "sourceFieldName": "/document/path-to-a-node-in-an-enriched-
document",
  "targetFieldName": "some-search-field-in-an-index",
  "mappingFunction": null
}
]

```

[\[\] Expand table](#)

Property	Description
sourceFieldName	Required. Specifies a path to enriched content. An example might be <code>/document/content</code> . See Reference enrichments in an Azure AI Search skillset for path syntax and examples.
targetFieldName	Optional. Specifies the search field that receives the enriched content. Target fields must be top-level simple fields or collections. It can't be a path to a subfield in a complex type. If you want to retrieve specific nodes in a complex structure, you can flatten individual nodes in memory, and then send the output to a string collection in your index.
mappingFunction	Optional. Adds extra processing provided by mapping functions supported by indexers. For enrichment nodes, encoding and decoding are the most commonly used functions.

3. The `targetFieldName` is always the name of the field in the search index.
4. The `sourceFieldName` is a path to a node in the enriched document. It's the output of a skill. The path always starts with `/document`, and if you're indexing from a blob, the second element of the path is `/content`. The third element is the value produced by the skill. For more information and examples, see [Reference enrichments in an Azure AI Search skillset](#).

This example adds entities and sentiment labels extracted from a blob's content property to fields in a search index.

JSON

```
{  
    "name": "myIndexer",  
    "dataSourceName": "myDataSource",  
    "targetIndexName": "myIndex",  
    "skillsetName": "myFirstSkillSet",  
    "fieldMappings": [],  
    "outputFieldMappings": [  
        {  
            "sourceFieldName":  
                "/document/content/organizations/*/description",  
            "targetFieldName": "descriptions",  
            "mappingFunction": {  
                "name": "base64Decode"  
            }  
        },  
        {  
            "sourceFieldName": "/document/content/organizations",  
            "targetFieldName": "orgNames"  
        },  
        {  
            "sourceFieldName": "/document/content/sentiment",  
            "targetFieldName": "sentiment"  
        }  
    ]  
}
```

5. Assign any [mapping functions](#) needed to transform the content of a field before it's stored in the index. For enrichment nodes, encoding and decoding are the most commonly used functions.

One-to-many output field mapping

You can use an output field mapping to route a single source field to multiple fields in a search index. You might do this for comparison testing or if you want fields with different attributes.

Assume a skillset that generates embeddings for a vector field, and an index that has multiple vector fields that vary by algorithm and compression settings. Within the indexer, map the embedding skill's output to each of the multiple vector fields in a search index.

JSON

```

"outputFieldMappings": [
    { "sourceFieldName" : "/document/content/text_vector", "targetFieldName" :
"vector_hnsw" },
    { "sourceFieldName" : "/document/content/text_vector", "targetFieldName" :
"vector_eknn" },
    { "sourceFieldName" : "/document/content/text_vector", "targetFieldName" :
"vector_narrow" },
    { "sourceFieldName" : "/document/content/text_vector", "targetFieldName" :
"vector_no_stored" },
    { "sourceFieldName" : "/document/content/text_vector", "targetFieldName" :
"vector_scalar" }
]

```

The source field path is skill output. In this example, the output is *text_vector*. Target name is an optional property. If you don't give the output mapping a target name, the path would be *embedding* or more precisely, */document/content/embedding*.

JSON

```
{
    "name": "test-vector-size-ss",
    "description": "Generate embeddings using Azure OpenAI Service",
    "skills": [
        {
            "@odata.type": "#Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill",
            "name": "#1",
            "description": null,
            "context": "/document/content",
            "resourceUri": "https://my-demo-eastus.openai.azure.com",
            "apiKey": null,
            "deploymentId": "text-embedding-ada-002",
            "dimensions": 1536,
            "modelName": "text-embedding-ada-002",
            "inputs": [
                {
                    "name": "text",
                    "source": "/document/content"
                }
            ],
            "outputs": [
                {
                    "name": "embedding",
                    "targetName": "text_vector"
                }
            ],
            "authIdentity": null
        }
    ]
}
```

Flatten complex structures into a string collection

If your source data is composed of nested or hierarchical JSON, you can't use field mappings to set up the data paths. Instead, your search index must mirror the source data structure for at each level for a full import.

This section walks you through an import process that produces a one-to-one reflection of a complex document on both the source and target sides. Next, it uses the same source document to illustrate the retrieval and flattening of individual nodes into string collections.

Here's an example of a document in Azure Cosmos DB with nested JSON:

```
JSON

{
  "palette": "primary colors",
  "colors": [
    {
      "name": "blue",
      "medium": [
        "acrylic",
        "oil",
        "pastel"
      ]
    },
    {
      "name": "red",
      "medium": [
        "acrylic",
        "pastel",
        "watercolor"
      ]
    },
    {
      "name": "yellow",
      "medium": [
        "acrylic",
        "watercolor"
      ]
    }
  ]
}
```

If you wanted to fully index this source document, you'd create an index definition where the field names, levels, and types are reflected as a complex type. Because field mappings aren't supported for complex types in the search index, your index definition must mirror the source document.

```
JSON
```

```
{
  "name": "my-test-index",
  "defaultScoringProfile": "",
  "fields": [
    { "name": "id", "type": "Edm.String", "searchable": false, "retrievable": true, "key": true},
    { "name": "palette", "type": "Edm.String", "searchable": true, "retrievable": true },
    { "name": "colors", "type": "Collection(Edm.ComplexType)", "fields": [
      {
        "name": "name",
        "type": "Edm.String",
        "searchable": true,
        "retrievable": true
      },
      {
        "name": "medium",
        "type": "Collection(Edm.String)",
        "searchable": true,
        "retrievable": true,
      }
    ]
  }
}
```

Here's a sample indexer definition that executes the import. Notice there are no field mappings and no skillset.

JSON

```
{
  "name": "my-test-indexer",
  "dataSourceName": "my-test-ds",
  "skillsetName": null,
  "targetIndexName": "my-test-index",

  "fieldMappings": [],
  "outputFieldMappings": []
}
```

The result is the following sample search document, similar to the original in Azure Cosmos DB.

JSON

```
{
  "value": [
    {
      "@search.score": 1,
```

```

"id": "11bb11bb-cc22-dd33-ee44-55ff55ff55ff",
"palette": "primary colors",
"colors": [
  {
    "name": "blue",
    "medium": [
      "acrylic",
      "oil",
      "pastel"
    ]
  },
  {
    "name": "red",
    "medium": [
      "acrylic",
      "pastel",
      "watercolor"
    ]
  },
  {
    "name": "yellow",
    "medium": [
      "acrylic",
      "watercolor"
    ]
  }
]
}

```

An alternative rendering in a search index is to flatten individual nodes in the source's nested structure into a string collection in a search index.

To accomplish this task, you'll need an `outputFieldMappings` that maps an in-memory node to a string collection in the index. Although output field mappings primarily apply to skill outputs, you can also use them to address nodes after [document cracking](#) where the indexer opens a source document and reads it into memory.

The following sample index definition uses string collections to receive flattened output:

JSON

```
{
  "name": "my-new-flattened-index",
  "defaultScoringProfile": "",
  "fields": [
    { "name": "id", "type": "Edm.String", "searchable": false, "retrievable": true, "key": true },
    { "name": "palette", "type": "Edm.String", "searchable": true, "retrievable": true },
    { "name": "blue", "type": "Edm.String", "searchable": false, "retrievable": true },
    { "name": "red", "type": "Edm.String", "searchable": false, "retrievable": true },
    { "name": "yellow", "type": "Edm.String", "searchable": false, "retrievable": true }
  ]
}
```

```

        { "name": "color_names", "type": "Collection(Edm.String)", "searchable": true,
      "retrievable": true },
        { "name": "color_mediums", "type": "Collection(Edm.String)", "searchable": true,
      "retrievable": true}
    ]
}

```

Here's the sample indexer definition, using `outputFieldMappings` to associate the nested JSON with the string collection fields. Notice that the source field uses the path syntax for enrichment nodes, even though there's no skillset. Enriched documents are created in the system during document cracking, which means you can access nodes in each document tree as long as those nodes exist when the document is cracked.

JSON

```
{
  "name": "my-test-indexer",
  "dataSourceName": "my-test-ds",
  "skillsetName": null,
  "targetIndexName": "my-new-flattened-index",
  "parameters": { },
  "fieldMappings": [ ],
  "outputFieldMappings": [
    {
      "sourceFieldName": "/document/colors/*/name",
      "targetFieldName": "color_names"
    },
    {
      "sourceFieldName": "/document/colors/*/medium",
      "targetFieldName": "color_mediums"
    }
  ]
}
```

Results from the definition are as follows. Simplifying the structure loses context in this case. There's no longer any associations between a given color and the mediums it's available in. However, depending on your scenario, a result similar to the following example might be exactly what you need.

JSON

```
{
  "value": [
    {
      "@search.score": 1,
      "id": "11bb11bb-cc22-dd33-ee44-55ff55ff55ff",
      "palette": "primary colors",
      "color_names": [
        "blue",
        "red",
        "green"
      ]
    }
  ]
}
```

```
        "red",
        "yellow"
    ],
    "color_mediums": [
        "[\"acrylic\", \"oil\", \"pastel\"]",
        "[\"acrylic\", \"pastel\", \"watercolor\"]",
        "[\"acrylic\", \"watercolor\"]"
    ]
}
```

Extract text and information from images by using AI enrichment

Images often contain useful information that's relevant in search scenarios. Azure AI Search doesn't query image content in real time, but you can extract information about an image during indexing and make that content searchable. To represent images in a search index, you can use these approaches:

- [Vectorize images](#) to represent visual content as a searchable vector.
- [Verbalize images](#) using the GenAI Prompt skill that sends a verbalization request to a chat completion model to describe the image.
- [Analyze images](#) using an image analysis skill to generate a text representation of an image, such as *dandelion* for a photo of a dandelion, or the color *yellow*. You can also extract metadata about the image, such as its size.
- [Use OCR](#) to extract text from photos or pictures, such as the word *STOP* in a stop sign.

You can also create a [custom skill](#) to invoke any external image processing that you want to provide.

This article focuses on image analysis and OCR, custom skills that provide external processing, working with embedded images, and overlaying visualizations on original images. If verbalization or vectorization is your preferred approach, see [Multimodal search](#) instead.

To work with image content in a skillset, you need:

- ✓ Source files that include images
- ✓ A search indexer, configured for image actions
- ✓ A skillset with built-in or custom skills that invoke OCR or image analysis
- ✓ A search index with fields to receive the analyzed text output, plus output field mappings in the indexer that establish association

Optionally, you can define projections to accept image-analyzed output into a [knowledge store](#) for data mining scenarios.

Set up source files

Image processing is indexer-driven, which means that the raw inputs must be in a [supported data source](#).

- Image analysis supports JPEG, PNG, GIF, and BMP
- OCR supports JPEG, PNG, BMP, and TIF

Images are either standalone binary files or embedded in documents, such as PDF, RTF, or Microsoft application files. A maximum of 1,000 images can be extracted from a given document. If there are more than 1,000 images in a document, the first 1,000 are extracted and then a warning is generated.

Azure Blob Storage is the most frequently used storage for image processing in Azure AI Search. There are three main tasks related to retrieving images from a blob container:

- Enable access to content in the container. If you're using a full access connection string that includes a key, the key gives you permission to the content. Alternatively, you can authenticate using a [managed identity](#) or [connect as a trusted service](#).
- [Create a data source](#) of type *azureblob* that connects to the blob container storing your files.
- Review [service tier limits](#) to make sure that your source data is under maximum size and quantity limits for indexers and enrichment.

Configure indexers for image processing

After the source files are set up, enable image normalization by setting the `imageAction` parameter in indexer configuration. Image normalization helps make images more uniform for downstream processing. Image normalization includes the following operations:

- Large images are resized to a maximum height and width to make them uniform.
- For images that have metadata that specifies orientation, image rotation is adjusted for vertical loading.

Note that enabling `imageAction` (setting this parameter to other than `none`) will incur an additional charge for image extraction according to [Azure AI Search pricing](#).

Metadata adjustments are captured in a complex type created for each image. You can't opt out of the image normalization requirement. Skills that iterate over images, such as OCR and image analysis, expect normalized images.

1. [Create or update an indexer](#) to set the configuration properties:

JSON

```
{  
  "parameters":  
  {  
    "configuration":  
    {  
      "dataToExtract": "contentAndMetadata",  
    }  
  }  
}
```

```
        "parsingMode": "default",
        "imageAction": "generateNormalizedImages"
    }
}
```

2. Set `dataToExtract` to `contentAndMetadata` (required).

3. Verify that the `parsingMode` is set to *default* (required).

This parameter determines the granularity of search documents created in the index. The default mode sets up a one-to-one correspondence so that one blob results in one search document. If documents are large, or if skills require smaller chunks of text, you can add the Text Split skill that subdivides a document into paging for processing purposes. But for search scenarios, one blob per document is required if enrichment includes image processing.

4. Set `imageAction` to enable the `normalized_images` node in an enrichment tree (required):

- `generateNormalizedImages` to generate an array of normalized images as part of document cracking.
- `generateNormalizedImagePerPage` (applies to PDF only) to generate an array of normalized images where each page in the PDF is rendered to one output image. For non-PDF files, the behavior of this parameter is similar as if you had set `generateNormalizedImages`. However, setting `generateNormalizedImagePerPage` can make indexing operation less performant by design (especially for large documents) since several images would have to be generated.

5. Optionally, adjust the width or height of the generated normalized images:

- `normalizedImageMaxWidth` in pixels. Default is 2,000. Maximum value is 10,000.
- `normalizedImageMaxHeight` in pixels. Default is 2,000. Maximum value is 10,000.

The default of 2,000 pixels for the normalized images maximum width and height is based on the maximum sizes supported by the [OCR skill](#) and the [image analysis skill](#). The [OCR skill](#) supports a maximum width and height of 4,200 for non-English languages, and 10,000 for English. If you increase the maximum limits, processing could fail on larger images depending on your skillset definition and the language of the documents.

6. Optionally, [set file type criteria](#) if the workload targets a specific file type. Blob indexer configuration includes file inclusion and exclusion settings. You can filter out files you don't want.

JSON

```
{  
  "parameters" : {  
    "configuration" : {  
      "indexedFileNameExtensions" : ".pdf, .docx",  
      "excludedFileNameExtensions" : ".png, .jpeg"  
    }  
  }  
}
```

About normalized images

When `imageAction` is set to a value other than `none`, the new `normalized_images` field contains an array of images. Each image is a complex type that has the following members:

[] [Expand table](#)

Image member	Description
data	BASE64 encoded string of the normalized image in JPEG format.
width	Width of the normalized image in pixels.
height	Height of the normalized image in pixels.
originalWidth	The original width of the image before normalization.
originalHeight	The original height of the image before normalization.
rotationFromOriginal	Counter-clockwise rotation in degrees that occurred to create the normalized image. A value between 0 degrees and 360 degrees. This step reads the metadata from the image that is generated by a camera or scanner. Usually a multiple of 90 degrees.
contentOffset	The character offset within the content field where the image was extracted from. This field is only applicable for files with embedded images. The <code>contentOffset</code> for images extracted from PDF documents is always at the end of the text on the page it was extracted from in the document. This means images appear after all text on that page, regardless of the original location of the image in the page.
pageNumber	If the image was extracted or rendered from a PDF, this field contains the page number in the PDF it was extracted or rendered from, starting from 1. If the image isn't from a PDF, this field is 0.
boundingPolygon	If the image was extracted or rendered from a PDF, this field contains the coordinates of the bounding polygon that encloses the image on the page. The polygon is represented as a nested array of points, where each point has x and y

Image member	Description
	coordinates normalized to the dimensions of the page. This only applies to images extracted using <code>imageAction: generateNormalizedImages</code> .

Sample value of `normalized_images`:

JSON

```
[  
  {  
    "data": "BASE64 ENCODED STRING OF A JPEG IMAGE",  
    "width": 500,  
    "height": 300,  
    "originalWidth": 5000,  
    "originalHeight": 3000,  
    "rotationFromOriginal": 90,  
    "contentOffset": 500,  
    "pageNumber": 2,  
    "boundingPolygon": "[[{"x":0.0,"y":0.0},{x:500.0,y:0.0},  
    {"x":0.0,y:300.0},{x:500.0,y:300.0}]]"  
  }  
]
```

(!) Note

Bounding polygon data is represented as a string containing a double-nested, JSON-encoded array of polygons. Each polygon is an array of points, where each point has x and y coordinates. Coordinates are relative to the PDF page, with the origin (0, 0) at the top-left corner. Currently, images extracted using `imageAction: generateNormalizedImages` will always produce a single polygon, but the double-nested structure is maintained for consistency with the Document Layout skill, which supports multiple polygons.

Define skillsets for image processing

This section supplements the [skill reference](#) articles by providing context for working with skill inputs, outputs, and patterns, as they relate to image processing.

1. [Create or update a skillset](#) to add skills.
2. Add templates for OCR and image analysis from the Azure portal, or copy the definitions from the [skill reference](#) documentation. Insert them into the skills array of your skillset definition.

3. If necessary, [include a Microsoft Foundry resource key](#) in the skillset. Azure AI Search makes calls to a billable Foundry resource for OCR and image analysis for transactions that exceed the free limit (20 per indexer per day). The Foundry resource must be in the same region as your search service.
4. If original images are embedded in PDF or application files like PPTX or DOCX, you need to add a Text Merge skill if you want image output and text output together. Working with embedded images is discussed further on in this article.

Once the basic framework of your skillset is created and Foundry Tools is configured, you can focus on each individual image skill, defining inputs and source context, and mapping outputs to fields in either an index or knowledge store.

 **Note**

For an example skillset that combines image processing with downstream natural language processing, see [REST Tutorial: Use REST and AI to generate searchable content from Azure blobs](#). It shows how to feed skill imaging output into entity recognition and key phrase extraction.

Inputs for image processing

As noted, images are extracted during document cracking and then normalized as a preliminary step. The normalized images are the inputs to any image processing skill, and are always represented in an enriched document tree in either one of two ways:

- `/document/normalized_images/*` is for documents that are processed whole.
- `/document/normalized_images/*/pages` is for documents that are processed in chunks (pages).

Whether you're using OCR and image analysis in the same, inputs have virtually the same construction:

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",  
  "context": "/document/normalized_images/*",  
  "detectOrientation": true,  
  "inputs": [  
    {  
      "name": "image",  
      "source": "/document/normalized_images/*"
```

```

        },
    ],
    "outputs": [ ]
},
{
    "@odata.type": "#Microsoft.Skills.Vision.ImageAnalysisSkill",
    "context": "/document/normalized_images/*",
    "visualFeatures": [ "tags", "description" ],
    "inputs": [
        {
            "name": "image",
            "source": "/document/normalized_images/*"
        }
    ],
    "outputs": [ ]
}

```

Map outputs to search fields

In a skillset, Image Analysis and OCR skill output is always text. Output text is represented as nodes in an internal enriched document tree, and each node must be mapped to fields in a search index, or to projections in a knowledge store, to make the content available in your app.

1. In the skillset, review the `outputs` section of each skill to determine which nodes exist in the enriched document:

JSON

```

{
    "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",
    "context": "/document/normalized_images/*",
    "detectOrientation": true,
    "inputs": [ ],
    "outputs": [
        {
            "name": "text",
            "targetName": "text"
        },
        {
            "name": "layoutText",
            "targetName": "layoutText"
        }
    ]
}

```

2. [Create or update a search index](#) to add fields to accept the skill outputs.

In the following fields collection example, *content* is blob content.

Metadata_storage_name contains the name of the file (set `retrievable` to *true*).

Metadata_storage_path is the unique path of the blob and is the default document key.
Merged_content is output from Text Merge (useful when images are embedded).

Text and *layoutText* are OCR skill outputs and must be a string collection in order to the capture all of the OCR-generated output for the entire document.

JSON

```
"fields": [
  {
    "name": "content",
    "type": "Edm.String",
    "filterable": false,
    "retrievable": true,
    "searchable": true,
    "sortable": false
  },
  {
    "name": "metadata_storage_name",
    "type": "Edm.String",
    "filterable": true,
    "retrievable": true,
    "searchable": true,
    "sortable": false
  },
  {
    "name": "metadata_storage_path",
    "type": "Edm.String",
    "filterable": false,
    "key": true,
    "retrievable": true,
    "searchable": false,
    "sortable": false
  },
  {
    "name": "merged_content",
    "type": "Edm.String",
    "filterable": false,
    "retrievable": true,
    "searchable": true,
    "sortable": false
  },
  {
    "name": "text",
    "type": "Collection(Edm.String)",
    "filterable": false,
    "retrievable": true,
    "searchable": true
  },
  {
    "name": "layoutText",
    "type": "Collection(Edm.String)",
    "filterable": false,
```

```
        "retrievable": true,  
        "searchable": true  
    },  
],
```

3. Update the indexer to map skillset output (nodes in an enrichment tree) to index fields.

Enriched documents are internal. To externalize the nodes in an enriched document tree, set up an output field mapping that specifies which index field receives node content.

Enriched data is accessed by your app through an index field. The following example shows a *text* node (OCR output) in an enriched document that's mapped to a *text* field in a search index.

JSON

```
"outputFieldMappings": [  
    {  
        "sourceFieldName": "/document/normalized_images/*/text",  
        "targetFieldName": "text"  
    },  
    {  
        "sourceFieldName": "/document/normalized_images/*/layoutText",  
        "targetFieldName": "layoutText"  
    }  
]
```

4. Run the indexer to invoke source document retrieval, image processing, and indexing.

Verify results

Run a query against the index to check the results of image processing. Use [Search Explorer](#) as a search client, or any tool that sends HTTP requests. The following query selects fields that contain the output of image processing.

HTTP

```
POST /indexes/[index name]/docs/search?api-version=[api-version]  
{  
    "search": "*",  
    "select": "metadata_storage_name, text, layoutText, imageCaption, imageTags"  
}
```

OCR recognizes text in image files. This means that OCR fields (*text* and *layoutText*) are empty if source documents are pure text or pure imagery. Similarly, image analysis fields (*imageCaption* and *imageTags*) are empty if source document inputs are strictly text. Indexer execution emits warnings if imaging inputs are empty. Such warnings are to be expected when nodes are unpopulated in the enriched document. Recall that blob indexing lets you include or exclude

file types if you want to work with content types in isolation. You can use these settings to reduce noise during indexer runs.

An alternate query for checking results might include the *content* and *merged_content* fields. Notice that those fields include content for any blob file, even those where there was no image processing performed.

About skill outputs

Skill outputs include `text` (OCR), `layoutText` (OCR), `merged_content`, `captions` (image analysis), `tags` (image analysis):

- `text` stores OCR-generated output. This node should be mapped to field of type `Collection(Edm.String)`. There's one `text` field per search document consisting of comma-delimited strings for documents that contain multiple images. The following illustration shows OCR output for three documents. First is a document containing a file with no images. Second is a document (image file) containing one word, *Microsoft*. Third is a document containing multiple images, some without any text ("").

JSON

```
"value": [
  {
    "@search.score": 1,
    "metadata_storage_name": "facts-about-microsoft.html",
    "text": []
  },
  {
    "@search.score": 1,
    "metadata_storage_name": "guthrie.jpg",
    "text": [ "Microsoft" ]
  },
  {
    "@search.score": 1,
    "metadata_storage_name": "Foundry Tools and Content Intelligence.pptx",
    "text": [
      "",
      "Microsoft",
      "",
      "",
      "",
      "",
      "Azure AI Search and Augmentation Combining Foundry Tools and Azure
Search"
    ]
  }
]
```

- `layoutText` stores OCR-generated information about text location on the page, described in terms of bounding boxes and coordinates of the normalized image. This node should be mapped to field of type `Collection(Edm.String)`. There's one `layoutText` field per search document consisting of comma-delimited strings.
- `merged_content` stores the output of a Text Merge skill, and it should be one large field of type `Edm.String` that contains raw text from the source document, with embedded `text` in place of an image. If files are text-only, then OCR and image analysis have nothing to do, and `merged_content` is the same as `content` (a blob property that contains the content of the blob).
- `imageCaption` captures a description of an image as individuals tags and a longer text description.
- `imageTags` stores tags about an image as a collection of keywords, one collection for all images in the source document.

The following screenshot is an illustration of a PDF that includes text and embedded images. Document cracking detected three embedded images: flock of seagulls, map, eagle. Other text in the example (including titles, headings, and body text) was extracted as text and excluded from image processing.

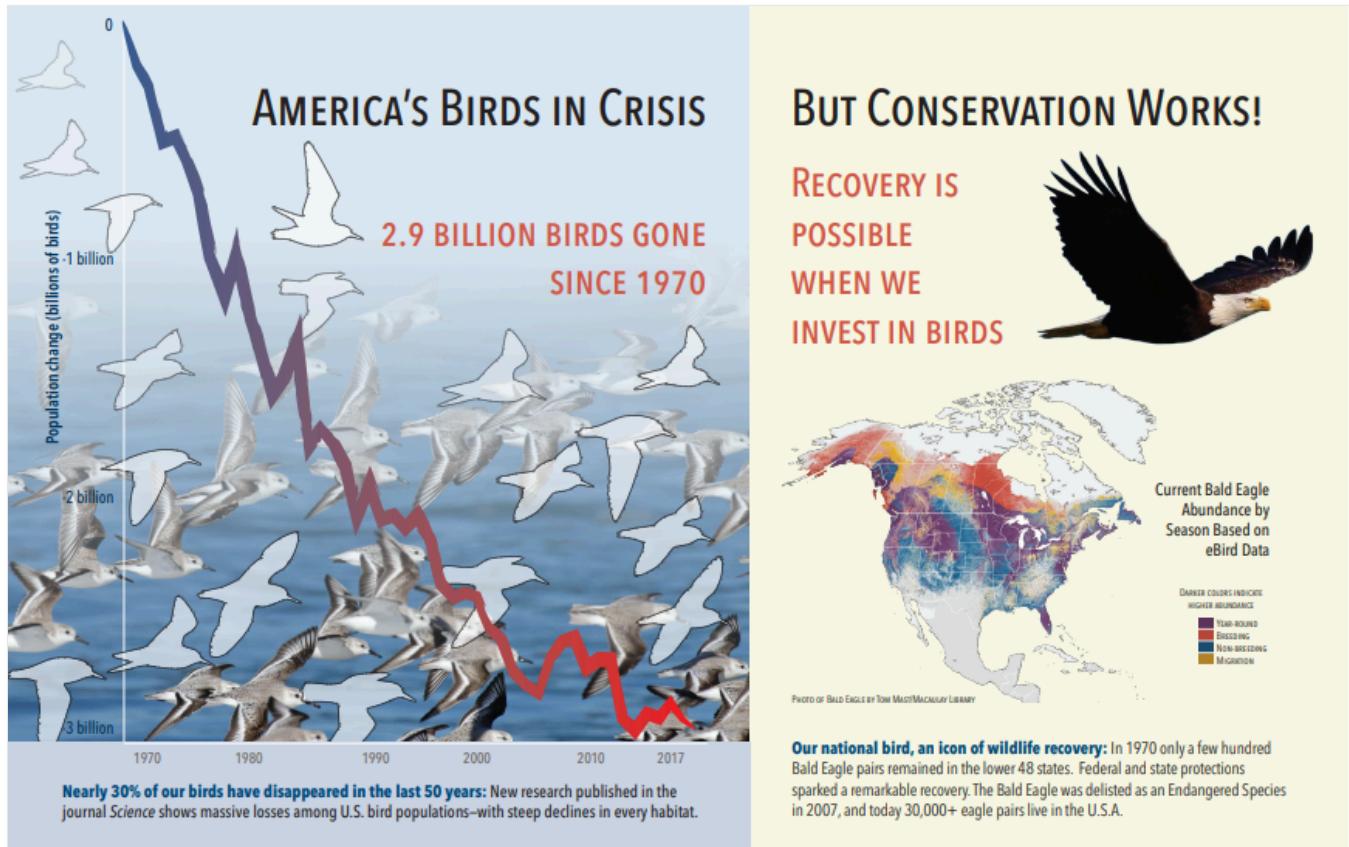

Image analysis output is illustrated in the following JSON (search result). The skill definition allows you to specify which [visual features](#) are of interest. For this example, tags and

descriptions were produced, but there are more outputs to choose from.

- `imageCaption` output is an array of descriptions, one per image, denoted by `tags` consisting of single words and longer phrases that describe the image. Notice the tags consisting of *a flock of seagulls are swimming in the water, or a close up of a bird*.
- `imageTags` output is an array of single tags, listed in the order of creation. Notice that tags repeat. There's no aggregation or grouping.

JSON

```
"imageCaption": [
    "{\"tags\": [
        \"bird\", \"outdoor\", \"water\", \"flock\", \"many\", \"lot\", \"bunch\", \"group\", \"several\",
        \"gathered\", \"pond\", \"lake\", \"different\", \"family\", \"flying\", \"standing\",
        \"little\", \"air\", \"beach\", \"swimming\", \"large\", \"dog\", \"landing\", \"jumping\",
        \"playing\"], \"captions\": [{\"text\": \"a flock of seagulls are swimming in the
        water\", \"confidence\": 0.70419257326275686}]}",
    "{\"tags\": [\"map\"], \"captions\": [
        {\"text\": \"map\", \"confidence\": 0.99942880868911743}]}",
    "{\"tags\": [
        \"animal\", \"bird\", \"raptor\", \"eagle\", \"sitting\", \"table\"], \"captions\": [
        {\"text\": \"a close up of a bird\", \"confidence\": 0.89643581933539462}]}",
    ...
],
"imageTags": [
    "bird",
    "outdoor",
    "water",
    "flock",
    "animal",
    "bunch",
    "group",
    "several",
    "drink",
    "gathered",
    "pond",
    "different",
    "family",
    "same",
    "map",
    "text",
    "animal",
    "bird",
    "bird of prey",
    "eagle"
]
}
```

Scenario: Embedded images in PDFs

When the images you want to process are embedded in other files, such as PDF or DOCX, the enrichment pipeline extracts just the images and then passes them to OCR or image analysis for processing. Image extraction occurs during the document cracking phase, and once the images are separated, they remain separate unless you explicitly merge the processed output back into the source text.

Text Merge is used to put image processing output back into the document. Although Text Merge isn't a hard requirement, it's frequently invoked so that image output (OCR text, OCR layoutText, image tags, image captions) can be reintroduced into the document. Depending on the skill, the image output replaces an embedded binary image with an in-place text equivalent. Image Analysis output can be merged at image location. OCR output always appears at the end of each page.

The following workflow outlines the process of image extraction, analysis, merging, and how to extend the pipeline to push image-processed output into other text-based skills such as Entity Recognition or Text Translation.

1. After connecting to the data source, the indexer loads and cracks source documents, extracting images and text, and queuing each content type for processing. An enriched document consisting only of a root node (*document*) is created.
2. Images in the queue are **normalized** and passed into enriched documents as a [`document/normalized_images`](#) node.
3. Image enrichments execute, using [`/document/normalized_images`](#) as input.
4. Image outputs are passed into the enriched document tree, with each output as a separate node. Outputs vary by skill (text and layoutText for OCR; tags and captions for Image Analysis).
5. Optional but recommended if you want search documents to include both text and image-origin text together, **Text Merge** runs, combining the text representation of those images with the raw text extracted from the file. Text chunks are consolidated into a single large string, where the text is inserted first in the string and then the OCR text output or image tags and captions.

The output of Text Merge is now the definitive text to analyze for any downstream skills that perform text processing. For example, if your skillset includes both OCR and Entity Recognition, the input to Entity Recognition should be [`"document/merged_text"`](#) (the `targetName` of the Text Merge skill output).

6. After all skills have executed, the enriched document is complete. In the last step, indexers refer to **output field mappings** to send enriched content to individual fields in the search index.

The following example skillset creates a `merged_text` field containing the original text of your document with embedded OCRed text in place of embedded images. It also includes an Entity Recognition skill that uses `merged_text` as input.

Request body syntax

JSON

```
{
  "description": "Extract text from images and merge with content text to produce merged_text",
  "skills": [
    {
      "description": "Extract text (plain and structured) from image.",
      "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",
      "context": "/document/normalized_images/*",
      "defaultLanguageCode": "en",
      "detectOrientation": true,
      "inputs": [
        {
          "name": "image",
          "source": "/document/normalized_images/*"
        }
      ],
      "outputs": [
        {
          "name": "text"
        }
      ]
    },
    {
      "@odata.type": "#Microsoft.Skills.Text.MergeSkill",
      "description": "Create merged_text, which includes all the textual representation of each image inserted at the right location in the content field.",
      "context": "/document",
      "insertPreTag": " ",
      "insertPostTag": " ",
      "inputs": [
        {
          "name": "text", "source": "/document/content"
        },
        {
          "name": "itemsToInsert", "source": "/document/normalized_images/*/text"
        },
        {
          "name": "offsets", "source": "/document/normalized_images/*/contentOffset"
        }
      ],
      "outputs": [
        {
          "name": "mergedText", "targetName" : "merged_text"
        }
      ]
    }
  ]
}
```

```

        double rotationFromOriginal)
{
    Point original = new Point();
    double angle = rotationFromOriginal % 360;

    if (angle == 0 )
    {
        original.X = normalized.X;
        original.Y = normalized.Y;
    } else if (angle == 90)
    {
        original.X = normalized.Y;
        original.Y = (width - normalized.X);
    } else if (angle == 180)
    {
        original.X = (width - normalized.X);
        original.Y = (height - normalized.Y);
    } else if (angle == 270)
    {
        original.X = height - normalized.Y;
        original.Y = normalized.X;
    }

    double scalingFactor = (angle % 180 == 0) ? originalHeight / height :
originalHeight / width;
    original.X = (int) (original.X * scalingFactor);
    original.Y = (int)(original.Y * scalingFactor);

    return original;
}

```

Scenario: Custom image skills

Images can also be passed into and returned from custom skills. A skillset base64-encodes the image being passed into the custom skill. To use the image within the custom skill, set `"/document/normalized_images/*/data"` as the input to the custom skill. Within your custom skill code, base64-decode the string before converting it to an image. To return an image to the skillset, base64-encode the image before returning it to the skillset.

The image is returned as an object with the following properties.

JSON

```
{
    "$type": "file",
    "data": "base64String"
}
```

The [Azure Search Python samples](#) repository has a complete sample implemented in Python of a custom skill that enriches images.

Passing images to custom skills

For scenarios where you require a custom skill to work on images, you can pass images to the custom skill, and have it return text or images. The following skillset is from a sample.

The following skillset takes the normalized image (obtained during document cracking), and outputs slices of the image.

Sample skillset

JSON

```
{  
    "description": "Extract text from images and merge with content text to produce merged_text",  
    "skills":  
    [  
        {  
            "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",  
            "name": "ImageSkill",  
            "description": "Segment Images",  
            "context": "/document/normalized_images/*",  
            "uri": "https://your.custom.skill.url",  
            "httpMethod": "POST",  
            "timeout": "PT30S",  
            "batchSize": 100,  
            "degreeOfParallelism": 1,  
            "inputs": [  
                {  
                    "name": "image",  
                    "source": "/document/normalized_images/*"  
                }  
            ],  
            "outputs": [  
                {  
                    "name": "slices",  
                    "targetName": "slices"  
                }  
            ],  
            "httpHeaders": {}  
        }  
    ]  
}
```

Custom skill example

The custom skill itself is external to the skillset. In this case, it's Python code that first loops through the batch of request records in the custom skill format, then converts the base64-encoded string to an image.

Python

```
# deserialize the request, for each item in the batch
for value in values:
    data = value['data']
    base64String = data["image"]["data"]
    base64Bytes = base64String.encode('utf-8')
    inputBytes = base64.b64decode(base64Bytes)
    # Use numpy to convert the string to an image
    jpg_as_np = np.frombuffer(inputBytes, dtype=np.uint8)
    # you now have an image to work with
```

Similarly to return an image, return a base64 encoded string within a JSON object with a `$type` property of *file*.

Python

```
def base64EncodeImage(image):
    is_success, im_buf_arr = cv2.imencode(".jpg", image)
    byte_im = im_buf_arr.tobytes()
    base64Bytes = base64.b64encode(byte_im)
    base64String = base64Bytes.decode('utf-8')
    return base64String

base64String = base64EncodeImage(jpg_as_np)
result = {
    "$type": "file",
    "data": base64String
}
```

- [Map enriched output to fields](#)

Configure an enrichment cache

08/27/2025

ⓘ Important

This feature is in public preview under [supplemental terms of use](#). [Preview REST APIs](#) support this feature.

This article explains how to add caching to an enrichment pipeline so that you can modify downstream enrichment steps without having to rebuild in full every time. By default, a skillset is stateless, and changing any part of its composition requires a full rerun of the indexer. With an *enrichment cache*, the indexer can determine which parts of the document tree must be refreshed based on changes detected in the skillset or indexer definitions. Existing processed output is preserved and reused wherever possible.

Cached content is placed in Azure Storage using account information that you provide. The container, named `ms-az-search-indexercache-<alpha-numerical-string>`, is created when you run the indexer. It should be considered an internal component managed by your search service and must not be modified.

Prerequisites

- [Azure Storage](#) for storing cached enrichments. The storage account must be [general purpose v2](#).
- [For blob indexing only](#), if you need synchronized document removal from both the cache and index when blobs are deleted from your data source, enable a [deletion policy](#) in the indexer. Without this policy, document deletion from the cache isn't supported.

You should be familiar with setting up indexers and skillsets. Start with [indexer overview](#) and then continue on to [skillsets](#) to learn about enrichment pipelines.

Limitations

ⓘ Caution

If you're using the [SharePoint Online indexer \(Preview\)](#), you should avoid incremental enrichment. Under certain circumstances, the cache becomes invalid, requiring an [indexer reset and full rebuild](#), should you choose to reload it.

Permissions

Azure AI Search needs write-access to Azure Storage. If you're using a managed identity for your search service, make sure it's assigned to the **Storage Blob Data Contributor** and **Storage Table Data Contributor** roles. For more information, see [Connect to Azure Storage using a managed identity \(Azure AI Search\)](#).

Enable on new indexers

You can use the Azure portal, preview APIs, or preview Azure SDK packages to enable an enrichment cache on an indexer.

Azure portal

The screenshot shows the 'Add indexer' configuration screen in the Azure portal. It includes fields for 'Enable incremental enrichment' (checked) and 'Indexer cache location' (containing a connection string). A callout highlights the 'Indexer cache location' field, which contains a purple URL and a 'Choose an existing connection' link.

1. On the left, select **Indexers**, and then select **Add indexer**.
2. Provide an indexer name and an existing index, data source, and skillset.
3. Enable incremental caching and set the Azure Storage account.

Enable on existing indexers

For existing indexers that already have a skillset, use the following steps to add caching. As a one-time operation, reset and rerun the indexer in full to load the cache.

Step 1: Get the indexer definition

Start with a valid, work indexer that has these components: data source, skillset, index. Using an API client, send a [GET Indexer](#) request to retrieve the indexer. When you use the preview API version to the GET the indexer, a `cache` property set to null is added to the definition automatically.

HTTP

```
GET https://[YOUR-SEARCH-SERVICE].search.windows.net/indexers/[YOUR-INDEXER-NAME]?
api-version=2025-08-01-preview
Content-Type: application/json
api-key: [YOUR-ADMIN-KEY]
```

Step 2: Set the cache property

In the index definition, modify `cache` to include the following required and optional properties:

- (Required) `storageConnectionString` must be set to an Azure Storage connection string.
- (Optional) `enableReprocessing` boolean property (`true` by default), indicates that incremental enrichment is enabled. Set to `false` if you want to suspend incremental processing while other resource-intensive operations, such as indexing new documents, are underway and then switch back to `true` later.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-08-01-
preview
{
    "name": "<YOUR-INDEXER-NAME>",
    "targetIndexName": "<YOUR-INDEX-NAME>",
    "dataSourceName": "<YOUR-DATASOURCE-NAME>",
    "skillsetName": "<YOUR-SKILLSET-NAME>",
    `cache` : {
        "storageConnectionString" : "<YOUR-STORAGE-ACCOUNT-CONNECTION-
STRING>",
        "enableReprocessing": true
    },
    "fieldMappings" : [],
    "outputFieldMappings": [],
    "parameters": []
}
```

Step 3: Reset the indexer

[Reset Indexer](#) is required when setting up incremental enrichment for existing indexers to ensure all documents are in a consistent state. You can use the Azure portal or an API client for this task.

https

```
POST https://[YOUR-SEARCH-SERVICE].search.windows.net/indexers/[YOUR-INDEXER-
NAME]/reset?api-version=2025-08-01-preview
```

```
Content-Type: application/json  
api-key: [YOUR-ADMIN-KEY]
```

Step 4: Save the indexer

Update Indexer with a PUT request, where the body of the request includes `cache`.

HTTP

```
PUT https://[YOUR-SEARCH-SERVICE].search.windows.net/indexers/[YOUR-INDEXER-NAME]?  
api-version=2025-08-01-preview  
Content-Type: application/json  
api-key: [YOUR-ADMIN-KEY]  
{  
    "name" : "<YOUR-INDEXER-NAME>",  
    ...  
    `cache` : {  
        "storageConnectionString": "<YOUR-STORAGE-ACCOUNT-CONNECTION-STRING>",  
        "enableReprocessing": true  
    }  
}
```

If you now issue another GET request on the indexer, the response from the service includes an `ID` property in the `cache` object. The string is appended to the name of the container containing all the cached results and intermediate state of each document processed by this indexer. The ID is used to uniquely name the cache in Blob storage.

HTTP

```
`cache` : {  
    "ID": "<ALPHA-NUMERIC STRING>",  
    "enableReprocessing": true,  
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<YOUR-STORAGE-ACCOUNT>;AccountKey=<YOUR-STORAGE-KEY>;EndpointSuffix=core.windows.net"  
}
```

Step 5: Run the indexer

To run indexer, you can use the Azure portal or the API. In the Azure portal, from the indexers list, select the indexer and select **Run**. One advantage to using the Azure portal is that you can monitor indexer status, note the duration of the job, and how many documents are processed. Portal pages are refreshed every few minutes.

Alternatively, you can use REST to [run the indexer](#):

HTTP

```
POST https://[YOUR-SEARCH-SERVICE].search.windows.net/indexers/[YOUR-INDEXER-  
NAME]/run?api-version=2025-08-01-preview  
Content-Type: application/json  
api-key: [YOUR-ADMIN-KEY]
```

! Note

A reset and rerun of the indexer results in a full rebuild so that content can be cached. All cognitive enrichments will be rerun on all documents. Reusing enriched content from the cache begins after the cache is loaded.

Check for cached output

Find the cache in Azure Storage, under Blob container. The container name is `ms-az-search-indexercache-<some-alphanumeric-string>`.

A cache is created and used by an indexer. Its content isn't human readable.

To verify whether the cache is operational, modify a skillset and run the indexer, then compare before-and-after metrics for execution time and document counts.

Skillsets that include image analysis and Optical Character Recognition (OCR) of scanned documents make good test cases. If you modify a downstream text skill or any skill that isn't image-related, the indexer can retrieve all of the previously processed image and OCR content from cache, updating and processing only the text-related changes indicated by your edits. You can expect to see fewer documents in the indexer execution document count, shorter execution times, and fewer charges on your bill.

The [file set](#) used in [cog-search-demo tutorials](#) is a useful test case because it contains 14 files of various formats JPG, PNG, HTML, DOCX, PPTX, and other types. Change `en` to `es` or another language in the text translation skill for proof-of-concept testing of incremental enrichment.

Common errors

The following error occurs if you forget to specify a preview API version on the request:

```
"The request is invalid. Details: indexer : A resource without a type name was found, but  
no expected type was specified. To allow entries without type information, the expected  
type must also be specified when the model is specified."
```

A 400 Bad Request error will also occur if you're missing an indexer requirement. The error message specifies any missing dependencies.

Next step

Incremental enrichment is applicable on indexers that contain skillsets, providing reusable content for both indexes and knowledge stores. The following link provides more information about cache management.

- ✓ [Manage an enrichment cache](#)

Manage an enrichment cache

08/27/2025

ⓘ Important

This feature is in public preview under [supplemental terms of use](#). The [preview REST API](#) supports this feature.

An *enrichment cache* is an optional feature that stores reusable enriched content created during [skillset execution](#) so that only new and changed skills and documents incur standard processing charges during future indexer and skillset processing.

The cache contains the output from [document cracking](#), plus the outputs of each skill for every document. Although caching is billable (it uses Azure Storage), the overall cost of enrichment is reduced because the costs of storage are less than image extraction and AI processing.

If you have configured an enrichment cache, this article explains how to manage skill and data source updates so that you get maximum utility from cached enrichments.

Prerequisites

- An [indexer](#) and [skillset](#)
- An [enrichment cache](#)

Limitations

✗ Caution

If you're using the [SharePoint Online indexer \(Preview\)](#), you should avoid incremental enrichment. Under certain circumstances, the cache becomes invalid, requiring an [indexer reset and full rebuild](#), should you choose to reload it.

Cache configuration

Physically, the cache is stored in a blob container or table in your Azure Storage account, one per indexer. Each indexer is assigned a unique and immutable cache identifier that corresponds to the container it's using.

The cache is created when you specify the "cache" property and run the indexer. Only enriched content can be cached. If your indexer doesn't have an attached skillset, then caching doesn't apply.

The following example illustrates an indexer with caching enabled. See [Configure enrichment caching](#) for full instructions.

To set the cache property, use latest preview REST API for [Create or Update Indexer](#) or a preview Azure SDK package that provides the feature. You can also enable enrichment caching in the Import data wizard in the Azure portal.

JSON

```
POST https://[YOUR-SEARCH-SERVICE-NAME].search.windows.net/indexers?api-version=2025-08-01-preview
{
    "name": "myIndexerName",
    "targetIndexName": "myIndex",
    "dataSourceName": "myDatasource",
    "skillsetName": "mySkillset",
    "cache" : {
        "storageConnectionString" : "<Your storage account connection string>",
        "enableReprocessing": true
    },
    "fieldMappings" : [],
    "outputFieldMappings": [],
    "parameters": []
}
```

Cache management

The lifecycle of the cache is managed by the indexer. If an indexer is deleted, its cache is also deleted. If the `cache` property on the indexer is set to null or the connection string is changed, the existing cache is deleted on the next indexer run.

While incremental enrichment is designed to detect and respond to changes with no intervention on your part, there are parameters you can use to invoke specific behaviors:

- [Prioritize new documents](#)
- [Bypass skillset checks](#)
- [Bypass data source checks](#)
- [Force skillset evaluation](#)

Prioritize new documents

The cache property includes an `enableReprocessing` parameter. It's used to control processing over incoming documents already represented in the cache. When true (default), documents already in the cache are reprocessed when you rerun the indexer, assuming your skill update affects that doc.

When false, existing documents aren't reprocessed, effectively prioritizing new, incoming content over existing content. You should only set `enableReprocessing` to false on a temporary basis. Having `enableReprocessing` set to true most of the time ensures that all documents, both new and existing, are valid per the current skillset definition.

Bypass skillset evaluation

Modifying a skill and reprocessing of that skill typically go hand in hand. However, some changes to a skill shouldn't result in reprocessing (for example, deploying a custom skill to a new location or with a new access key). Most likely, these are peripheral modifications that have no genuine impact on the substance of the skill output itself.

If you know that a change to the skill is indeed superficial, you should override skill evaluation by setting the `disableCacheReprocessingChangeDetection` parameter to true:

1. Call [Update Skillset](#) and modify the skillset definition.
2. Append the "disableCacheReprocessingChangeDetection=true" parameter on the request.
3. Submit the change.

Setting this parameter ensures that only updates to the skillset definition are committed and the change isn't evaluated for effects on the existing cache. Use a preview API version, 2020-06-30-Preview or later. We recommend the latest preview API.

HTTP

```
PUT https://[servicename].search.windows.net/skillsets/[skillset name]?api-version=2025-08-01-preview&disableCacheReprocessingChangeDetection
```

Bypass data source validation checks

Most changes to a data source definition will invalidate the cache. However, for scenarios where you know that a change shouldn't invalidate the cache - such as changing a connection string or rotating the key on the storage account - append the `ignoreResetRequirement` parameter on the [data source update](#). Setting this parameter to true allows the commit to go

through, without triggering a reset condition that would result in all objects being rebuilt and populated from scratch.

HTTP

```
PUT https://[search service].search.windows.net/datasources/[data source name]?
api-version=2025-08-01-preview&ignoreResetRequirement
```

Force skillset evaluation

The purpose of the cache is to avoid unnecessary processing, but suppose you make a change to a skill that the indexer doesn't detect (for example, changing something in external code, such as a custom skill).

In this case, you can use the [Reset Skills](#) to force reprocessing of a particular skill, including any downstream skills that have a dependency on that skill's output. This API accepts a POST request with a list of skills that should be invalidated and marked for reprocessing. After Reset Skills, follow with a [Run Indexer](#) request to invoke the pipeline processing.

Re-cache specific documents

[Resetting an indexer](#) will result in all documents in the search corpus being reprocessed.

In scenarios where only a few documents need to be reprocessed, use [Reset Documents \(preview\)](#) to force reprocessing of specific documents. When a document is reset, the indexer invalidates the cache for that document, which is then reprocessed by reading it from the data source. For more information, see [Run or reset indexers, skills, and documents](#).

To reset specific documents, the request provides a list of document keys as read from the search index. If the key is mapped to a field in the external data source, the value that you provide should be the one used in the search index.

Depending on how you call the API, the request will either append, overwrite, or queue up the key list:

- Calling the API multiple times with different keys appends the new keys to the list of document keys reset.
- Calling the API with the "overwrite" query string parameter set to true will overwrite the current list of document keys to be reset with the request's payload.

- Calling the API only results in the document keys being added to the queue of work the indexer performs. When the indexer is next invoked, either as scheduled or on demand, it will prioritize processing the reset document keys before any other changes from the data source.

The following example illustrates a reset document request:

HTTP

```
POST https://[search service name].search.windows.net/indexers/[indexer  
name]/resetdocs?api-version=2025-08-01-preview  
{  
    "documentKeys" : [  
        "key1",  
        "key2",  
        "key3"  
    ]  
}
```

Changes that invalidate the cache

Once you enable a cache, the indexer evaluates changes in your pipeline composition to determine which content can be reused and which needs reprocessing. This section enumerates changes that invalidate the cache outright, followed by changes that trigger incremental processing.

An invalidating change is one where the entire cache is no longer valid. An example of an invalidating change is one where your data source is updated. Here's the complete list of changes to any part of the indexer pipeline that would invalidate your cache:

- Changing the data source type
- Changing data source container
- Changing data source credentials
- Changing data source change detection policy
- Changing data source delete detection policy
- Changing indexer field mappings
- Changing indexer parameters:
 - Parsing Mode
 - Excluded File Name Extensions
 - Indexed File Name Extensions
 - Index storage metadata only for oversized documents
 - Delimited text headers
 - Delimited text delimiter

- Document Root
- Image Action (Changes to how images are extracted)

Changes that trigger incremental processing

Incremental processing evaluates your skillset definition and determines which skills to rerun, selectively updating the affected portions of the document tree. Here's the complete list of changes resulting in incremental enrichment:

- Changing the skill type (the OData type of the skill is updated)
- Skill-specific parameters are updated, for example a URL, defaults, or other parameters
- Skill output changes, the skill returns additional or different outputs
- Skill input changes resulting in different ancestry, skill chaining has changed
- Any upstream skill invalidation, if a skill that provides an input to this skill is updated
- Updates to the knowledge store projection location, results in re-projecting documents
- Changes to the knowledge store projections, results in re-projecting documents
- Output field mappings changed on an indexer results in re-projecting documents to the index

APIs used for caching

Preview APIs provide extra properties on indexers. We recommend the latest preview API.

Skillsets and data sources can use the generally available version. In addition to the reference documentation, see [Configure caching for incremental enrichment](#) for details about order of operations.

- [Create or Update Indexer \(api-version=2025-08-01-preview\)](#)
- [Reset Skills \(api-version=2025-08-01-preview\)](#)
- [Create or Update Skillset \(api-version=2025-08-01-preview\)](#) (New URI parameter on the request)
- [Create or Update Data Source \(api-version=2025-08-01-preview\)](#), when called with a preview API version, provides a new parameter named "ignoreResetRequirement", which should be set to true when your update action shouldn't invalidate the cache. Use "ignoreResetRequirement" sparingly as it could lead to unintended inconsistency in your data that won't be detected easily.

Generate captions for images in another language

07/28/2025

In this article, learn how to generate captions using AI enrichment and a skillset. Images often contain useful information that's relevant in search scenarios. You can [vectorize images](#) to represent visual content in your search index. Or, you can use [AI enrichment and skillsets](#) to create and extract searchable *text* from images.

The GenAI Prompt skill (preview) generates a description of each image in your data source and the indexer pushes that description into a search index. To view the descriptions, you can run a query that includes them in the response.

Prerequisites

To work with image content in a skillset, you need:

- A [supported data source](#). We recommend Azure Storage.
- Files or blobs containing images.
- Read access to the supported data source. This article uses key-based authentication, but indexers can also connect using the search service identity and Microsoft Entra ID authentication. For role-based access control, assign roles on the data source to allow read access by the service identity. If you're testing on a local development machine, make sure you also have read access on the supported data source.
- A [search indexer](#), configured for image actions.
- A skillset with the new custom genAI prompt skill.
- A search index with fields to receive the verbalized text output, plus output field mappings in the indexer that establish association.

Optionally, you can define projections to accept image-analyzed output into a [knowledge store](#) for data mining scenarios.

Configure indexers for image processing

After the source files are set up, enable image normalization by setting the `imageAction` parameter in the indexer configuration. Image normalization helps make images more uniform for downstream processing. Image normalization includes the following operations:

- Large images are resized to a maximum height and width to make them uniform.

- For images that have metadata that specifies orientation, image rotation is adjusted for vertical loading.

Note that enabling `imageAction` (setting this parameter to other than `none`) will incur an additional charge for image extraction according to [Azure AI Search pricing](#).

1. [Create or update an indexer](#) to set the configuration properties:

```
JSON

{
  "parameters": {
    "configuration": {
      "dataToExtract": "contentAndMetadata",
      "parsingMode": "default",
      "imageAction": "generateNormalizedImages"
    }
  }
}
```

2. Set `dataToExtract` to `contentAndMetadata` (required).

3. Verify that the `parsingMode` is set to `default` (required).

This parameter determines the granularity of search documents created in the index. The default mode sets up a one-to-one correspondence so that one blob results in one search document. If documents are large, or if skills require smaller chunks of text, you can add the Text Split skill that subdivides a document into paging for processing purposes. But for search scenarios, one blob per document is required if enrichment includes image processing.

4. Set `imageAction` to enable the `normalized_images` node in an enrichment tree (required):

- `generateNormalizedImages` to generate an array of normalized images as part of document cracking.
- `generateNormalizedImagePerPage` (applies to PDF only) to generate an array of normalized images where each page in the PDF is rendered to one output image. For non-PDF files, the behavior of this parameter is similar as if you had set `generateNormalizedImages`. However, setting `generateNormalizedImagePerPage` can make indexing operation less performant by design (especially for large documents) since several images would have to be generated.

5. Optionally, adjust the width or height of the generated normalized images:

- `normalizedImageMaxWidth` in pixels. Default is 2,000. Maximum value is 10,000.
- `normalizedImageMaxHeight` in pixels. Default is 2,000. Maximum value is 10,000.

About normalized images

When `imageAction` is set to a value other than `none`, the new `normalized_images` field contains an array of images. Each image is a complex type that has the following members:

 [Expand table](#)

Image member	Description
<code>data</code>	BASE64 encoded string of the normalized image in JPEG format.
<code>width</code>	Width of the normalized image in pixels.
<code>height</code>	Height of the normalized image in pixels.
<code>originalWidth</code>	The original width of the image before normalization.
<code>originalHeight</code>	The original height of the image before normalization.
<code>rotationFromOriginal</code>	Counter-clockwise rotation in degrees that occurred to create the normalized image. A value between 0 degrees and 360 degrees. This step reads the metadata from the image that is generated by a camera or scanner. Usually a multiple of 90 degrees.
<code>contentOffset</code>	The character offset within the content field where the image was extracted from. This field is only applicable for files with embedded images. The <code>contentOffset</code> for images extracted from PDF documents is always at the end of the text on the page it was extracted from in the document. This means images appear after all text on that page, regardless of the original location of the image in the page.
<code>pageNumber</code>	If the image was extracted or rendered from a PDF, this field contains the page number in the PDF it was extracted or rendered from, starting from 1. If the image isn't from a PDF, this field is 0.

Sample value of `normalized_images`:

JSON

```
[  
  {  
    "data": "BASE64 ENCODED STRING OF A JPEG IMAGE",  
    "width": 500,  
    "height": 300,  
    "originalWidth": 5000,  
    "originalHeight": 3000,  
  }]
```

```
        "rotationFromOriginal": 90,  
        "contentOffset": 500,  
        "pageNumber": 2  
    }  
]
```

Define skillsets for image processing

This section supplements the [skill reference](#) articles by providing context for working with skill inputs, outputs, and patterns, as they relate to image processing.

- Create or update a skillset to add skills.

Once the basic framework of your skillset is created and Azure AI services is configured, you can focus on each individual image skill, defining inputs and source context, and mapping outputs to fields in either an index or knowledge store.

 **Note**

For an example skillset that combines image processing with downstream natural language processing, see [REST Tutorial: Use REST and AI to generate searchable content from Azure blobs](#). It shows how to feed skill imaging output into entity recognition and key phrase extraction.

Example inputs for image processing

As noted, images are extracted during document cracking and then normalized as a preliminary step. The normalized images are the inputs to any image processing skill, and are always represented in an enriched document tree in either one of two ways:

- `/document/normalized_images/*` is for documents that are processed whole.

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.ChatCompletionSkill",  
    "context": "/document/normalized_images/*",  
    "uri": "https://contoso.openai.azure.com/openai/deployments/contoso-gpt-  
4o/chat/completions?api-version=2025-01-01-preview",  
    "timeout": "PT1M",  
    "apiKey": "<YOUR-API-KEY here>"  
    "inputs": [  
        {  
            "name": "image",  
            "type": "Image"  
        }  
    ]  
}
```

```

        "source": "/document/normalized_images/*/data"
    },
    {
        "name": "systemMessage",
        "source": "'You are a useful artificial intelligence assistant that
helps people.'"
    },
    {
        "name": "userMessage",
        "source": "'Describe what you see in this image in 20 words or less in
Spanish.'"
    }
],
"outputs": [
{
    "name": "response",
    "targetName": "captionedImage"
}
]
},

```

Example using json schema responses with text inputs

This example illustrates how you can use structured outputs for language models. Note that this capability is mainly supported mostly by OpenAI language models, although that may change in the future.

JSON

```

{
    "@odata.type": "#Microsoft.Skills.Custom.ChatCompletionSkill",
    "context": "/document/content",
    "uri": "https://contoso.openai.azure.com/openai/deployments/contoso-gpt-
4o/chat/completions?api-version=2025-01-01-preview",
    "timeout": "PT1M",
    "apiKey": "<YOUR-API-KEY here>"
    "inputs": [
        {
            "name": "systemMessage",
            "source": "'You are a useful artificial intelligence assistant that
helps people.'"
        },
        {
            "name": "userMessage",
            "source": "'How many languages are there in the world and what are
they?'"
        }
    ],
    "response_format": {
        "type": "json_schema",
        "json_schema": {

```

```

    "name": "structured_output",
    "strict": true,
    "schema": {
        "type": "object",
        "properties": {
            "total": { "type": "number" },
            "languages": {
                "type": "array",
                "items": {
                    "type": "string"
                }
            }
        },
        "required": ["total", "languages"],
        "additionalProperties": false
    }
},
"outputs": [
{
    "name": "response",
    "targetName": "responseJsonForLanguages"
}
]
},

```

Map outputs to search fields

Output text is represented as nodes in an internal enriched document tree, and each node must be mapped to fields in a search index, or to projections in a knowledge store, to make the content available in your app.

1. [Create or update a search index](#) to add fields to accept the skill outputs.

In the following fields collection example, *content* is blob content.

Metadata_storage_name contains the name of the file (set `retrievable` to *true*).

Metadata_storage_path is the unique path of the blob and is the default document key.

Merged_content is output from Text Merge (useful when images are embedded).

captionedImage is the skill outputs and must be a string-type in order to capture all of the language model output in the search index.

JSON

```

"fields": [
{
    "name": "content",
    "type": "Edm.String",
    "filterable": false,
    "retrievable": true,

```

```

        "searchable": true,
        "sortable": false
    },
{
    "name": "metadata_storage_name",
    "type": "Edm.String",
    "filterable": true,
    "retrievable": true,
    "searchable": true,
    "sortable": false
},
{
    "name": "metadata_storage_path",
    "type": "Edm.String",
    "filterable": false,
    "key": true,
    "retrievable": true,
    "searchable": false,
    "sortable": false
},
{
    "name": "captioned_image",
    "type": "Edm.String",
    "filterable": false,
    "retrievable": true,
    "searchable": true,
    "sortable": false
}
]

```

2. Update the indexer to map skillset output (nodes in an enrichment tree) to index fields.

Enriched documents are internal. To externalize the nodes in an enriched document tree, set up an output field mapping that specifies which index field receives node content. Enriched data is accessed by your app through an index field. The following example shows a *text* node (OCR output) in an enriched document that's mapped to a *text* field in a search index.

JSON

```

"outputFieldMappings": [
{
    "sourceFieldName": "/document/normalized_images/*/captionedImage",
    "targetFieldName": "captioned_image"
}
]

```

3. Run the indexer to invoke source document retrieval, image processing via language model captions, and indexing.

Verify results

Run a query against the index to check the results of image processing. Use [Search Explorer](#) as a search client, or any tool that sends HTTP requests. The following query selects fields that contain the output of image processing.

HTTP

```
POST /indexes/[index name]/docs/search?api-version=[api-version]
{
  "search": "A cat in a picture",
  "select": "metadata_storage_name, captioned_image"
}
```

Best practices - GenAI Prompt skill

07/28/2025

Incorporating the GenAI Prompt custom skill as part of an indexer's ingestion flow allows developers to harness the content generation capabilities of language models to enrich the content from the data source. This document outlines some recommendations and best practices that can be incorporated when utilizing this capability to ensure good system performance and behavior.

Functionality of GenAI Prompt skill

The [GenAI Prompt custom skill](#) is a new addition to Azure AI Search's catalog of skills, allowing search customers to pass their document contents and customer-created prompts to a language model they own, hosted within Azure AI Foundry. The resulting enriched content, along with the source document is ingested into the search index. We envision developers utilizing this for various scenarios to power Retrieval Augmented Generation (RAG) applications. Some key scenarios are AI-generated document summaries, image captioning, and entity/fact finding based on customizable criteria through user specified prompts.

The content generation capabilities of language models are continuing to evolve rapidly and their integration into content ingestion pipeline offers exciting possibilities for search retrieval relevance. However, the challenge for developers would be to ensure that the prompts and data they use for their scenarios are safe and protect users against any inadvertent results from the language model.

Personas interacting with a RAG application

In order to list out the various challenges in incorporating AI content generation capabilities into an Azure AI Search indexer pipeline, it's important to understand the various personas that interact with the RAG application as each of them might carry a different set of challenges.

 Expand table

Persona	Description
End user	The person asking questions of the RAG application, expecting a well-cited answer to their question based on results from the source document. In addition to accuracy of the answer, the end-user expects that any citations provided by the application make it clear if it was from verbatim content from a source file or an AI-powered summary from the model.

Persona	Description
RAG application developer/search index admin	<p>The person responsible for configuring the search index schema, and setting up the indexer and skillset to ingest language model augmented data into the index. GenAI Prompt custom skill allows developers to configure free-form prompts to several models hosted in AI foundry, thereby offering significant flexibility to light up various scenarios. However, developers need to ensure that the combination of data and skills used in the pipeline doesn't produce harmful or unsafe content. Developers also need to evaluate the content generated by the language models for bias, inaccuracies, and incorrect information. Although this task can be challenging for documents at a large scale, it should be one of the first steps when building a RAG application, along with the index schema definition.</p>
Data authority	<p>The person expected to be the key subject matter expert (SME) for the content from the data source. The SME is expected to be the best judge of language model powered enrichments ingested into the index and the answer generated by the language model in the RAG application. The key role for the data authority to be able to get a representative sample and verify the quality of the enrichments and the answer, which can be challenging if dealing with data at large scale.</p>

The rest of this document lists out these various challenges along with tips and best practices that RAG application developers can follow to mitigate any risks.

Challenges

The following challenges are faced by the various personas that interact with a RAG systems that utilize language models to augment content ingested into a search index (using the GenAI Prompt custom skill) and to formulate answers for questions:

- Transparency: Users of RAG systems should understand that AI models might not always produce accurate or well-formulated answers. Azure AI Search has a robustly documented [Transparency Note](#) that developers should read through to understand the various ways in which AI is used to augment the capabilities of the core search engine. It's recommended that developers who build RAG applications share the transparency note to users of their applications, since they might be unaware of how AI interfaces with various aspects of the application being used. Additionally, when utilizing the GenAI Prompt custom skill developers should note that only part of the content ingested into the search index is generated by the language model and should highlight this to users of their applications.
- Content sampling/inspection of content quality: Developers and data SMEs should consider sampling some of the content ingested into the search index after being augmented by the GenAI Prompt custom skill in order to inspect the quality of the

enrichment performed by their language model. [Debug sessions](#) and [search explorer](#) on the Azure portal can be used for this purpose.

- Content safety filtering and evaluations: It's important for developers to ensure that the language models they use with the GenAI Prompt custom skill have appropriate filters to ensure safety of the content generated and after ingested into the search index. Developers and data SMEs should also make sure they evaluate the content generated by the language model on various metrics such as accuracy, task specific performance, bias, and risk. Azure AI Foundry offers a robust set of tools for developers to add [content safety filters](#) and [clear guidance for evaluation approaches](#).
- Agility in rolling back changes or modifying skill configuration: It's possible for the language model used with the GenAI Prompt custom skill to have issues over time (such as producing low-quality content). Developers should be prepared to roll back these changes either by altering their indexer and skillset configuration or by excluding index fields with AI generated content from search queries.

Best practices to mitigate risks

When utilizing the GenAI Prompt custom skill to power RAG applications, there's a risk of over-reliance on AI as outlined in the challenges from the previous section. In this part of the document, we present some patterns and strategies to use to mitigate the risks and overcome the challenges.

Content sampling and inspection before ingestion into the search index

[Debug sessions](#) is a tool built into the Azure portal. You can use it to inspect the state of enrichment for a single document. To start a debug session, create a skillset, and an indexer and have the indexer complete one run. We recommend that you begin with a "development" index before moving forward with solution. While the index is in development, use a debug session to inspect the entire structure and contents of the enriched document that will be written into the index. A single run of a debug session works with one specific live document, and will have the content generated by the language model show up in a specific part of the enriched document. Developers can utilize several runs of their debug session, pointing to different documents from their data source to get a reasonable idea of the state of the content produced by their language model (and its relationship to the enriched document structure).

The screenshots below show how developers can inspect both the configuration of a skill and the values produced by the skill after calling the language model.

Example: Inspect the configuration of the GenAI Prompt skill

The screenshot shows the configuration interface for a GenAI Prompt skill named "genai-prompt-skill". The interface includes a toolbar with Run, Stop, Commit changes, Add new skill, Undo, Redo, Save, Refresh, Settings, and Delete buttons. A status bar at the top indicates "Completed". The main area displays a flowchart with a "Document" input node connected to a "genai-pro... Chat Completion" node (Custom). The "genai-pro..." node has "Iterations: 1". To the right, there's a "Skill Settings" panel titled "Skill: genai-prompt-skill" showing "Iterations (1)", "Skill Settings", and "Errors/Warnings (0)". Below it is a table for "Iterations" with one row. The "Path" column shows the skill's path: "InputText" → "\$/document/content", "systemMessage" → "You are an expert AI agent, tasked with understanding and explaining the contents of arbitrary documents, which can have a mix of different language. Your answer will be precise, short and if there are multiple answers, they need to be separated by a comma", and "userMessage" → "What are the different languages in this document?". The "Outputs" column shows "response" with the path "/document/summary". On the far right, there are "Save" and "Cancel" buttons, and a magnifying glass icon.

Example: Inspect the output from the GenAI Prompt skill

The screenshot shows the "Expression evaluator" interface. It features a toolbar with Run, Stop, Commit changes, Add new skill, Undo, Redo, Save, Refresh, Settings, and a search icon. A status bar at the top indicates "Completed". The main area displays a flowchart similar to the previous one, with a "Document" input node and a "genai-pro... Chat Completion" node (Custom). A modal window titled "Expression evaluator" is open, showing the value "1" and the expression "English, Spanish". The "File Preview" tab is selected. To the right, there's a "Skill Settings" panel titled "Path" showing the skill's path: "document/content" → "You are an expert AI agent, tasked with understanding and explaining the contents of arbitrary documents, which can have a mix of different language. Your answer will be precise, short and if there are multiple answers, they need to be separated by a comma" and "What are the different languages in this document?". The "Outputs" column shows "response" with the path "/document/summary". On the far right, there are "Save" and "Cancel" buttons, and a magnifying glass icon.

Use Search Explorer to inspect output

In addition to debug sessions, Azure AI Search also offers the ability to explore multiple documents at once by querying the search index via the Azure portal [search explorer](#). Developers can issue a broad query to retrieve a large number of documents from their search index and can inspect the fields which have their content generated by the GenAI Prompt custom skill. To be able to view the contents of the field, when defining the index schema it

needs to be configured with the "Retrievable" property. For the same document that was inspected via the debug session, the image below shows the full contents of the search document that ends up into the index.

The screenshot shows the Azure AI Search interface. At the top, there are navigation links: Save, Discard, Refresh, Create demo app, Edit JSON, Delete, and Encryption. Below these are metrics: Documents (1), Total storage (6.05 KB), Vector index quota usage (0 Bytes), and Max storage (2 GB). The 'Search explorer' tab is selected, followed by Fields, CORS, Scoring profiles, Semantic configurations, and Vector profiles. On the right, there are 'Query options' and 'View' buttons. A search bar at the bottom has the placeholder 'Search' and a 'Search' button. The main area is titled 'Results' and displays a JSON response from a search query. The JSON output is as follows:

```
1 {  
2   "@odata.context": "https://arjagann-basic-canary.search.windows.net/indexes('genai-prompt-index')/$metadata",  
3   "@odata.count": 1,  
4   "value": [  
5     {  
6       "@search.score": 1,  
7       "id": "aHR0cHM6Ly9hcmpbz2Fubmpma2ZpbGVzLmJsb2IuY29yZS53aw5kb3dzLm5ldC9ha2ovSGVsbG8lMjB3b3JsZC50eHQ1",  
8       "content": "Hello world\r\nHola world\r\n",  
9       "summary": "English, Spanish"  
10    }  
11  ]  
12 }
```

Developers can utilize both of these tools to have a reasonable sampling of the data generated by their language models after it gets ingested into their "development" index. At this point, we recommend developers to work with data SMEs to ensure the sampled data meets quality and accuracy standards. Once desired bars have been met, developers can then transition the indexer to target a "production" index which will be the source of knowledge for their RAG applications.

Content safety filtering and evaluation

Azure AI content safety is an AI service that detects harmful user-generated and AI-generated content in applications and services. Azure AI Foundry has a [robust integration with the Azure AI content safety service](#) for many scenarios across both text and image content. The GenAI Prompt custom skill is flexible enough to allow developers to specify any kinds of prompts and content, since we want developers to tailor the skill configuration to their scenario. But this means that there's a possibility that the content generated by the model could be harmful, biased, explicit, or violent in nature. We highly encourage developers, who configure the GenAI Prompt skill to interact with Azure AI Foundry language models, to set up appropriate content safety filters for the models that they have deployed.

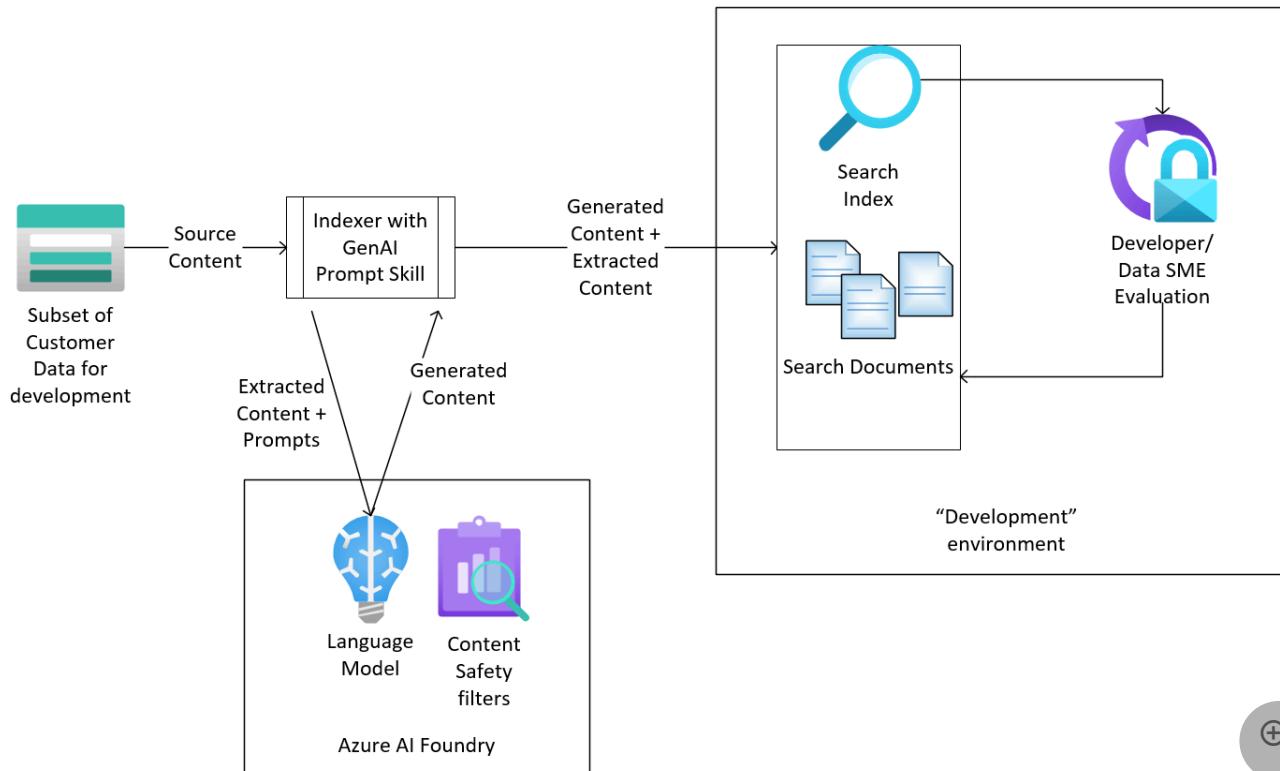

Azure AI Foundry has an [elaborate guide on responsible AI practices](#) and we strongly recommend developers review the contents of the guide and ensure they have implemented

them for the models being used with the GenAI Prompt custom skill. One of the key factors that can determine quality and accuracy of results produced by a language model is a well-crafted system message. Azure AI Foundry also has published a [system message template guide](#) to mitigate against potential RAI harms and guide systems to interact safely with users.

Azure AI Foundry has also published a [detailed guide on evaluation criteria](#) for selecting the models that developers can choose to deploy for their various applications. While the GenAI Prompt skill is flexible enough to work with almost all chat completion models in Azure AI Foundry, depending on the criteria for the end-user, some models might work better than others. Certain chat completion models have advanced image processing capabilities at a high level of accuracy, but come at the expense of cost. Some models might be more prone to attacks via prompts, incorrect information, and so on. Developers who configure the GenAI Prompt custom skill must be aware of these characteristics of the models they choose to utilize for content generation and ingestion into the search index. We strongly recommend developers utilize the "development" index and many sampling to clearly understand the nature of these models as they interact with data before switching it over to production.

Being agile in rolling back or modifying ingestion configuration

The previous two sections stressed the importance for developers to have a "development" environment, where they configure a "development" index with a built-in mechanism for developers/data SMEs to evaluate the contents of the search index.

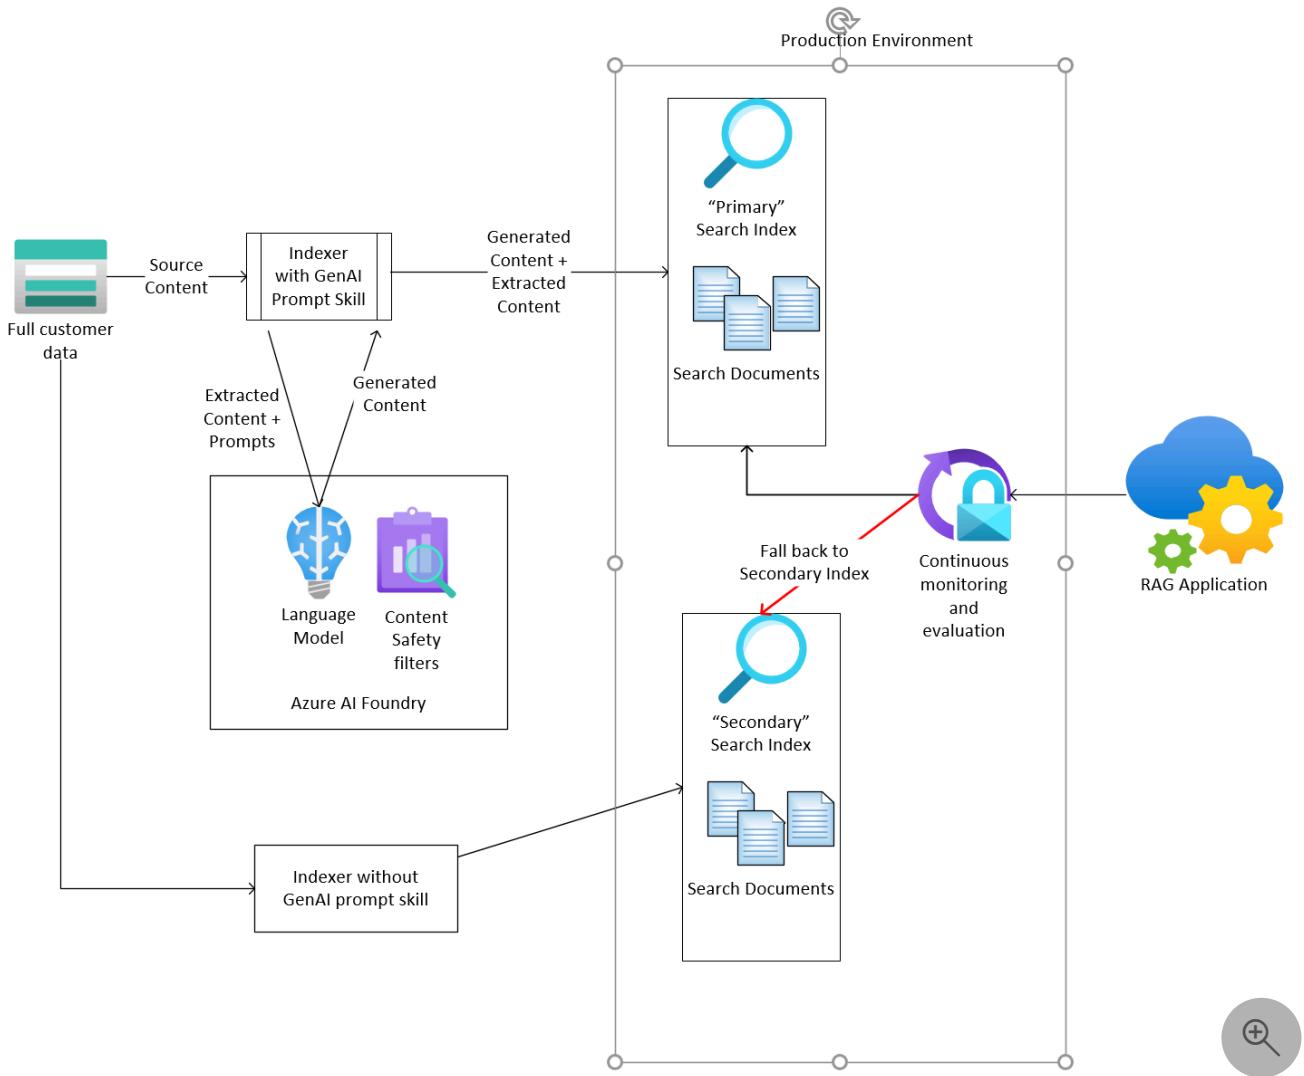

Once the evaluation in the development environment is satisfactory, developers should transition the ingestion process to a production environment, where the indexer operates on the full customer data. However, it's possible for there to be unexpected drops in quality or performance when operating on this data set. It's also possible for the model to be updated without undergoing evaluation in the development environment - both these cases can result in a suboptimal experience for users interacting with RAG applications, and developers need to be agile in detecting and mitigating such conditions. To catch such situations, developers should ensure that they also have a constant monitoring of their "production" index and be ready to modify configurations as needed. The following sections describe some patterns developers could adopt to be responsive to such scenarios.

Primary-Secondary index powering RAG applications

Developers should consider having a primary and a secondary index to power their RAG applications. The primary and secondary indexes would be similar in the configuration of fields - the only difference would be that the primary index will have an extra (searchable and retrievable) field which will contain content generated from the language model through the GenAI Prompt custom skill. Developers should configure their RAG applications such that the AI model being augmented can use either the primary or the secondary index as its knowledge source. The primary index should be preferred, but if the quality of the results produced by the RAG application seems to be adversely impacted, the application should swap to using the secondary index which doesn't have generated content as part of the knowledge source. This can be achieved without needing any code change/redeployment of the RAG app by utilizing the [index alias feature](#) and having the RAG application query the alias, and then swapping the indexes that map to the alias if necessary.

The following diagram illustrates this pattern.

Dropping use of generated field in search queries

A lighter weight alternative to having two copies of the search index, is to ensure that the RAG application can modify the search query issued to Azure AI Search easily. By default when a search query is issued, all searchable fields are scanned, however Azure AI Search allows specifying which fields must be analyzed to produce a set of search results.

Consider an index which has two content fields – a "name" field and a (verbose) "description" field for a sample data set containing hotel information. Let's say the RAG developer/search index admin has configured a third field called "summary", which will hold an AI generated summary of the description via the GenAI Prompt skill. When configuring a RAG application, developers can specify two kinds of search queries - the default search query which analyzes all searchable fields, and another specific query that only looks at those searchable fields whose content isn't generated by a language model. The following is an example of such a specific query, that explicitly omits the "summary" field.

HTTP

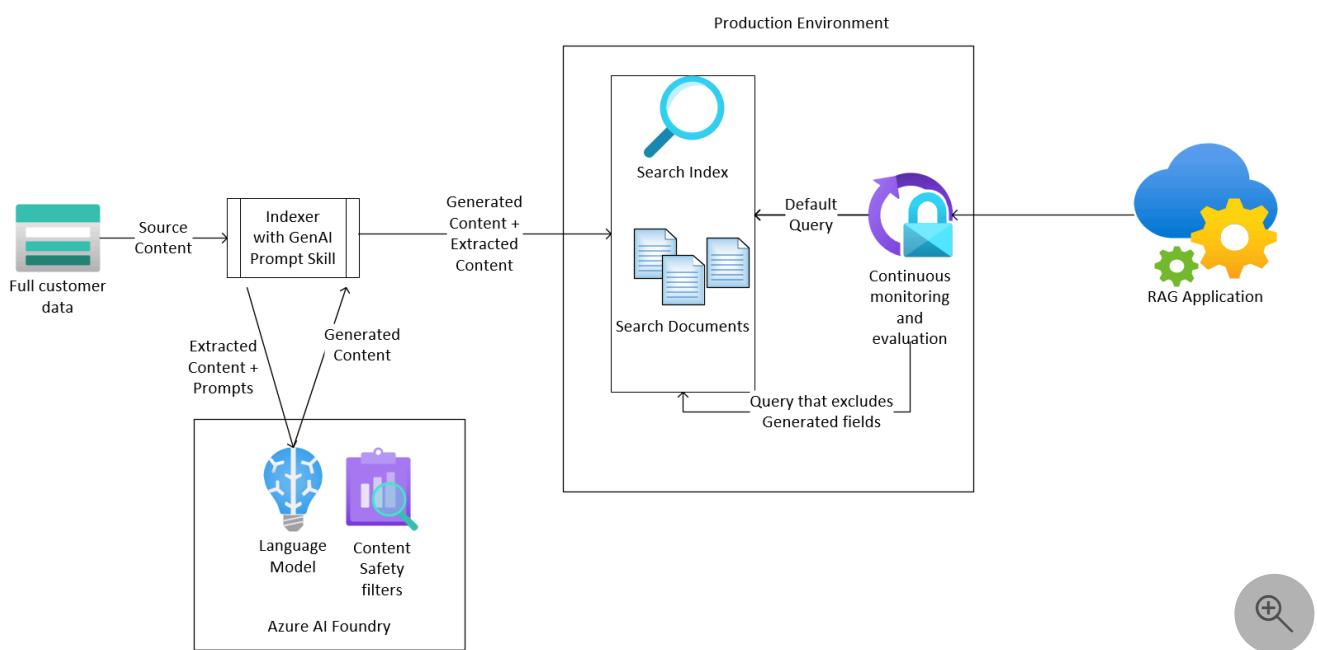

```

POST https://[service-name].search.windows.net/indexes/[index-name]?api-version=[api-version]

{
  "search": "Spacious, air-condition* +\"Ocean view\"",
  "searchFields": "description, name",
  "searchMode": "any",
  "queryType": "full"
}

```

The RAG application can fall back to this specific query (might require a code change/redeployment), if the default query starts to degrade in performance or evaluation metrics, illustrated by the following diagram.

Resetting indexer after modifying skill configuration

Sometimes the system or user message specified to the GenAI Prompt custom skill might be impacted due to new data in the "full" customer data set and tuning these messages might provide a faster alternative than the previous options. However we recommend developers to also [reset and rerun](#) an indexer if the system or user messages are modified for the GenAI Prompt custom skill, to apply this to all documents in the data source. This option can possibly incur additional costs.

Limitations

The risk mitigation strategies and patterns suggested in this document can have limitations based on either scenario specific or data dependent reasons as well as for storage and cost

reasons. It's the responsibility of the RAG developer to ensure that they fully understand any specific risks associated with AI content generation as part of the ingestion pipeline and have appropriate strategies in place to mitigate them.

Human in the loop oversight

Given the scale of data ingestion, it might not be feasible to have a human in the loop oversight for "production" applications. We recommend extensive validation by data SMEs in the "development" environment to minimize the need for this in production. Follow an evaluation process that: (1) uses some internal stakeholders to evaluate results, (2) uses A/B experimentation to roll out this capability to users and (3) incorporates key performance indicators (KPIs) and metrics monitoring when the capability is deployed.

Add a custom skill to an Azure AI Search enrichment pipeline

Article • 01/15/2025

An [AI enrichment pipeline](#) can include both [built-in skills](#) and [custom skills](#) that you personally create and publish. Your custom code executes externally from the search service (for example, as an Azure function), but accepts inputs and sends outputs to the skillset just like any other skill. Your data is processed in the [Geo](#) where your model is deployed.

Custom skills might sound complex but can be simple and straightforward in terms of implementation. If you have existing packages that provide pattern matching or classification models, the content you extract from blobs could be passed to these models for processing. Since AI enrichment is Azure-based, your model should be on Azure also. Some common hosting methodologies include using [Azure Functions](#) or [Containers](#).

If you're building a custom skill, this article describes the interface you use to integrate the skill into the pipeline. The primary requirement is the ability to accept inputs and emit outputs in ways that are consumable within the [skillset](#) as a whole. As such, the focus of this article is on the input and output formats that the enrichment pipeline requires.

Benefits of custom skills

Building a custom skill gives you a way to insert transformations unique to your content. For example, you could build custom classification models to differentiate business and financial contracts and documents, or add a speech recognition skill to reach deeper into audio files for relevant content. For a step-by-step example, see [Example: Creating a custom skill for AI enrichment](#).

Set the endpoint and time-out interval

The interface for a custom skill is specified through the [Custom Web API skill](#).

JSON

```
"@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",
"description": "This skill has a 230 second time-out",
"uri": "https://[your custom skill uri goes here]",
```

```
"authResourceId": "[for managed identity connections, your app's client ID goes here]",  
"timeout": "PT230S",
```

The URI is the HTTPS endpoint of your function or app. When setting the URI, make sure the URI is secure (HTTPS). If your code is hosted in an Azure function app, the URI should include an [API key in the header or as a URI parameter](#) to authorize the request.

If instead your function or app uses Azure managed identities and Azure roles for authentication and authorization, the custom skill can include an authentication token on the request. The following points describe the requirements for this approach:

- The search service, which sends the request on the indexer's behalf, must be [configured to use a managed identity](#) (either system or user-assigned) so that the caller can be authenticated by Microsoft Entra ID.
- Your function or app must be [configured for Microsoft Entra ID](#).
- Your [custom skill definition](#) must include an `authResourceId` property. This property takes an application (client) ID, in a [supported format](#): `api://<appId>`.

By default, the connection to the endpoint times out if a response isn't returned within a 30-second window (`PT30S`). The indexing pipeline is synchronous and indexing will produce a time-out error if a response isn't received in that time frame. You can increase the interval to a maximum value of 230 seconds by setting the `timeout` parameter (`PT230S`).

Format Web API inputs

The Web API must accept an array of records to be processed. Within each record, provide a property bag as input to your Web API.

Suppose you want to create a basic enricher that identifies the first date mentioned in the text of a contract. In this example, the custom skill accepts a single input "contractText" as the contract text. The skill also has a single output, which is the date of the contract. To make the enricher more interesting, return this "contractDate" in the shape of a multipart complex type.

Your Web API should be ready to receive a batch of input records. Each member of the "values" array represents the input for a particular record. Each record is required to have the following elements:

- A "recordId" member that is the unique identifier for a particular record. When your enricher returns the results, it must provide this "recordId" in order to allow the caller to match the record results to their input.
- A "data" member, which is essentially a bag of input fields for each record.

The resulting Web API request might look like this:

```
JSON

{
  "values": [
    {
      "recordId": "a1",
      "data": {
        "contractText": "This is a contract that was issued on November 3, 2023 and that involves..."
      }
    },
    {
      "recordId": "b5",
      "data": {
        "contractText": "In the City of Seattle, WA on February 5, 2018 there was a decision made..."
      }
    },
    {
      "recordId": "c3",
      "data": {
        "contractText": null
      }
    }
  ]
}
```

In practice, your code can be called with hundreds or thousands of records instead of only the three shown here.

Format Web API outputs

The format of the output is a set of records containing a "recordId", and a property bag. This particular example has only one output, but you could output more than one property. As a best practice, consider returning error and warning messages if a record couldn't be processed.

JSON

```
{  
  "values":  
  [  
    {  
      "recordId": "b5",  
      "data" :  
      {  
        "contractDate": { "day" : 5, "month": 2, "year" : 2018 }  
      }  
    },  
    {  
      "recordId": "a1",  
      "data" : {  
        "contractDate": { "day" : 3, "month": 11, "year" : 2023 }  
      }  
    },  
    {  
      "recordId": "c3",  
      "data" :  
      {  
      },  
      "errors": [ { "message": "contractText field required "} ],  
      "warnings": [ {"message": "Date not found" } ]  
    }  
  ]  
}
```

Add a custom skill to a skillset

When you create a Web API enricher, you can describe HTTP headers and parameters as part of the request. The following snippet shows how request parameters and optional HTTP headers can be included in the skillset definition. Setting an HTTP header is useful if you need to pass configuration settings to your code.

JSON

```
{  
  "skills": [  
    {  
      "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",  
      "name": "myCustomSkill",  
      "description": "This skill calls an Azure function, which in turn  
calls TA sentiment",  
      "uri": "https://indexer-e2e-  
webskill.azurewebsites.net/api/DateExtractor?language=en",  
      "context": "/document",  
      "httpHeaders": {  
        "DateExtractor-Api-Key": "foo"  
      }  
    }  
  ]  
}
```

```
        },
        "inputs": [
            {
                "name": "contractText",
                "source": "/document/content"
            }
        ],
        "outputs": [
            {
                "name": "contractDate",
                "targetName": "date"
            }
        ]
    }
}
```

Efficiently scale out a custom skill

Article • 01/18/2025

Custom skills are web APIs that implement a specific interface. A custom skill can be implemented on any publicly addressable resource. The most common implementations for custom skills are:

- Azure Functions for custom logic skills
- Azure Web apps for simple containerized AI skills
- Azure Kubernetes service for more complex or larger skills.

Skillset configuration

The following properties on a [custom skill](#) are used for scale. Review the [custom skill interface](#) for an introduction into the inputs and outputs that a custom skill should implement.

1. Set `batchSize` of the custom skill to configure the number of records sent to the skill in a single invocation of the skill.
2. Set the `degreeOfParallelism` to calibrate the number of concurrent requests the indexer makes to your skill.
3. Set `timeout` to a value sufficient for the skill to respond with a valid response.
4. In the `indexer` definition, set `batchSize` to the number of documents that should be read from the data source and enriched concurrently.

Considerations

There's no "one size fits all" set of recommendations. You should plan on testing different configurations to reach an optimum result. Scale up strategies are based on fewer large requests, or many small requests.

- Skill invocation cardinality: make sure you know whether the custom skill executes once for each document (`/document/content`) or multiple times per document (`/document/reviews_text/pages/*`). If it's multiple times per document, stay on the lower side of `batchSize` and `degreeOfParallelism` to reduce churn, and try setting indexer batch size to incrementally higher values for more scale.

- Coordinate custom skill `batchSize` and indexer `batchSize`, and make sure you're not creating bottlenecks. For example, if the indexer batch size is 5, and the skill batch size is 50, you would need 10 indexer batches to fill a custom skill request. Ideally, skill batch size should be less than or equal to indexer batch size.
- For `degreeOfParallelism`, use the average number of requests an indexer batch can generate to guide your decision on how to set this value. If your infrastructure hosting the skill, for example an Azure function, can't support high levels of concurrency, consider dialing down the degrees of parallelism. You can test your configuration with a few documents to validate your understanding of average number of requests.
- Although your object is scale and support of high volumes, testing with a smaller sample of documents helps quantify different stages of execution. For example, you can evaluate the execution time of your skill, relative to the overall time taken to process the subset of documents. This helps you answer the question: does your indexer spend more time building a batch or waiting for a response from your skill?
- Consider the upstream implications of parallelism. If the input to a custom skill is an output from a prior skill, are all the skills in the skillset scaled out effectively to minimize latency?

Error handling in the custom skill

Custom skills should return a success status code HTTP 200 when the skill completes successfully. If one or more records in a batch result in errors, consider returning multi-status code 207. The errors or warnings list for the record should contain the appropriate message.

Any items in a batch that errors will result in the corresponding document failing. If you need the document to succeed, return a warning.

Any status code over 299 is evaluated as an error and all the enrichments are failed resulting in a failed document.

Common error messages

- Could not execute skill because it did not execute within the time limit '00:00:30'. This is likely transient. Please try again later. For custom skills, consider increasing the 'timeout' parameter on your skill in the

`skillset`. Set the timeout parameter on the skill to allow for a longer execution duration.

- `Could not execute skill because Web Api skill response is invalid.` Indicative of the skill not returning a message in the custom skill response format. This could be the result of an uncaught exception in the skill.
- `Could not execute skill because the Web Api request failed.` Most likely caused by authorization errors or exceptions.
- `Could not execute skill.` Commonly the result of the skill response being mapped to an existing property in the document hierarchy.

Testing custom skills

Start by testing your custom skill with a REST API client to validate:

- The skill implements the custom skill interface for requests and responses
- The skill returns valid JSON with the `application/JSON` MIME type
- Returns a valid HTTP status code

Create a [debug session](#) to add your skill to the skillset and make sure it produces a valid enrichment. While a debug session doesn't allow you to tune the performance of the skill, it enables you to ensure that the skill is configured with valid values and returns the expected enriched objects.

Best practices

- While skills can accept and return larger payloads, consider limiting the response to 150 MB or less when returning JSON.
- Consider setting the batch size on the indexer and skill to ensure that each data source batch generates a full payload for your skill.
- For long running tasks, set the timeout to a high enough value to ensure the indexer doesn't error out when processing documents concurrently.
- Optimize the indexer batch size, skill batch size, and skill degrees of parallelism to generate the load pattern your skill expects, fewer large requests or many small requests.

- Monitor custom skills with detailed logs of failures as you can have scenarios where specific requests consistently fail as a result of the data variability.
-

Example: Create a custom skill using the Bing Entity Search API

Article • 01/18/2025

In this example, learn how to create a web API custom skill. This skill will accept locations, public figures, and organizations, and return descriptions for them. The example uses an [Azure Function](#) to wrap the [Bing Entity Search API](#) so that it implements the custom skill interface.

Prerequisites

- Read about [custom skill interface](#) article if you aren't familiar with the input/output interface that a custom skill should implement.
- Create a [Bing Search resource](#) through the Azure portal. A free tier is available and sufficient for this example.
- Install [Visual Studio](#) or later.

Create an Azure Function

Although this example uses an Azure Function to host a web API, it isn't required. As long as you meet the [interface requirements for a cognitive skill](#), the approach you take is immaterial. Azure Functions, however, make it easy to create a custom skill.

Create a project

1. In Visual Studio, select **New > Project** from the File menu.
2. Choose **Azure Functions** as the template and select **Next**. Type a name for your project, and select **Create**. The function app name must be valid as a C# namespace, so don't use underscores, hyphens, or any other special characters.
3. Select a framework that has long term support.
4. Choose **HTTP Trigger** for the type of function to add to the project.
5. Choose **Function** for the authorization level.
6. Select **Create** to create the function project and HTTP triggered function.

Add code to call the Bing Entity API

Visual Studio creates a project with boilerplate code for the chosen function type. The *FunctionName* attribute on the method sets the name of the function. The *HttpTrigger* attribute specifies that the function is triggered by an HTTP request.

Replace the contents of *Function1.cs* with the following code:

```
C#  
  
using System;  
using System.Collections.Generic;  
using System.IO;  
using System.Linq;  
using System.Net.Http;  
using System.Threading.Tasks;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Azure.WebJobs;  
using Microsoft.Azure.WebJobs.Extensions.Http;  
using Microsoft.AspNetCore.Http;  
using Microsoft.Extensions.Logging;  
using Newtonsoft.Json;  
  
namespace SampleSkills  
{  
    /// <summary>  
    /// Sample custom skill that wraps the Bing entity search API to connect  
    it with a  
    /// AI enrichment pipeline.  
    /// </summary>  
    public static class BingEntitySearch  
    {  
        #region Credentials  
        // IMPORTANT: Make sure to enter your credential and to verify the  
        API endpoint matches yours.  
        static readonly string bingApiEndpoint =  
"https://api.bing.microsoft.com/v7.0/entities";  
        static readonly string key = "<enter your api key here>";  
        #endregion

#region The Azure Function definition

[FunctionName("EntitySearch")]
public static async Task<IActionResult> Run(
    [HttpTrigger(AuthorizationLevel.Function, "post", Route = null)]
HttpRequest req,
    ILogger log)
{
    log.LogInformation("Entity Search function: C# HTTP trigger
function processed a request.");

    var response = new WebApiResponse
    {
        Values = new List<OutputRecord>()
    };

    string requestBody = new StreamReader(req.Body).ReadToEnd();
    var data = JsonConvert.DeserializeObject<WebApiRequest>
(requestBody);

    // Do some schema validation
    if (data == null)
    {
        return new BadRequestObjectResult("The request schema does
not match expected schema.");
    }
    if (data.Values == null)
    {
        return new BadRequestObjectResult("The request schema does
not match expected schema. Could not find values array.");
    }

    // Calculate the response for each value.
    foreach (var record in data.Values)
    {

```

```

        if (record == null || record.RecordId == null) continue;

        OutputRecord responseRecord = new OutputRecord
        {
            RecordId = record.RecordId
        };

        try
        {
            responseRecord.Data =
GetEntityMetadata(record.Data.Name).Result;
        }
        catch (Exception e)
        {
            // Something bad happened, log the issue.
            var error = new OutputRecord.OutputRecordMessage
            {
                Message = e.Message
            };

            responseRecord.Errors = new
List<OutputRecord.OutputRecordMessage>
            {
                error
            };
        }
        finally
        {
            response.Values.Add(responseRecord);
        }
    }

    return (ActionResult)new OkObjectResult(response);
}

#endregion

#region Methods to call the Bing API
/// <summary>
/// Gets metadata for a particular entity based on its name using
Bing Entity Search
/// </summary>
/// <param name="entityName">The name of the entity to extract data
for.</param>
/// <returns>Asynchronous task that returns entity data. </returns>
private async static Task<OutputRecord.OutputRecordData>
GetEntityMetadata(string entityName)
{
    var uri = bingApiEndpoint + "?q=" + entityName + "&mkt=en-
us&count=10&offset=0&safesearch=Moderate";
    var result = new OutputRecord.OutputRecordData();

    using (var client = new HttpClient())
    using (var request = new HttpRequestMessage {
        Method = HttpMethod.Get,

```

```

rule.LicenseNotice;
rootObject.LicenseUrl =
rule.License.Url;
break;
case "ContractualRules/LinkAttribution":
rootObject.Source = rule.Text;
rootObject.SourceUrl = rule.Url;
break;
}
}
}

return rootObject;
}
}

return new OutputRecord.OutputRecordData();
}
#endregion
}
}

```

Make sure to enter your own *key* value in the `key` constant based on the key you got when signing up for the Bing Entity search API.

Test the function from Visual Studio

Press **F5** to run the program and test function behaviors. In this case, we'll use the function below to look up two entities. Use a REST client to issue a call like the one shown below:

HTTP

`POST https://localhost:7071/api/EntitySearch`

Request body

JSON

```
{
  "values": [
    {
      "recordId": "e1",
      "data": {
        "name": "Pablo Picasso"
      }
    },
  ],
}
```

```
        {
            "recordId": "e2",
            "data":
            {
                "name": "Microsoft"
            }
        }
    ]
}
```

Response

You should see a response similar to the following example:

JSON

```
{
    "values": [
        {
            "recordId": "e1",
            "data": {
                "name": "Pablo Picasso",
                "description": "Pablo Ruiz Picasso was a Spanish painter
[...]",
                "source": "Wikipedia",
                "sourceUrl": "http://en.wikipedia.org/wiki/Pablo_Picasso",
                "licenseAttribution": "Text under CC-BY-SA license",
                "licenseUrl": "http://creativecommons.org/licenses/by-
sa/3.0/"
            },
            "errors": null,
            "warnings": null
        },
        ...
    ]
}
```

Publish the function to Azure

When you're satisfied with the function behavior, you can publish it.

1. In **Solution Explorer**, right-click the project and select **Publish**. Choose **Create New** > **Publish**.
2. If you haven't already connected Visual Studio to your Azure account, select **Add an account....**

3. Follow the on-screen prompts. You're asked to specify a unique name for your app service, the Azure subscription, the resource group, the hosting plan, and the storage account you want to use. You can create a new resource group, a new hosting plan, and a storage account if you don't already have these. When finished, select **Create**
4. After the deployment is complete, notice the Site URL. It is the address of your function app in Azure.
5. In the [Azure portal](#), navigate to the Resource Group, and look for the **EntitySearch** Function you published. Under the **Manage** section, you should see Host Keys. Select the **Copy** icon for the *default* host key.

Test the function in Azure

Now that you have the default host key, test your function as follows:

```
HTTP  
  
POST https://[your-entity-search-app-name].azurewebsites.net/api/EntitySearch?code=[enter default host key here]
```

Request Body

```
JSON  
  
{  
  "values": [  
    {  
      "recordId": "e1",  
      "data":  
        {  
          "name": "Pablo Picasso"  
        }  
    },  
    {  
      "recordId": "e2",  
      "data":  
        {  
          "name": "Microsoft"  
        }  
    }  
  ]  
}
```

This example should produce the same result you saw previously when running the function in the local environment.

Connect to your pipeline

Now that you have a new custom skill, you can add it to your skillset. The example below shows you how to call the skill to add descriptions to organizations in the document (this could be extended to also work on locations and people). Replace [your-entity-search-app-name] with the name of your app.

```
JSON

{
  "skills": [
    "[... your existing skills remain here]",
    {
      "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",
      "description": "Our new Bing entity search custom skill",
      "uri": "https://[your-entity-search-app-
name].azurewebsites.net/api/EntitySearch?code=[enter default host key
here]",
      "context": "/document/merged_content/organizations/*",
      "inputs": [
        {
          "name": "name",
          "source": "/document/merged_content/organizations/*"
        }
      ],
      "outputs": [
        {
          "name": "description",
          "targetName": "description"
        }
      ]
    }
  ]
}
```

Here, we're counting on the built-in [entity recognition skill](#) to be present in the skillset and to have enriched the document with the list of organizations. For reference, here's an entity extraction skill configuration that would be sufficient in generating the data we need:

```
JSON

{
  "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
  "name": "#1",
```

```
"description": "Organization name extraction",
"context": "/document/merged_content",
"categories": [ "Organization" ],
"defaultLanguageCode": "en",
"inputs": [
  {
    "name": "text",
    "source": "/document/merged_content"
  },
  {
    "name": "languageCode",
    "source": "/document/language"
  }
],
"outputs": [
  {
    "name": "organizations",
    "targetName": "organizations"
  }
]
},
```

Next steps

Congratulations! You've created your first custom skill. Now you can follow the same pattern to add your own custom functionality. Click the following links to learn more.

Create an index for agentic retrieval in Azure AI Search

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In Azure AI Search, agentic retrieval uses context and user questions to generate a range of subqueries that can execute against your content in a [knowledge source](#). A knowledge source can point to indexed content on Azure AI Search, or remote content that's retrieved using the APIs that are native to the provider. When indexes are used in agentic retrieval, they are either:

- An *existing index* containing searchable content. You can make an existing index available to agentic retrieval through a [search index knowledge source](#) definition.
- A *generated index* created from an indexed [knowledge source](#). Indexed knowledge sources create a copy of an external data source inside a search index using a full indexer pipeline (data source, skillset, indexer, and index) for agentic retrieval. Multiple knowledge sources can generate an indexer pipeline that results in a searchable index. These include:
 - [Azure blobs](#)
 - [Microsoft OneLake](#)
 - [SharePoint \(Indexed\)](#)

A generated index is based on a template that meets all of the criteria for knowledge bases and agentic retrieval.

This article explains which index elements affect agentic retrieval query logic. None of the required elements are new or specific to agentic retrieval, which means you can use an existing index if it meets the criteria identified in this article, even if it was created using earlier API versions.

! Note

The following knowledge sources access external sources directly and don't require a search index: [Web Knowledge Source \(Bing\)](#) and [SharePoint \(Remote\)](#).

Criteria for agentic retrieval

An index that's used in agentic retrieval must have these elements:

- String fields attributed as `searchable` and `retrievable`.
- A [semantic configuration](#), with a `defaultSemanticConfiguration` or a semantic configuration override in the knowledge source.

It should also have fields that can be used for citations, such as document or file name, page or chapter name, or at least a chunk ID.

It should have [vector fields and a vectorizer](#) if you want to include text-to-vector query conversion in the pipeline.

Optionally, the following index elements increase your opportunities for optimization:

- `scoringProfile` with a `defaultScoringProfile`, for boosting relevance
- `synonymMaps` for terminology or jargon
- `analyzers` for linguistics rules or patterns (like whitespace preservation, or special characters)

Example index definition

Here's an example index that works for agentic retrieval. It meets the criteria for required elements. It includes vector fields as a best practice.

JSON

```
{  
  "name": "earth_at_night",  
  "description": "Contains images and descriptions of our planet in darkness as  
captured from space by Earth-observing satellites and astronauts on the  
International Space Station over the past 25 years.",

            }
        }
    ],
    "compressions": []
}
}

```

Key points:

A well-designed index that's used for generative AI or retrieval augmented generation (RAG) structure has these components:

- A description that an LLM or agent can use to determine whether an index should be used or skipped.
- Chunks of human readable text that can be passed as input tokens to an LLM for answer formulation.
- A semantic ranker configuration because agentic retrieval uses level 2 (L2) semantic ranking to identify the most relevant chunks.
- Optionally, vector-equivalent versions of the human readable chunks of text for complementary vector search.

Chunked text is important because LLMs consume and emit tokenized strings of human readable plain text content. For this reason, you want `searchable` fields that provide plain text strings, and are `retrievable` in the response. In Azure AI Search, chunked text can be created using [built-in or third-party solutions](#).

A built-in assumption for chunked content is that the original source documents have large amounts of verbose content. If your source content is structured data, such as a product

database, then your index should forego chunking and instead include fields that map to the original data source (for example, a product name, category, description, and so forth). Attribution of `searchable` and `retrievable` applies to structured data as well. Searchable makes the content in-scope for queries, and retrievable adds it to the search results (grounding data).

Vector content can be useful because it adds *similarity search* to information retrieval. At query time, when vector fields are present in the index, the agentic retrieval engine executes a vector query in parallel to the text query. Because vector queries look for similar content rather than matching words, a vector query can find a highly relevant result that a text query might miss. Adding vectors can enhance and improve the quality of your grounding data, but aren't otherwise strictly required. Azure AI Search has a [built-in approach for vectorization](#).

Vector fields are used only for query execution on Azure AI Search. You don't need the vector in results because it isn't human or LLM readable. We recommend that you set `retrievable` and `stored` to false to minimize space requirements. For more information, see [Optimize vector storage and processing](#).

If you use vectors, having a `vectorizer` defined in the vector search configuration is critical. It determines whether your vector field is used during query execution. The vectorizer encodes string subqueries into vectors at query time for similarity search over the vectors. The vectorizer must be the same embedding model used to create the vectors in the index.

By default, all `searchable` fields are included in query execution, and all `retrievable` fields are returned in results. You can choose which fields to use for each action in the [search index knowledge source definition](#).

Add a description

An index `description` field is a user-defined string that you can use to provide guidance to LLMs and Model Context Protocol (MCP) servers when deciding to use a specific index for a query. This human-readable text is invaluable when a system must access several indexes and make a decision based on the description.

An index description is a schema update, and you can add it without having to rebuild the entire index.

- String length is 4,000 characters maximum.
- Content must be human-readable, in Unicode. Your use case should determine which language to use (for example, English or another language).

Add a semantic configuration

The index must have at least one semantic configuration. The semantic configuration must have:

- A named configuration.
- A `prioritizedContentFields` set to at least one string field that is both `searchable` and `retrievable`.

There are two ways to specify a semantic configuration by name. If index has `defaultSemanticConfiguration` set to a named configuration, retrieval uses it. Alternatively, you can specify the semantic configuration inside the [search index knowledge source](#).

Within the configuration, `prioritizedContentFields` is required. Title and keywords are optional. For chunked content, you might not have either. However, if you add [entity recognition](#) or [key phrase extraction](#), you might have some keywords associated with each chunk that can be useful in search scenarios, perhaps in a scoring profile.

Here's an example of a semantic configuration that works for agentic retrieval:

JSON

```
"semantic":{  
    "defaultConfiguration":"semantic_config",  
    "configurations": [  
        {  
            "name": "semantic_config",  
            "flightingOptIn": false,  
            "prioritizedFields": {  
                "prioritizedFields": {  
                    "titleField": {  
                        "fieldName": ""  
                    },  
                    "prioritizedContentFields": [  
                        {  
                            "fieldName": "page_chunk"  
                        }  
                    ],  
                    "prioritizedKeywordsFields": [  
                        {  
                            "fieldName": "Category"  
                        },  
                        {  
                            "fieldName": "Tags"  
                        },  
                        {  
                            "fieldName": "Location"  
                        }  
                    ]  
                }  
            }  
        }  
    ]  
}
```

```
        }
    }
]
}
```

⚠ Note

The response provides `title`, `terms`, and `content`, which map to the prioritized fields in this configuration.

Add a vectorizer

If you have vector fields in the index, the query plan includes them if they're `searchable` and have a `vectorizer` assignment.

A [vectorizer](#) specifies an embedding model that provides text-to-vector conversions at query time. It must point to the same embedding model used to encode the vector content in your index. You can use any embedding model supported by Azure AI Search. Vectorizers are specified on vector fields by way of a *vector profile*.

Recall the **vector field definition** in the index example. Attributes on a vector field include dimensions or the number of embeddings generated by the model, and the profile.

JSON

```
{
  "name": "page_chunk_text_3_large", "type": "Collection(Edm.Single)",
  "searchable": true, "retrievable": false, "filterable": false, "sortable": false,
  "facetable": false,
  "dimensions": 3072,
  "vectorSearchProfile": "hnsw_text_3_large",
  "stored": false,
  "synonymMaps": []
}
```

Vector profiles are configurations of vectorizers, algorithms, and compression techniques. Each vector field can only use one profile, but your index can have many in case you want unique profiles for every vector field.

Querying vectors and calling a vectorizer adds latency to the overall request, but if you want similarity search it might be worth the trade-off.

Here's an example of a vectorizer that works for agentic retrieval, as it appears in a `vectorSearch` configuration. There's nothing in the vectorizer definition that needs to be

changed to work with agentic retrieval.

JSON

```
"vectorSearch": {  
    "algorithms": [  
        {  
            "name": "alg",  
            "kind": "hnsw",  
            "hnswParameters": {  
                "metric": "cosine",  
                "m": 4,  
                "efConstruction": 400,  
                "efSearch": 500  
            }  
        }  
    ],  
    "profiles": [  
        {  
            "name": "hnsw_text_3_large",  
            "algorithm": "alg",  
            "vectorizer": "azure_openai_text_3_large"  
        }  
    ],  
    "vectorizers": [  
        {  
            "name": "azure_openai_text_3_large",  
            "kind": "azureOpenAI",  
            "azureOpenAIParameters": {  
                "resourceUri": "https://YOUR-AOAI-RESOURCE.openai.azure.com",  
                "deploymentId": "text-embedding-3-large",  
                "apiKey": "<redacted>",  
                "modelName": "text-embedding-3-large"  
            }  
        }  
    ],  
    "compressions": []  
}
```

Add a scoring profile

Scoring profiles are criteria for relevance boosting. They're applied to non-vector fields (text and numbers) and are evaluated during query execution, although the precise behavior depends on the API version used to create the index.

A scoring profile is more likely to add value to your solution if your index is based on structured data. Structured data is indexed into multiple discrete fields, which means your scoring profile can have criteria that target the content or characteristics of a specific field.

If you create the index using 2025-05-01-preview or later, the scoring profile executes last. If the index is created using an earlier API version, scoring profiles are evaluated before semantic reranking. Because agentic retrieval is available in newer preview APIs, the scoring profile executes last. The actual order of semantically ranked results is determined by the [rankingOrder](#) property in the index, which is either set to `boostedRerankerScore` (a scoring profile was applied) or `rerankerScore` (no scoring profile).

You can use any scoring profile that makes sense for your index. Here's an example of one that boosts the search score of a match if the match is found in a specific field. Fields are weighted by boosting multipliers. For example if a match was found in the "Category" field, the boosted score is multiplied by 5.

JSON

```
"scoringProfiles": [
  {
    "name": "boostSearchTerms",
    "text": {
      "weights": {
        "Location": 2,
        "Category": 5
      }
    }
  }
]
```

Add analyzers

[Analyzers](#) apply to text fields and can be language analyzers or custom analyzers that control tokenization in the index, such as preserving special characters or whitespace.

Analyzers are defined within a search index and assigned to fields. The [fields collection example](#) includes an analyzer reference on the text chunks. In this example, the default analyzer (standard Lucene) is replaced with a Microsoft language analyzer for the English language.

JSON

```
{
  "name": "page_chunk", "type": "Edm.String",
  "searchable": true, "retrievable": true, "filterable": false, "sortable": false,
  "facetable": false,
  "analyzer": "en.microsoft",
  "stored": true,
  "synonymMaps": []
}
```

Add a synonym map

Synonym maps expand queries by adding synonyms for named terms. For example, you might have scientific or medical terms for common terms.

Synonym maps are defined as a top-level resource on a search index and assigned to fields. The [fields collection example](#) doesn't include a synonym map, but if you had variant spellings of country names in synonym map, here's what an example might look like if it was assigned to a hypothetical "locations" field.

JSON

```
{  
  "name": "locations",  
  "type": "Edm.String",  
  "searchable": true,  
  "synonymMaps": [ "country-synonyms" ]  
}
```

Add your index to a knowledge source

If you have a standalone index that already exists, and it isn't generated by a knowledge source, create the following objects:

- A [searchIndex knowledge source](#) to encapsulate your indexed content.
- A [knowledge base](#) that represents one or more knowledge sources and other instructions for knowledge retrieval.

Related content

What is a knowledge source?

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

A knowledge source specifies the content used for agentic retrieval. It encapsulates a search index which may be populated by an external data source, or a direct connection to a remote source such as Bing or Sharepoint that is queried directly. A knowledge source is a required definition in a knowledge base.

- Create a knowledge source as a top-level resource on your search service. Each knowledge source points to exactly one data structure, either a search index that [meets the criteria for agentic retrieval](#) or a supported external resource.
- Reference one or more knowledge sources in a knowledge base. In an agentic retrieval pipeline, it's possible to query against multiple knowledge sources in a single request. Subqueries are generated for each knowledge source. Top results are returned in the retrieval response.
- For certain knowledge sources, you can use a knowledge source definition to generate a full indexer pipeline (data source, skillset, indexer, and index) that works for agentic retrieval. Instead of creating multiple objects manually, information in the knowledge source is used to generate all objects, including a populated, chunked, and searchable index.

Make sure you have at least one knowledge source before creating a knowledge base. The full specification of a knowledge source and a knowledge base is in the [preview REST API reference](#).

Working with a knowledge source

- Creation path: first create a knowledge source, then create a knowledge base.
- Deletion path: update or delete knowledge bases to remove references to a knowledge source, and then delete the knowledge source last.
- A knowledge source, its index, and the knowledge base must all exist on the same search service. External content is either accessed over the public internet (Bing) or in a Microsoft

tenant (remote SharePoint).

Supported knowledge sources

Here are the knowledge sources you can create in this preview:

- "[searchIndex](#)" API wraps an existing index.
- "[azureBlob](#)" API generates an indexer pipeline that pulls from a blob container.
- "[indexedOneLake](#)" API generates an indexer pipeline that pulls from a lakehouse.
- "[indexedSharePoint](#)" API generates an indexer pipeline that pulls from a SharePoint site.
- "[remoteSharePoint](#)" API retrieves content directly from SharePoint.
- "[webParameters](#)" API retrieves real-time grounding data from Microsoft Bing.

Creating knowledge sources

You must have [Search Service Contributor](#) permissions to create objects on a search service. You also need [Search Index Data Contributor](#) permissions to load an index if you're using a knowledge source that creates an indexer pipeline. Alternatively, you can [use an API admin key](#) instead of roles.

You can use the REST API or an Azure SDK preview package to create a knowledge source. Azure portal support is available for select knowledge sources. The following links provide instructions for creating a knowledge source:

- [How to create a search index knowledge source \(wraps an existing index\)](#)
- [How to create a blob knowledge source \(generates an indexer pipeline\)](#)
- [How to create a OneLake knowledge source \(generates an indexer pipeline\)](#)
- [How to create a SharePoint \(indexed\) knowledge source \(generates an indexer pipeline\)](#)
- [How to create a SharePoint \(remote\) knowledge source \(queries SharePoint directly\)](#)
- [How to create a Web Knowledge Source resource \(connects to Bing's public endpoint\)](#)

After the knowledge source is created, you can reference it in a knowledge base.

Using knowledge sources

Properties on the [knowledge base](#) determine which knowledge sources are used.

- "[knowledgeSources](#)" REST array specifies the knowledge sources available to the knowledge base.
- "[retrievalReasoningEffort](#)" REST properties determine the amount of effort put into a retrieval. For more information, see [Set the retrieval reasoning effort](#).

- "outputMode" REST affects query output and what goes in the response.

The knowledge base uses the [retrieve action](#) to send queries to the index specified in the knowledge source. In the retrieve action, some knowledge base and source defaults can be overridden at retrieval time.

Use multiple knowledge sources simultaneously

When you have multiple knowledge sources, set the following properties to bias query planning to a specific knowledge source.

- Setting `alwaysQuerySource` forces query planning to always include the knowledge source.
- Setting `retrievalInstructions` provides guidance that includes or excludes a knowledge source.

Retrieval instructions are sent as a user-defined prompt to the large language model (LLM) used for query planning. This prompt is helpful when you have multiple knowledge sources and want to provide guidance on when to use each one. For example, if you have separate indexes for product information, job postings, and technical support, the retrieval instructions might say "use the jobs index only if the question is about a job application."

The `alwaysQuerySource` property overrides `retrievalInstructions`. Set `alwaysQuerySource` to false when providing retrieval instructions.

Use a retrieval reasoning effort to control LLM usage

Not all solutions benefit from LLM query planning and execution. If simplicity and speed outweigh the benefits the LLM query planning and context engineering provide, you can omit the LLM from your pipeline.

The retrieval reasoning effort determines the level of processing that goes into a retrieval action. For more information, see [Set the retrieval reasoning effort](#).

! Note

If you used `attemptFastPath` in the previous preview, that approach is now replaced with `retrievalReasoningEffort` set to `minimal`.

Create a blob knowledge source from Azure Blob Storage and ADLS Gen2

!Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Use a *blob knowledge source* to index and query Azure blob content in an agentic retrieval pipeline. [Knowledge sources](#) are created independently, referenced in a [knowledge base](#), and used as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

Unlike a [search index knowledge source](#), which specifies an existing and qualified index, a blob knowledge source specifies an external data source, models, and properties to automatically generate the following Azure AI Search objects:

- A data source that represents a blob container.
- A skillset that chunks and optionally vectorizes multimodal content from the container.
- An index that stores enriched content and meets the criteria for agentic retrieval.
- An indexer that uses the previous objects to drive the indexing and enrichment pipeline.

!Note

If user access is specified at the document (blob) level in Azure Storage, a knowledge source can carry permission metadata forward to indexed content in Azure AI Search. For more information, see [ADLS Gen2 permission metadata](#) or [Blob RBAC scopes](#).

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#).
- An [Azure Blob Storage](#) or [Azure Data Lake Storage \(ADLS\) Gen2](#) account.
- A blob container with [supported content types](#) for text content. For optional image verbalization, the supported content type depends on whether your chat completion model can analyze and describe the image file.

- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).

! Note

Although you can use the Azure portal to create blob knowledge sources, the portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}
```

```
response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a blob knowledge source.

JSON

```
{
  "name": "my-blob-ks",
  "kind": "azureBlob",
  "description": "A sample blob knowledge source.",
  "encryptionKey": null,
  "azureBlobParameters": {
    "connectionString": "<REDACTED>",
    "containerName": "blobcontainer",
    "folderPath": null,
    "isADLSGen2": false,
    "ingestionParameters": {
      "disableImageVerbalization": false,
      "ingestionPermissionOptions": [],
      "contentExtractionMode": "standard",
      "identity": null,
      "embeddingModel": {
        "kind": "azureOpenAI",
        "azureOpenAIParameters": {
          "resourceUri": "<REDACTED>",
          "deploymentId": "text-embedding-3-large",
          "apiKey": "<REDACTED>",
          "modelName": "text-embedding-3-large",
          "authIdentity": null
        }
      },
      "chatCompletionModel": {
        "kind": "azureOpenAI",
        "azureOpenAIParameters": {
          "resourceUri": "<REDACTED>",
          "deploymentId": "gpt-5-mini",
          "apiKey": "<REDACTED>",
          "modelName": "gpt-5-mini",
          "authIdentity": null
        }
      },
      "ingestionSchedule": null,
      "assetStore": null,
      "aiServices": {
        "uri": "<REDACTED>",
        "apiKey": "<REDACTED>"
      }
    },
    "createdResources": {
      "datasource": "my-blob-ks-datasource",
      "indexer": "my-blob-ks-indexer",
      "skillset": "my-blob-ks-skillset",
      "index": "my-blob-ks-index"
    }
  }
}
```

```
    }  
}  
}
```

! Note

Sensitive information is redacted. The generated resources appear at the end of the response.

Create a knowledge source

Run the following code to create a blob knowledge source.

Python

```
# Create a blob knowledge source  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient  
from azure.search.documents.indexes.models import AzureBlobKnowledgeSource,  
AzureBlobKnowledgeSourceParameters, KnowledgeBaseAzureOpenAIModel,  
AzureOpenAIVectorizerParameters, KnowledgeSourceAzureOpenAIVectorizer,  
KnowledgeSourceContentExtractionMode, KnowledgeSourceIngestionParameters  
  
index_client = SearchIndexClient(endpoint = "search_url", credential =  
AzureKeyCredential("api_key"))  
  
knowledge_source = AzureBlobKnowledgeSource(  
    name = "my-blob-ks",  
    description = "This knowledge source pulls from a blob storage container.",  
    encryption_key = None,  
    azure_blob_parameters = AzureBlobKnowledgeSourceParameters(  
        connection_string = "blob_connection_string",  
        container_name = "blob_container_name",  
        folder_path = None,  
        is_adls_gen2 = False,  
        ingestion_parameters = KnowledgeSourceIngestionParameters(  
            identity = None,  
            disable_image_verbalization = False,  
            chat_completion_model = KnowledgeBaseAzureOpenAIModel(  
                azure_open_ai_parameters = AzureOpenAIVectorizerParameters(  
                    # TRIMMED FOR BREVITY  
                )  
,  
            embedding_model = KnowledgeSourceAzureOpenAIVectorizer(  
                azure_open_ai_parameters=AzureOpenAIVectorizerParameters(  
                    # TRIMMED FOR BREVITY  
                )  
,  
            content_extraction_mode = KnowledgeSourceContentExtractionMode.MINIMAL,
```

```

        ingestion_schedule = None,
        ingestion_permission_options = None
    )
)
)

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated
successfully.")

```

Source-specific properties

You can pass the following properties to create a blob knowledge source.

[] Expand table

Name	Description	Type	Editable	Required
<code>name</code>	The name of the knowledge source, which must be unique within the knowledge sources collection and follow the naming guidelines for objects in Azure AI Search.	String	No	Yes
<code>description</code>	A description of the knowledge source.	String	Yes	No
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in both the knowledge source and the generated objects.	Object	Yes	No
<code>azure_blob_parameters</code>	Parameters specific to blob knowledge sources: <code>connection_string</code> , <code>container_name</code> , <code>folder_path</code> , and <code>is_adls_gen2</code> .	Object		No
<code>connection_string</code>	A key-based connection string or, if you're using a managed identity, the resource ID.	String	No	Yes
<code>container_name</code>	The name of the blob storage container.	String	No	Yes
<code>folder_path</code>	A folder within the container.	String	No	No
<code>is_adls_gen2</code>	The default is <code>False</code> . Set to <code>True</code> if you're using an ADLS Gen2 storage account.	Boolean	No	No

`ingestionParameters` properties

For indexed knowledge sources only, you can pass the following `ingestionParameters` properties to control how content is ingested and processed.

[Expand table](#)

Name	Description	Type	Editable	Required
<code>identity</code>	A managed identity to use in the generated indexer.	Object	Yes	No
<code>disable_image_verbalization</code>	Enables or disables the use of image verbalization. The default is <code>False</code> , which <i>enables</i> image verbalization. Set to <code>True</code> to <i>disable</i> image verbalization.	Boolean	No	No
<code>chat_completion_model</code>	A chat completion model that verbalizes images or extracts content. Supported models are <code>gpt-4o</code> , <code>gpt-4o-mini</code> , <code>gpt-4.1</code> , <code>gpt-4.1-mini</code> , <code>gpt-4.1-nano</code> , <code>gpt-5</code> , <code>gpt-5-mini</code> , and <code>gpt-5-nano</code> . The GenAI Prompt skill will be included in the generated skillset. Setting this parameter also requires that <code>disable_image_verbalization</code> is set to <code>False</code> .	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No
<code>embedding_model</code>	A text embedding model that vectorizes text and image content during indexing and at query time. Supported models are <code>text-embedding-ada-002</code> , <code>text-embedding-3-small</code> , and <code>text-embedding-3-large</code> . The Azure OpenAI Embedding skill will be included in the generated skillset, and the Azure OpenAI vectorizer will be included in the generated index.	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No
<code>content_extraction_mode</code>	Controls how content is extracted from files. The default is <code>minimal</code> , which uses standard content extraction for text and images. Set to <code>standard</code> for advanced document cracking and chunking using the Azure	String	No	No

Name	Description	Type	Editable	Required
	<p>Content Understanding skill, which will be included in the generated skillset. For standard only, the ai_services and asset_store parameters are specifiable.</p>			
ai_services	A Microsoft Foundry resource to access Azure Content Understanding in Foundry Tools. Setting this parameter requires that content_extraction_mode is set to standard.	Object	Only api_key is editable	Yes
asset_store	A blob container to store extracted images. Setting this parameter requires that content_extraction_mode is set to standard.	Object	No	No
ingestion_schedule	Adds scheduling information to the generated indexer. You can also add a schedule later to automate data refresh.	Object	Yes	No
ingestion_permission_options	The document-level permissions to ingest from select knowledge sources: either ADLS Gen2 or indexed SharePoint. If you specify user_ids, group_ids, or rbac_scope, the generated ADLS Gen2 indexer or SharePoint indexer will include the ingested permissions.	Array	No	No

Check ingestion status

Run the following code to monitor ingestion progress and health, including indexer status for knowledge sources that generate an indexer pipeline and populate a search index.

Python

```
# Check knowledge source ingestion status
import requests
```

```

import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}/status"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))

```

A response for a request that includes ingestion parameters and is actively ingesting content might look like the following example.

JSON

```
{
  "synchronizationStatus": "active", // creating, active, deleting
  "synchronizationInterval" : "1d", // null if no schedule
  "currentSynchronizationState" : { // spans multiple indexer "runs"
    "startTime": "2025-10-27T19:30:00Z",
    "itemUpdatesProcessed": 1100,
    "itemsUpdatesFailed": 100,
    "itemsSkipped": 1100,
  },
  "lastSynchronizationState" : { // null on first sync
    "startTime": "2025-10-27T19:30:00Z",
    "endTime": "2025-10-27T19:40:01Z", // this value appears on the activity record
on each /retrieve
    "itemUpdatesProcessed": 1100,
    "itemsUpdatesFailed": 100,
    "itemsSkipped": 1100,
  },
  "statistics": { // null on first sync
    "totalSynchronization": 25,
    "averageSynchronizationDuration": "00:15:20",
    "averageItemsProcessedPerSynchronization" : 500
  }
}
```

Review the created objects

When you create a blob knowledge source, your search service also creates an indexer, index, skillset, and data source. We don't recommend that you edit these objects, as introducing an error or incompatibility can break the pipeline.

After you create a knowledge source, the response lists the created objects. These objects are created according to a fixed template, and their names are based on the name of the knowledge source. You can't change the object names.

We recommend using the Azure portal to validate output creation. The workflow is:

1. Check the indexer for success or failure messages. Connection or quota errors appear here.
2. Check the index for searchable content. Use Search Explorer to run queries.
3. Check the skillset to learn how your content is chunked and optionally vectorized.
4. Check the data source for connection details. Our example uses API keys for simplicity, but you can use Microsoft Entra ID for authentication and role-based access control for authorization.

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
    "@odata.context": "https://my-search-  
service.search.windows.net/$metadata#knowledgebases(name)",  
    "value": [  
        {  
            "name": "my-kb"  
        },  
        {  
            "name": "my-kb-2"  
        }  
    ]  
}
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition  
import requests  
import json  
  
endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"  
params = {"api-version": "2025-11-01-preview"}  
headers = {"api-key": "{api_key}"}  
  
response = requests.get(endpoint, params = params, headers = headers)  
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
    "name": "my-kb",  
    "description": null,  
    "retrievalInstructions": null,  
    "answerInstructions": null,  
    "outputMode": null,  
    "knowledgeSources": [  
        {  
            "name": "my-blob-ks",  
        }  
    ],  
    "models": [],  
    "encryptionKey": null,  
    "retrievalReasoningEffort": {  
        "kind": "low"  
    }  
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_base("knowledge_base_name")
print(f"Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_source("knowledge_source_name")
print(f"Knowledge source deleted successfully.")
```

Create a OneLake knowledge source

(!) Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Use a *OneLake knowledge source* to index and query Microsoft OneLake files in an agentic retrieval pipeline. [Knowledge sources](#) are created independently, referenced in a [knowledge base](#), and used as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

When you create a OneLake knowledge source, you specify an external data source, models, and properties to automatically generate the following Azure AI Search objects:

- A data source that represents a lakehouse.
- A skillset that chunks and optionally vectorizes multimodal content from the lakehouse.
- An index that stores enriched content and meets the criteria for agentic retrieval.
- An indexer that uses the previous objects to drive the indexing and enrichment pipeline.

The generated indexer conforms to the *OneLake indexer*, whose prerequisites, supported tasks, supported document formats, supported shortcuts, and limitations also apply to OneLake knowledge sources. For more information, see the [OneLake indexer documentation](#).

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#).
- Completion of the [OneLake indexer prerequisites](#).
- Completion of the [OneLake indexer data preparation](#).
- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a OneLake knowledge source.

JSON

```
{
  "name": "my-onelake-ks",
  "kind": "indexedOneLake",
  "description": "A sample indexed OneLake knowledge source.",
  "encryptionKey": null,
  "indexedOneLakeParameters": {
    "fabricWorkspaceId": "<REDACTED>",
    "lakehouseId": "<REDACTED>",
    "targetPath": null,
    "ingestionParameters": {
      "disableImageVerbalization": false,
      "ingestionPermissionOptions": [],
      "contentExtractionMode": "standard",
      "identity": null,
```

```
"embeddingModel": {  
    "kind": "azureOpenAI",  
    "azureOpenAIParameters": {  
        "resourceUri": "<REDACTED>",  
        "deploymentId": "text-embedding-3-large",  
        "apiKey": "<REDACTED>",  
        "modelName": "text-embedding-3-large"  
    }  
},  
"chatCompletionModel": {  
    "kind": "azureOpenAI",  
    "azureOpenAIParameters": {  
        "resourceUri": "<REDACTED>",  
        "deploymentId": "gpt-5-mini",  
        "apiKey": "<REDACTED>",  
        "modelName": "gpt-5-mini"  
    }  
},  
"ingestionSchedule": null,  
"aiServices": {  
    "uri": "<REDACTED>",  
    "apiKey": "<REDACTED>"  
},  
"createdResources": {  
    "datasource": "my-onelake-ks-datasource",  
    "indexer": "my-onelake-ks-indexer",  
    "skillset": "my-onelake-ks-skillset",  
    "index": "my-onelake-ks-index"  
}  
}  
}  
}
```

ⓘ Note

Sensitive information is redacted. The generated resources appear at the end of the response.

Create a knowledge source

Run the following code to create a OneLake knowledge source.

Python

```
# Create a OneLake knowledge source  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient  
from azure.search.documents.indexes.models import IndexedOneLakeKnowledgeSource,  
IndexedOneLakeKnowledgeSourceParameters, KnowledgeBaseAzureOpenAIModel,
```

```

AzureOpenAIVectorizerParameters, KnowledgeSourceAzureOpenAIVectorizer,
KnowledgeSourceContentExtractionMode, KnowledgeSourceIngestionParameters

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))

knowledge_source = IndexedOneLakeKnowledgeSource(
    name = "my-onelake-ks",
    description= "This knowledge source pulls content from a lakehouse.",
    encryption_key = None,
    indexed_one_lake_parameters = IndexedOneLakeKnowledgeSourceParameters(
        fabric_workspace_id = "fabric_workspace_id",
        lakehouse_id = "lakehouse_id",
        target_path = None,
        ingestion_parameters = KnowledgeSourceIngestionParameters(
            identity = None,
            disable_image_verbalization = False,
            chat_completion_model = KnowledgeBaseAzureOpenAIModel(
                azure_open_ai_parameters = AzureOpenAIVectorizerParameters(
                    # TRIMMED FOR BREVITY
                )
            ),
            embedding_model = KnowledgeSourceAzureOpenAIVectorizer(
                azure_open_ai_parameters=AzureOpenAIVectorizerParameters(
                    # TRIMMED FOR BREVITY
                )
            ),
            content_extraction_mode = KnowledgeSourceContentExtractionMode.MINIMAL,
            ingestion_schedule = None,
            ingestion_permission_options = None
        )
    )
)
)

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated
successfully.")

```

Source-specific properties

You can pass the following properties to create a OneLake knowledge source.

[] Expand table

Name	Description	Type	Editable	Required
name	The name of the knowledge source, which must be unique within the knowledge sources collection and follow the naming guidelines for objects in Azure AI Search.	String	Yes	Yes

Name	Description	Type	Editable	Required
<code>description</code>	A description of the knowledge source.	String	Yes	No
<code>encryption</code>	A customer-managed key to encrypt sensitive information in both the knowledge source and the generated objects.	Object	Yes	No
<code>indexed_one_lake_parameters</code>	Parameters specific to OneLake knowledge sources: <code>fabric_workspace_id</code> , <code>lakehouse_id</code> , and <code>target_path</code> .	Object		Yes
<code>fabric_workspace_id</code>	The GUID of the workspace that contains the lakehouse.	String	No	Yes
<code>lakehouse_id</code>	The GUID of the lakehouse.	String	No	Yes
<code>target_path</code>	A folder or shortcut within the lakehouse. When unspecified, the entire lakehouse is indexed.	String	No	No

ingestionParameters properties

For indexed knowledge sources only, you can pass the following `ingestionParameters` properties to control how content is ingested and processed.

[\[+\]](#) Expand table

Name	Description	Type	Editable	Required
<code>identity</code>	A managed identity to use in the generated indexer.	Object	Yes	No
<code>disable_image_verbalization</code>	Enables or disables the use of image verbalization. The default is <code>False</code> , which enables image verbalization. Set to <code>True</code> to disable image verbalization.	Boolean	No	No
<code>chat_completion_model</code>	A chat completion model that verbalizes images or extracts content. Supported models are <code>gpt-40</code> , <code>gpt-40-mini</code> , <code>gpt-4.1</code> , <code>gpt-4.1-mini</code> , <code>gpt-4.1-nano</code> , <code>gpt-5</code> , <code>gpt-5-mini</code> , and	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No

Name	Description	Type	Editable	Required
	<p><code>gpt-5-nano</code>. The GenAI Prompt skill will be included in the generated skillset. Setting this parameter also requires that <code>disable_image_verbalization</code> is set to <code>False</code>.</p>			
<code>embedding_model</code>	<p>A text embedding model that vectorizes text and image content during indexing and at query time. Supported models are <code>text-embedding-ada-002</code>, <code>text-embedding-3-small</code>, and <code>text-embedding-3-large</code>. The Azure OpenAI Embedding skill will be included in the generated skillset, and the Azure OpenAI vectorizer will be included in the generated index.</p>	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No
<code>content_extraction_mode</code>	<p>Controls how content is extracted from files. The default is <code>minimal</code>, which uses standard content extraction for text and images. Set to <code>standard</code> for advanced document cracking and chunking using the Azure Content Understanding skill, which will be included in the generated skillset. For <code>standard</code> only, the <code>ai_services</code> and <code>asset_store</code> parameters are specifiable.</p>	String	No	No
<code>ai_services</code>	<p>A Microsoft Foundry resource to access Azure Content Understanding in Foundry Tools. Setting this parameter requires that <code>content_extraction_mode</code> is set to <code>standard</code>.</p>	Object	Only <code>api_key</code> is editable	Yes
<code>asset_store</code>	<p>A blob container to store extracted images. Setting this parameter requires that</p>	Object	No	No

Name	Description	Type	Editable	Required
	<code>content_extraction_mode</code> is set to <code>standard</code> .			
<code>ingestion_schedule</code>	Adds scheduling information to the generated indexer. You can also add a schedule later to automate data refresh.	Object	Yes	No
<code>ingestion_permission_options</code>	The document-level permissions to ingest from select knowledge sources: either ADLS Gen2 or indexed SharePoint . If you specify <code>user_ids</code> , <code>group_ids</code> , or <code>rbac_scope</code> , the generated ADLS Gen2 indexer or SharePoint indexer will include the ingested permissions.	Array	No	No

Check ingestion status

Run the following code to monitor ingestion progress and health, including indexer status for knowledge sources that generate an indexer pipeline and populate a search index.

Python

```
# Check knowledge source ingestion status
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}/status"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

A response for a request that includes ingestion parameters and is actively ingesting content might look like the following example.

JSON

```
{
  "synchronizationStatus": "active", // creating, active, deleting
  "synchronizationInterval" : "1d", // null if no schedule
  "currentSynchronizationState" : { // spans multiple indexer "runs"
```

```
"startTime": "2025-10-27T19:30:00Z",
"itemUpdatesProcessed": 1100,
"itemsUpdatesFailed": 100,
"itemsSkipped": 1100,
},
"lastSynchronizationState" : { // null on first sync
  "startTime": "2025-10-27T19:30:00Z",
  "endTime": "2025-10-27T19:40:01Z", // this value appears on the activity record
on each /retrieve
  "itemUpdatesProcessed": 1100,
  "itemsUpdatesFailed": 100,
  "itemsSkipped": 1100,
},
"statistics": { // null on first sync
  "totalSynchronization": 25,
  "averageSynchronizationDuration": "00:15:20",
  "averageItemsProcessedPerSynchronization" : 500
}
}
```

Review the created objects

When you create a OneLake knowledge source, your search service also creates an indexer, index, skillset, and data source. We don't recommend that you edit these objects, as introducing an error or incompatibility can break the pipeline.

After you create a knowledge source, the response lists the created objects. These objects are created according to a fixed template, and their names are based on the name of the knowledge source. You can't change the object names.

We recommend using the Azure portal to validate output creation. The workflow is:

1. Check the indexer for success or failure messages. Connection or quota errors appear here.
2. Check the index for searchable content. Use Search Explorer to run queries.
3. Check the skillset to learn how your content is chunked and optionally vectorized.
4. Check the data source for connection details. Our example uses API keys for simplicity, but you can use Microsoft Entra ID for authentication and role-based access control for authorization.

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

For any knowledge base that specifies a OneLake knowledge source, be sure to set `includeReferenceSourceData` to `true`. This step is necessary for pulling the source document URL into the citation.

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
    "@odata.context": "https://my-search-
service.search.windows.net/$metadata#knowledgebases(name)",
    "value": [
        {
            "name": "my-kb"
        },
        {
            "name": "my-kb-2"
        }
    ]
}
```

```
    ]  
}
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition  
import requests  
import json  
  
endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"  
params = {"api-version": "2025-11-01-preview"}  
headers = {"api-key": "{api_key}"}  
  
response = requests.get(endpoint, params = params, headers = headers)  
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
  "name": "my-kb",  
  "description": null,  
  "retrievalInstructions": null,  
  "answerInstructions": null,  
  "outputMode": null,  
  "knowledgeSources": [  
    {  
      "name": "my-blob-ks",  
    }  
  ],  
  "models": [],  
  "encryptionKey": null,  
  "retrievalReasoningEffort": {  
    "kind": "low"  
  }  
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient  
  
index_client = SearchIndexClient(endpoint = "search_url", credential =  
AzureKeyCredential("api_key"))
```

```
index_client.delete_knowledge_base("knowledge_base_name")
print(f"Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_source("knowledge_source_name")
print(f"Knowledge source deleted successfully.")
```

Create an indexed SharePoint knowledge source

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Use an *indexed SharePoint knowledge source* to index and query SharePoint content in an agentic retrieval pipeline. [Knowledge sources](#) are created independently, referenced in a [knowledge base](#), and used as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

When you create an indexed SharePoint knowledge source, you specify a SharePoint connection string, models, and properties to automatically generate the following Azure AI Search objects:

- A data source that points to SharePoint sites.
- A skillset that chunks and optionally vectorizes multimodal content.
- An index that stores enriched content and meets the criteria for agentic retrieval.
- An indexer that uses the previous objects to drive the indexing and enrichment pipeline.

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#).
- Completion of the [SharePoint indexer prerequisites](#).
- Completion of three SharePoint indexer configuration steps:
 - [Step 1: Enable a managed identity for Azure AI Search](#)
 - [Step 2: Choose between delegated or application permissions](#)
 - [Step 3: Application registration step for Microsoft Entra ID authentication](#)
- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for an indexed SharePoint knowledge source.

JSON

```
{
  "name": "my-indexed-sharepoint-ks",
  "kind": "indexedSharePoint",
  "description": "A sample indexed SharePoint knowledge source",
  "encryptionKey": null,
  "indexedSharePointParameters": {
    "connectionString": "<redacted>",
    "containerName": "defaultSiteLibrary",
    "query": null,
    "ingestionParameters": {
      "disableImageVerbalization": false,
```

```
"ingestionPermissionOptions": [],
"contentExtractionMode": "minimal",
"identity": null,
"embeddingModel": {
    "kind": "azureOpenAI",
    "azureOpenAIParameters": {
        "resourceUri": "<redacted>",
        "deploymentId": "text-embedding-3-large",
        "apiKey": "<redacted>",
        "modelName": "text-embedding-3-large",
        "authIdentity": null
    }
},
"chatCompletionModel": null,
"ingestionSchedule": null,
"assetStore": null,
"aiServices": null
},
"createdResources": {
    "datasource": "my-indexed-sharepoint-ks-datasource",
    "indexer": "my-indexed-sharepoint-ks-indexer",
    "skillset": "my-indexed-sharepoint-ks-skillset",
    "index": "my-indexed-sharepoint-ks-index"
}
},
"indexedOneLakeParameters": null
}
```

ⓘ Note

Sensitive information is redacted. The generated resources appear at the end of the response.

Create a knowledge source

Run the following code to create an indexed SharePoint knowledge source.

Python

```
# Create an indexed SharePoint knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import IndexedSharePointKnowledgeSource,
IndexedSharePointKnowledgeSourceParameters, KnowledgeBaseAzureOpenAIModel,
AzureOpenAIVectorizerParameters, KnowledgeSourceAzureOpenAIVectorizer,
KnowledgeSourceContentExtractionMode, KnowledgeSourceIngestionParameters

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
```

```

knowledge_source = IndexedSharePointKnowledgeSource(
    name = "my-indexed-sharepoint-ks",
    description = "A sample indexed SharePoint knowledge source.",
    encryption_key = None,
    indexed_share_point_parameters = IndexedSharePointKnowledgeSourceParameters(
        connection_string = "connection_string",
        container_name = "defaultSiteLibrary",
        query = None,
        ingestion_parameters = KnowledgeSourceIngestionParameters(
            identity = None,
            disable_image_verbalization = False,
            chat_completion_model = KnowledgeBaseAzureOpenAIModel(
                azure_open_ai_parameters = AzureOpenAIVectorizerParameters(
                    # TRIMMED FOR BREVITY
                )
            ),
            embedding_model = KnowledgeSourceAzureOpenAIVectorizer(
                azure_open_ai_parameters=AzureOpenAIVectorizerParameters(
                    # TRIMMED FOR BREVITY
                )
            ),
            content_extraction_mode = KnowledgeSourceContentExtractionMode.MINIMAL,
            ingestion_schedule = None,
            ingestion_permission_options = None
        )
    )
)
)

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated successfully.")

```

Source-specific properties

You can pass the following properties to create an indexed SharePoint knowledge source.

[] Expand table

Name	Description	Type	Editable	Required
name	The name of the knowledge source, which must be unique within the knowledge sources collection and follow the naming guidelines for objects in Azure AI Search.	String	No	Yes
description	A description of the knowledge source.	String	Yes	No

Name	Description	Type	Editable	Required
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in both the knowledge source and the generated objects.	Object	Yes	No
<code>indexed_share_point_parameters</code>	Parameters specific to indexed SharePoint knowledge sources: <code>connection_string</code> , <code>container_name</code> , and <code>query</code> .	Object	No	No
<code>connection_string</code>	The connection string to a SharePoint site. For more information, see Connection string syntax .	String	Yes	Yes
<code>container_name</code>	The SharePoint library to access. Use <code>defaultSiteLibrary</code> to index content from the site's default document library or <code>allSiteLibraries</code> to index content from every document library in the site. Ignore <code>useQuery</code> for now.	String	No	Yes
<code>query</code>	Ignore for now.	String	Yes	No

ingestion_parameters properties

For indexed knowledge sources only, you can pass the following `ingestionParameters` properties to control how content is ingested and processed.

[Expand table](#)

Name	Description	Type	Editable	Required
<code>identity</code>	A managed identity to use in the generated indexer.	Object	Yes	No
<code>disable_image_verbalization</code>	Enables or disables the use of image verbalization. The default is <code>False</code> , which <i>enables</i> image verbalization. Set to <code>True</code> to <i>disable</i> image verbalization.	Boolean	No	No
<code>chat_completion_model</code>	A chat completion model that verbalizes images or extracts content. Supported models are <code>gpt-40</code> , <code>gpt-40-mini</code> , <code>gpt-</code>	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No

Name	Description	Type	Editable	Required
	<p>4.1, gpt-4.1-mini, gpt-4.1-nano, gpt-5, gpt-5-mini, and gpt-5-nano. The GenAI Prompt skill will be included in the generated skillset. Setting this parameter also requires that <code>disable_image_verbalization</code> is set to <code>False</code>.</p>			
<code>embedding_model</code>	<p>A text embedding model that vectorizes text and image content during indexing and at query time. Supported models are <code>text-embedding-ada-002</code>, <code>text-embedding-3-small</code>, and <code>text-embedding-3-large</code>. The Azure OpenAI Embedding skill will be included in the generated skillset, and the Azure OpenAI vectorizer will be included in the generated index.</p>	Object	Only <code>api_key</code> and <code>deployment_name</code> are editable	No
<code>content_extraction_mode</code>	<p>Controls how content is extracted from files. The default is <code>minimal</code>, which uses standard content extraction for text and images. Set to <code>standard</code> for advanced document cracking and chunking using the Azure Content Understanding skill, which will be included in the generated skillset. For <code>standard</code> only, the <code>ai_services</code> and <code>asset_store</code> parameters are specifiable.</p>	String	No	No
<code>ai_services</code>	<p>A Microsoft Foundry resource to access Azure Content Understanding in Foundry Tools. Setting this parameter requires that <code>content_extraction_mode</code> is set to <code>standard</code>.</p>	Object	Only <code>api_key</code> is editable	Yes

Name	Description	Type	Editable	Required
<code>asset_store</code>	A blob container to store extracted images. Setting this parameter requires that <code>content_extraction_mode</code> is set to <code>standard</code> .	Object	No	No
<code>ingestion_schedule</code>	Adds scheduling information to the generated indexer. You can also add a schedule later to automate data refresh.	Object	Yes	No
<code>ingestion_permission_options</code>	The document-level permissions to ingest from select knowledge sources: either ADLS Gen2 or indexed SharePoint . If you specify <code>user_ids</code> , <code>group_ids</code> , or <code>rbac_scope</code> , the generated ADLS Gen2 indexer or SharePoint indexer will include the ingested permissions.	Array	No	No

Check ingestion status

Run the following code to monitor ingestion progress and health, including indexer status for knowledge sources that generate an indexer pipeline and populate a search index.

Python

```
# Check knowledge source ingestion status
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}/status"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

A response for a request that includes ingestion parameters and is actively ingesting content might look like the following example.

JSON

```
{
  "synchronizationStatus": "active", // creating, active, deleting
  "synchronizationInterval" : "1d", // null if no schedule
  "currentSynchronizationState" : { // spans multiple indexer "runs"
    "startTime": "2025-10-27T19:30:00Z",
    "itemUpdatesProcessed": 1100,
    "itemsUpdatesFailed": 100,
    "itemsSkipped": 1100,
  },
  "lastSynchronizationState" : { // null on first sync
    "startTime": "2025-10-27T19:30:00Z",
    "endTime": "2025-10-27T19:40:01Z", // this value appears on the activity record
    on each /retrieve
    "itemUpdatesProcessed": 1100,
    "itemsUpdatesFailed": 100,
    "itemsSkipped": 1100,
  },
  "statistics": { // null on first sync
    "totalSynchronization": 25,
    "averageSynchronizationDuration": "00:15:20",
    "averageItemsProcessedPerSynchronization" : 500
  }
}
```

Review the created objects

When you create an indexed SharePoint knowledge source, your search service also creates an indexer, index, skillset, and data source. We don't recommend that you edit these objects, as introducing an error or incompatibility can break the pipeline.

After you create a knowledge source, the response lists the created objects. These objects are created according to a fixed template, and their names are based on the name of the knowledge source. You can't change the object names.

We recommend using the Azure portal to validate output creation. The workflow is:

1. Check the indexer for success or failure messages. Connection or quota errors appear here.
2. Check the index for searchable content. Use Search Explorer to run queries.
3. Check the skillset to learn how your content is chunked and optionally vectorized.
4. Check the data source for connection details. Our example uses API keys for simplicity, but you can use Microsoft Entra ID for authentication and role-based access control for authorization.

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

For any knowledge base that specifies an indexed SharePoint knowledge source, be sure to set `includeReferenceSourceData` to `true`. This step is necessary for pulling the source document URL into the citation.

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
    "@odata.context": "https://my-search-
service.search.windows.net/$metadata#knowledgebases(name)",
    "value": [
        {
            "name": "my-kb"
        },
    ],
}
```

```
{  
    "name": "my-kb-2"  
}  
]  
}
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition  
import requests  
import json  
  
endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"  
params = {"api-version": "2025-11-01-preview"}  
headers = {"api-key": "{api_key}"}  
  
response = requests.get(endpoint, params = params, headers = headers)  
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
    "name": "my-kb",  
    "description": null,  
    "retrievalInstructions": null,  
    "answerInstructions": null,  
    "outputMode": null,  
    "knowledgeSources": [  
        {  
            "name": "my-blob-ks",  
        }  
    ],  
    "models": [],  
    "encryptionKey": null,  
    "retrievalReasoningEffort": {  
        "kind": "low"  
    }  
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient
```

```
index_client = SearchIndexClient(endpoint = "search_url", credential =  
    AzureKeyCredential("api_key"))  
index_client.delete_knowledge_base("knowledge_base_name")  
print(f"Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient  
  
index_client = SearchIndexClient(endpoint = "search_url", credential =  
    AzureKeyCredential("api_key"))  
index_client.delete_knowledge_source("knowledge_source_name")  
print(f"Knowledge source deleted successfully.")
```

Create a remote SharePoint knowledge source

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

A *remote SharePoint knowledge source* uses the [Copilot Retrieval API](#) to query textual content directly from SharePoint in Microsoft 365, returning results to the agentic retrieval engine for merging, ranking, and response formulation. There's no search index used by this knowledge source, and only textual content is queried.

At query time, the remote SharePoint knowledge source calls the Copilot Retrieval API on behalf of the user identity, so no connection strings are needed in the knowledge source definition. All content to which a user has access is in-scope for knowledge retrieval. To limit sites or constrain search, set a [filter expression](#). Your Azure tenant and the Microsoft 365 tenant must use the same Microsoft Entra ID tenant, and the caller's identity must be recognized by both tenants.

- You can use filters to scope search by URLs, date ranges, file types, and other metadata.
- SharePoint permissions and Purview labels are honored in requests for content.
- Usage is billed through Microsoft 365 and a Copilot license.

Like any other knowledge source, you specify a remote SharePoint knowledge source in a [knowledge base](#) and use the results as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#).
- SharePoint in a Microsoft 365 tenant that's under the same Microsoft Entra ID tenant as Azure.
- A personal access token for local development or a user's identity from a client application.

- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible.

For local development, the agentic retrieval engine uses your access token to call SharePoint on your behalf. For more information about using a personal access token on requests, see [Connect to Azure AI Search](#).

Limitations

The following limitations in the [Copilot Retrieval API](#) apply to remote SharePoint knowledge sources.

- There's no support for Copilot connectors or OneDrive content. Content is retrieved from SharePoint sites only.
- Limit of 200 requests per user per hour.
- Query character limit of 1,500 characters.
- Hybrid queries are only supported for the following file extensions: .doc, .docx, .pptx, .pdf, .aspx, and .one.
- Multimodal retrieval (nontextual content, including tables, images, and charts) isn't supported.
- Maximum of 25 results from a query.
- Results are returned by Copilot Retrieval API as unordered.
- Invalid Keyword Query Language (KQL) filter expressions are ignored and the query continues to execute without the filter.

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
```

```
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a remote SharePoint knowledge source.

JSON

```
{
  "name": "my-sharepoint-ks",
  "kind": "remoteSharePoint",
  "description": "A sample remote SharePoint knowledge source",
  "encryptionKey": null,
  "remoteSharePointParameters": {
    "filterExpression": "filetype:docx",
    "containerTypeId": null,
    "resourceMetadata": [
      "Author",
      "Title"
    ]
  }
}
```

Create a knowledge source

Run the following code to create a remote SharePoint knowledge source.

API keys are used for your client connection to Azure AI Search and Azure OpenAI. Your access token is used by Azure AI Search to connect to SharePoint in Microsoft 365 on your behalf. You

can only retrieve content that you're permitted to access. For more information about getting a personal access token and other values, see [Connect to Azure AI Search](#).

! Note

You can also use your personal access token to access Azure AI Search and Azure OpenAI if you [set up role assignments on each resource](#). Using API keys allows you to omit this step in this example.

Python

```
# Create a remote SharePoint knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import RemoteSharePointKnowledgeSource,
RemoteSharePointKnowledgeSourceParameters

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))

knowledge_source = RemoteSharePointKnowledgeSource(
    name = "my-remote-sharepoint-ks",
    description= "This knowledge source queries .docx files in a trusted Microsoft
365 tenant.",
    encryption_key = None,
    remote_share_point_parameters = RemoteSharePointKnowledgeSourceParameters(
        filter_expression = "filetype:docx",
        resource_metadata = ["Author", "Title"],
        container_type_id = None
    )
)

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated
successfully.")
```

Source-specific properties

You can pass the following properties to create a remote SharePoint knowledge source.

[+] Expand table

Name	Description	Type	Editable	Required
name	The name of the knowledge source, which must be unique within the knowledge sources collection and	String	No	Yes

Name	Description	Type	Editable	Required
	follow the naming guidelines for objects in Azure AI Search.			
<code>description</code>	A description of the knowledge source.	String	Yes	No
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in the knowledge source.	Object	Yes	No
<code>remote_share_point_parameters</code>	Parameters specific to remote SharePoint knowledge sources: <code>filter_expression</code> , <code>resource_metadata</code> , and <code>container_type_id</code> .	Object	No	No
<code>filter_expression</code>	An expression written in the SharePoint KQL , which is used to specify sites and paths to content.	String	Yes	No
<code>resource_metadata</code>	A comma-delimited list of standard metadata fields: author, file name, creation date, content type, and file type.	Array	Yes	No
<code>container_type_id</code>	Container ID for the SharePoint Embedded connection. When unspecified, SharePoint Online is used.	String	Yes	No

Filter expression examples

Not all SharePoint properties are supported in the `filterExpression`. For a list of supported properties, see the [API reference](#). Here's some more information about queryable properties that you can use in filter: [queryable properties](#).

Learn more about [KQL filters](#) in the syntax reference.

[Expand table](#)

Example	Filter expression
Filter to a single site by ID	<code>"filterExpression": "SiteID:\\"00aa00aa-bb11-cc22-dd33-44ee44ee44ee\\""</code>
Filter to multiple sites by ID	<code>"filterExpression": "SiteID:\\"00aa00aa-bb11-cc22-dd33-44ee44ee44ee\\" OR SiteID:\\"11bb11bb-cc22-dd33-ee44-55ff55ff55ff\\\""</code>
Filter to files under a specific path	<code>"filterExpression": "Path:\\"https://my-demosharepoint.sharepoint.com/sites/mysite/Shared Documents/en/mydocs\\""</code>

Example	Filter expression
Filter to a specific date range	<code>"filterExpression": "LastModifiedTime >= 2024-07-22 AND LastModifiedTime <= 2025-01-08"</code>
Filter to files of a specific file type	<code>"filterExpression": "FileExtension:\"docx\" OR FileExtension:\"pdf\" OR FileExtension:\"pptx\""</code>
Filter to files of a specific information protection label	<code>"filterExpression": "InformationProtectionLabelId:\"f0ddcc93-d3c0-4993-b5cc-76b0a283e252\""</code>

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Query a knowledge base

The [retrieve action](#) on the knowledge base provides the user identity that authorizes access to content in Microsoft 365.

Azure AI Search uses the access token to call the Copilot Retrieval API on behalf of the user identity. The access token is provided in the retrieve endpoint as a `x-ms-query-source-authorization` HTTP header.

Python

```
from azure.identity import DefaultAzureCredential, get_bearer_token_provider
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.knowledgebases import KnowledgeBaseRetrievalClient
from azure.search.documents.knowledgebases.models import KnowledgeBaseMessage,
KnowledgeBaseMessageTextContent, KnowledgeBaseRetrievalRequest,
RemoteSharePointKnowledgeSourceParams

# Get access token
identity_token_provider = get_bearer_token_provider(DefaultAzureCredential(),
"https://search.azure.com/.default")
token = identity_token_provider()

# Create knowledge base retrieval client
kb_client = KnowledgeBaseRetrievalClient(endpoint = "search_url",
knowledge_base_name = "knowledge_base_name", credential =
AzureKeyCredential("api_key"))
```

```

# Create retrieval request
request = KnowledgeBaseRetrievalRequest(
    include_activity = True,
    messages = [
        KnowledgeBaseMessage(role = "user", content =
[KnowledgeBaseMessageTextContent(text = "What was covered in the keynote doc for
Ignite 2024?")])
    ],
    knowledge_source_params = [
        RemoteSharePointKnowledgeSourceParams(
            knowledge_source_name = "my-remote-sharepoint-ks",
            filter_expression_add_on = "ModifiedBy:\\"Adele Vance\\\"",
            include_references = True,
            include_reference_source_data = True
        )
    ]
)

# Pass access token to retrieve from knowledge base
result = kb_client.retrieve(retrieval_request = request,
x_ms_query_source_authorization = token)
print(result.response[0].content[0].text)

```

The retrieve request also takes a [KQL filter](#) (`filter_expression_add_on`) if you want to apply constraints at query time. If you specify `filter_expression_add_on` on both the knowledge source and knowledge base retrieve action, the filters are AND'd together.

Queries asking questions about the content itself are more effective than questions about where a file is located or when it was last updated. For example, if you ask, "Where is the keynote doc for Ignite 2024", you might get "No relevant content was found for your query" because the content itself doesn't disclose its location. A filter on metadata is a better solution for file location or date-specific queries.

A better question to ask is, "What is the keynote doc for Ignite 2024". The response includes the synthesized answer, query activity and token counts, plus the URL and other metadata.

JSON

```
{
    "resourceMetadata": {
        "Author": "Nutan Amarathunga; Nurul Izzati",
        "Title": "Ignite 2024 Keynote Address"
    },

    "searchSensitivityLabelInfo": {
        "displayName": "Confidential\\Contoso Extended",
        "sensitivityLabelId": "aaaaaaaa-0b0b-1c1c-2d2d-333333333333",
        "tooltip": "Data is classified and protected. Contoso Full Time Employees"
    }
}
```

(FTE) and non-employees can edit, reply, forward and print. Recipient can unprotect content with the right justification.",

```
    "priority": 5,  
    "color": "#FF8C00",  
    "isEncrypted": true  
}
```

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases  
import requests  
import json  
  
endpoint = "{search_url}/knowledgebases"  
params = {"api-version": "2025-11-01-preview", "$select": "name"}  
headers = {"api-key": "{api_key}"}  
  
response = requests.get(endpoint, params = params, headers = headers)  
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
    "@odata.context": "https://my-search-  
service.search.windows.net/$metadata#knowledgebases(name)",  
    "value": [  
        {  
            "name": "my-kb"  
        },  
        {  
            "name": "my-kb-2"  
        }  
    ]}
```

```
    ]  
}
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition  
import requests  
import json  
  
endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"  
params = {"api-version": "2025-11-01-preview"}  
headers = {"api-key": "{api_key}"}  
  
response = requests.get(endpoint, params = params, headers = headers)  
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{  
  "name": "my-kb",  
  "description": null,  
  "retrievalInstructions": null,  
  "answerInstructions": null,  
  "outputMode": null,  
  "knowledgeSources": [  
    {  
      "name": "my-blob-ks",  
    }  
  ],  
  "models": [],  
  "encryptionKey": null,  
  "retrievalReasoningEffort": {  
    "kind": "low"  
  }  
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient  
  
index_client = SearchIndexClient(endpoint = "search_url", credential =  
AzureKeyCredential("api_key"))
```

```
index_client.delete_knowledge_base("knowledge_base_name")
print(f"Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_source("knowledge_source_name")
print(f"Knowledge source deleted successfully.")
```

Create a search index knowledge source

(!) Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

A *search index knowledge source* specifies a connection to an Azure AI Search index that provides searchable content in an agentic retrieval pipeline. [Knowledge sources](#) are created independently, referenced in a [knowledge base](#), and used as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#).
- A search index containing plain text or vector content with a semantic configuration.
[Review the index criteria for agentic retrieval](#). The index must be on the same search service as the knowledge base.
- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).

(!) Note

Although you can use the Azure portal to create search index knowledge sources, the portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a search index knowledge source. Notice that the knowledge source specifies a single index name and which fields in the index to include in the query.

JSON

```
{
  "name": "my-search-index-ks",
  "kind": "searchIndex",
  "description": "A sample search index knowledge source.",
  "encryptionKey": null,
  "searchIndexParameters": {
    "searchIndexName": "my-search-index",
    "semanticConfigurationName": null,
    "sourceDataFields": [],
    "searchFields": []
  }
}
```

Create a knowledge source

Run the following code to create a search index knowledge source.

Python

```
# Create a search index knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import SearchIndexKnowledgeSource,
SearchIndexKnowledgeSourceParameters, SearchIndexFieldReference

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))

knowledge_source = SearchIndexKnowledgeSource(
    name = "my-search-index-ks",
    description= "This knowledge source pulls from an existing index designed for
    agentic retrieval.",
    encryption_key = None,
    search_index_parameters = SearchIndexKnowledgeSourceParameters(
        search_index_name = "search_index_name",
        semantic_configuration_name = "semantic_configuration_name",
        source_data_fields = [
            SearchIndexFieldReference(name="description"),
            SearchIndexFieldReference(name="category"),
        ],
        search_fields = [
            SearchIndexFieldReference(name="id")
        ],
    ),
)
)

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated
successfully.")
```

Source-specific properties

You can pass the following properties to create a search index knowledge source.

[Expand table](#)

Name	Description	Type	Editable	Required
name	The name of the knowledge source, which must be unique within the knowledge sources collection and follow	String	No	Yes

Name	Description	Type	Editable	Required
	the naming guidelines for objects in Azure AI Search.			
<code>description</code>	A description of the knowledge source.	String	Yes	No
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in both the knowledge source and the generated objects.	Object	Yes	No
<code>search_index_parameters</code>	Parameters specific to search index knowledge sources: <code>search_index_name</code> , <code>semantic_configuration_name</code> , <code>source_data_fields</code> , and <code>search_fields</code> .	Object	Yes	Yes
<code>search_index_name</code>	The name of the existing search index.	String	Yes	Yes
<code>semantic_configuration_name</code>	Overrides the default semantic configuration for the search index.	String	Yes	No
<code>source_data_fields</code>	The index fields returned when you specify <code>include_reference_source_data</code> in the knowledge base definition. These fields are used for citations and should be <code> retrievable</code> . Examples include the document name, file name, page numbers, or chapter numbers.	Array	Yes	No
<code>search_fields</code>	The index fields to specifically search against. When unspecified, all fields are searched.	Array	Yes	No

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
    "@odata.context": "https://my-search-
service.search.windows.net/$metadata#knowledgebases(name)",
    "value": [
        {
            "name": "my-kb"
        },
        {
            "name": "my-kb-2"
        }
    ]
}
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition
import requests
import json

endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}
```

```
response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
  "name": "my-kb",
  "description": null,
  "retrievalInstructions": null,
  "answerInstructions": null,
  "outputMode": null,
  "knowledgeSources": [
    {
      "name": "my-blob-ks",
    }
  ],
  "models": [],
  "encryptionKey": null,
  "retrievalReasoningEffort": {
    "kind": "low"
  }
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_base("knowledge_base_name")
print("Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
```

```
index_client.delete_knowledge_source("knowledge_source_name")
print(f"Knowledge source deleted successfully.")
```

Create a Web Knowledge Source resource

Important

- Web Knowledge Source, which uses Grounding with Bing Search and/or Grounding with Bing Custom Search, is a [First Party Consumption Service](#) governed by the [Grounding with Bing terms of use](#) and the [Microsoft Privacy Statement](#).
- The [Microsoft Data Protection Addendum](#) doesn't apply to data sent to Web Knowledge Source. When Customer uses Web Knowledge Source, Customer Data flows outside the Azure compliance and Geo boundary. This also means use of Web Knowledge Source waives all elevated Government Community Cloud security and compliance commitments to include data sovereignty and screened/citizenship-based support, as applicable.
- Use of Web Knowledge Source incurs costs; learn more about [pricing](#).
- Learn more about how Azure admins can [manage access to use of Web Knowledge Source](#).

Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Web Knowledge Source enables retrieval of real-time web data from Microsoft Bing in an agentic retrieval pipeline. [Knowledge sources](#) are created independently, referenced in a [knowledge base](#), and used as grounding data when an agent or chatbot calls a [retrieve action](#) at query time.

Bing Custom Search is always the search provider for Web Knowledge Source. Although you can't specify alternative search providers or engines, you can include or exclude specific *domains*, such as <https://learn.microsoft.com>. When no domains are specified, Web Knowledge Source has unrestricted access to the entire public internet.

Web Knowledge Source works best alongside other knowledge sources. Use Web Knowledge Source when your proprietary content doesn't provide complete, up-to-date answers or when you want to supplement results with information from a commercial search engine.

When you use Web Knowledge Source, keep the following in mind:

- The response is always a single, formulated answer to the query instead of raw search results from the web.
- Because Web Knowledge Source doesn't support extractive data, your knowledge base must use [answer synthesis](#) and [low or medium reasoning effort](#). You also can't define answer instructions.

Prerequisites

- An Azure subscription with [access to Web Knowledge Source](#). By default, access is enabled. Contact your admin if access is disabled.
- An Azure AI Search service in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#). The service must also be in an [Azure public region](#), as Web Knowledge Source isn't supported in private or sovereign clouds.
- The latest preview version of the [azure-search-documents client library](#) for Python.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#), but you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).

Check for existing knowledge sources

A knowledge source is a top-level, reusable object. Knowing about existing knowledge sources is helpful for either reuse or naming new objects.

Run the following code to list knowledge sources by name and type.

Python

```
# List knowledge sources by name and type
import requests
import json

endpoint = "{search_url}/knowledgesources"
params = {"api-version": "2025-11-01-preview", "$select": "name, kind"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge source by name to review its JSON definition.

Python

```
# Get a knowledge source definition
import requests
import json

endpoint = "{search_url}/knowledgesources/{knowledge_source_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a Web Knowledge Source resource.

JSON

```
{
  "name": "my-web-ks",
  "kind": "web",
  "description": "A sample Web Knowledge Source.",
  "encryptionKey": null,
  "webParameters": {
    "domains": null
  }
}
```

Create a knowledge source

Run the following code to create a Web Knowledge Source resource.

Python

```
# Create Web Knowledge Source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import WebKnowledgeSource,
WebKnowledgeSourceParameters, WebKnowledgeSourceDomains

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))

knowledge_source = WebKnowledgeSource(
    name = "my-web-ks",
    description = "A sample Web Knowledge Source.",
    encryption_key = None,
    web_parameters = WebKnowledgeSourceParameters(
        domains = WebKnowledgeSourceDomains(
            allowed_domains = [ { "address": "learn.microsoft.com",
"include_subpages": True } ],
            blocked_domains = [ { "address": "bing.com", "include_subpages": False } ])))
```

```

        ]
    )
}

index_client.create_or_update_knowledge_source(knowledge_source)
print(f"Knowledge source '{knowledge_source.name}' created or updated
successfully.")

```

Source-specific properties

You can pass the following properties to create a Web Knowledge Source resource.

[Expand table](#)

Name	Description	Type	Editable	Required
<code>name</code>	The name of the knowledge source, which must be unique within the knowledge sources collection and follow the naming guidelines for objects in Azure AI Search.	String	Yes	Yes
<code>description</code>	A description of the knowledge source. When unspecified, Azure AI Search applies a default description.	String	Yes	No
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in the knowledge source.	Object	Yes	No
<code>web_parameters</code>	Parameters specific to Web Knowledge Source. Currently, this is only <code>domains</code> .	Object	Yes	No
<code>domains</code>	Domains to allow or block from the search space. By default, the knowledge source uses Grounding with Bing Search to search the entire public internet. When you specify domains, the knowledge source uses Grounding with Bing Custom Search to restrict results to the specified domains. In both cases, Bing Custom Search is the search provider.	Object	Yes	No
<code>allowed_domains</code>	Domains to include in the search space. For each domain, you must specify its <code>address</code> in the <code>website.com</code> format. You can also specify whether to include the domain's subpages by setting <code>include_subpages</code> to <code>true</code> or <code>false</code> .	Array	Yes	No
<code>blocked_domains</code>	Domains to exclude from the search space. For each domain, you must specify its <code>address</code> in the <code>website.com</code> format. You can also specify whether to	Array	Yes	No

Name	Description	Type	Editable	Required
	include the domain's subpages by setting <code>include_subpages</code> to <code>true</code> or <code>false</code> .			

Assign to a knowledge base

If you're satisfied with the knowledge source, continue to the next step: specify the knowledge source in a [knowledge base](#).

After the knowledge base is configured, use the [retrieve action](#) to query the knowledge source.

Delete a knowledge source

Before you can delete a knowledge source, you must delete any knowledge base that references it or update the knowledge base definition to remove the reference. For knowledge sources that generate an index and indexer pipeline, all *generated objects* are also deleted. However, if you used an existing index to create a knowledge source, your index isn't deleted.

If you try to delete a knowledge source that's in use, the action fails and returns a list of affected knowledge bases.

To delete a knowledge source:

1. Get a list of all knowledge bases on your search service.

Python

```
# Get knowledge bases
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
    "@odata.context": "https://my-search-
service.search.windows.net/$metadata#knowledgebases(name)",
```

```
        "value": [
            {
                "name": "my-kb"
            },
            {
                "name": "my-kb-2"
            }
        ]
    }
```

2. Get an individual knowledge base definition to check for knowledge source references.

Python

```
# Get a knowledge base definition
import requests
import json

endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

An example response might look like the following:

JSON

```
{
    "name": "my-kb",
    "description": null,
    "retrievalInstructions": null,
    "answerInstructions": null,
    "outputMode": null,
    "knowledgeSources": [
        {
            "name": "my-blob-ks",
        }
    ],
    "models": [],
    "encryptionKey": null,
    "retrievalReasoningEffort": {
        "kind": "low"
    }
}
```

3. Either delete the knowledge base or [update the knowledge base](#) to remove the knowledge source if you have multiple sources. This example shows deletion.

Python

```
# Delete a knowledge base
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_base("knowledge_base_name")
print(f"Knowledge base deleted successfully.")
```

4. Delete the knowledge source.

Python

```
# Delete a knowledge source
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))
index_client.delete_knowledge_source("knowledge_source_name")
print(f"Knowledge source deleted successfully.")
```

Last updated on 11/21/2025

Manage access to Web Knowledge Source in your Azure subscription

ⓘ Important

- Web Knowledge Source, which uses Grounding with Bing Search and/or Grounding with Bing Custom Search, is a [First Party Consumption Service](#) governed by the [Grounding with Bing terms of use](#) and the [Microsoft Privacy Statement](#).
- The [Microsoft Data Protection Addendum](#) doesn't apply to data sent to Web Knowledge Source. When Customer uses Web Knowledge Source, Customer Data flows outside the Azure compliance and Geo boundary. This also means use of Web Knowledge Source waives all elevated Government Community Cloud security and compliance commitments to include data sovereignty and screened/citizenship-based support, as applicable.
- Use of Web Knowledge Source incurs costs; learn more about [pricing](#).

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

As an Azure admin, you can use the Azure CLI to enable or disable the use of [Web Knowledge Source](#) at the subscription level. This setting applies to all search services within the specified subscription.

Prerequisites

- Have **Owner** or **Contributor** access to the subscription.
- Have the [Azure CLI](#) installed. If you're not already signed in to Azure, run `az login`.

Check the current access state

To check the current status of Web Knowledge Source access, run the following command.

PowerShell

Azure CLI

```
az feature show --name WebKnowledgeSourceDisabled --namespace Microsoft.Search -  
-subscription "<subscription-id>"
```

The output shows the `state` property, which indicates the current registration status:

- `Registered` means access is **disabled**.
- `Unregistered` means access is **enabled**, which is the default state.

Enable use of Web Knowledge Source

Access to Web Knowledge Source is enabled by default. If access has been disabled, you can run the following command to enable it.

PowerShell

PowerShell

```
az feature unregister --name WebKnowledgeSourceDisabled --namespace  
Microsoft.Search --subscription "<subscription-id>"
```

Disable use of Web Knowledge Source

Run the following command to disable access to Web Knowledge Source.

PowerShell

PowerShell

```
az feature register --name WebKnowledgeSourceDisabled --namespace  
Microsoft.Search --subscription "<subscription-id>"
```

Create a knowledge base in Azure AI Search

⚠ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In Azure AI Search, a *knowledge base* is a top-level object that orchestrates [agentic retrieval](#). It defines which knowledge sources to query and the default behavior for retrieval operations. At query time, the [retrieve method](#) targets the knowledge base to run the configured retrieval pipeline.

A knowledge base specifies:

- One or more knowledge sources that point to searchable content.
- An optional LLM that provides reasoning capabilities for query planning and answer formulation.
- A retrieval reasoning effort that determines whether an LLM is invoked and manages cost, latency, and quality.
- Custom properties that control routing, source selection, output format, and object encryption.

After you create a knowledge base, you can update its properties at any time. If the knowledge base is in use, updates take effect on the next retrieval.

ⓘ Important

2025-11-01-preview renames the 2025-08-01-preview *knowledge agent* to *knowledge base*. This is a breaking change. We recommend [migrating existing code](#) to the new APIs as soon as possible.

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#). You must have [semantic ranker enabled](#). If you're using a [managed identity](#) for role-based access to deployed models, your search service must be on the Basic pricing tier or higher.

- Azure OpenAI with a [supported LLM](#) deployment.
- One or more [knowledge sources](#) on your search service.
- Permission to create and use objects on Azure AI Search. We recommend [role-based access](#). **Search Service Contributor** can create and manage a knowledge base. **Search Index Data Reader** can run queries. Alternatively, you can use [API keys](#) if a role assignment isn't feasible. For more information, see [Connect to a search service](#).
- The latest preview version of the [azure-search-documents client library](#) for Python.

 **Note**

Although you can use the Azure portal to create knowledge bases, the portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Supported models

Use one of the following LLMs from Azure OpenAI or an equivalent open-source model. For deployment instructions, see [Deploy Azure OpenAI models with Microsoft Foundry](#).

- `gpt-4o`
- `gpt-4o-mini`
- `gpt-4.1`
- `gpt-4.1-nano`
- `gpt-4.1-mini`
- `gpt-5`
- `gpt-5-nano`
- `gpt-5-mini`

Configure access

Azure AI Search needs access to the LLM from Azure OpenAI. We recommend Microsoft Entra ID for authentication and role-based access for authorization. You must be an **Owner** or **User Access Administrator** to assign roles. If roles aren't feasible, use key-based authentication instead.

[Use roles](#)

1. Configure Azure AI Search to use a managed identity.
2. On your model provider, such as Foundry Models, assign **Cognitive Services User** to the managed identity of your search service. If you're testing locally, assign the same role to your user account.
3. For local testing, follow the steps in [Quickstart: Connect without keys](#) to sign in to a specific subscription and tenant. Use `DefaultAzureCredential` instead of `AzureKeyCredential` in each request, which should look similar to the following example:

Python

```
# Authenticate using roles
from azure.identity import DefaultAzureCredential
index_client = SearchIndexClient(endpoint = "search_url", credential =
DefaultAzureCredential())
```

Important

Code snippets in this article use API keys. If you use role-based authentication, update each request accordingly. In a request that specifies both approaches, the API key takes precedence.

Check for existing knowledge bases

Knowing about existing knowledge bases is helpful for either reuse or naming new objects. Any 2025-08-01-preview knowledge agents are returned in the knowledge bases collection.

Run the following code to list existing knowledge bases by name.

Python

```
# List knowledge bases by name
import requests
import json

endpoint = "{search_url}/knowledgebases"
params = {"api-version": "2025-11-01-preview", "$select": "name"}
headers = {"api-key": "{api_key}"}
```

```
response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

You can also return a single knowledge base by name to review its JSON definition.

Python

```
# Get a knowledge base definition
import requests
import json

endpoint = "{search_url}/knowledgebases/{knowledge_base_name}"
params = {"api-version": "2025-11-01-preview"}
headers = {"api-key": "{api_key}"}

response = requests.get(endpoint, params = params, headers = headers)
print(json.dumps(response.json(), indent = 2))
```

The following JSON is an example response for a knowledge base.

JSON

```
{
  "name": "my-kb",
  "description": "A sample knowledge base.",
  "retrievalInstructions": null,
  "answerInstructions": null,
  "outputMode": null,
  "knowledgeSources": [
    {
      "name": "my-blob-ks"
    }
  ],
  "models": [],
  "encryptionKey": null,
  "retrievalReasoningEffort": {
    "kind": "low"
  }
}
```

Create a knowledge base

A knowledge base drives the agentic retrieval pipeline. In application code, it's called by other agents or chatbots.

A knowledge base connects knowledge sources (searchable content) to an LLM deployment from Azure OpenAI. Properties on the LLM establish the connection, while properties on the knowledge source establish defaults that inform query execution and the response.

Run the following code to create a knowledge base.

Python

```
# Create a knowledge base
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import KnowledgeBase,
KnowledgeBaseAzureOpenAIModel, KnowledgeSourceReference,
AzureOpenAIVectorizerParameters, KnowledgeRetrievalOutputMode,
KnowledgeRetrievalLowReasoningEffort

index_client = SearchIndexClient(endpoint = "search_url", credential =
AzureKeyCredential("api_key"))

aoai_params = AzureOpenAIVectorizerParameters(
    resource_url = "aoai_endpoint",
    deployment_name = "aoai_gpt_deployment",
    model_name = "aoai_gpt_model",
)

knowledge_base = KnowledgeBase(
    name = "my-kb",
    description = "This knowledge base handles questions directed at two unrelated sample indexes.",
    retrieval_instructions = "Use the hotels knowledge source for queries about where to stay, otherwise use the earth at night knowledge source.",
    answer_instructions = "Provide a two sentence concise and informative answer based on the retrieved documents.",
    output_mode = KnowledgeRetrievalOutputMode.ANSWER_SYNTHESIS,
    knowledge_sources = [
        KnowledgeSourceReference(name = "hotels-ks"),
        KnowledgeSourceReference(name = "earth-at-night-ks"),
    ],
    models = [KnowledgeBaseAzureOpenAIModel(azure_open_ai_parameters =
aoai_params)],
    encryption_key = None,
    retrieval_reasoning_effort = KnowledgeRetrievalLowReasoningEffort,
)

index_client.create_or_update_knowledge_base(knowledge_base)
print(f"Knowledge base '{knowledge_base.name}' created or updated successfully.")
```

Knowledge base properties

You can pass the following properties to create a knowledge base.

 Expand table

Name	Description	Type	Required
<code>name</code>	The name of the knowledge base, which must be unique within the knowledge bases collection and follow the naming guidelines for objects in Azure AI Search.	String	Yes
<code>description</code>	A description of the knowledge base. The LLM uses the description to inform query planning.	String	No
<code>retrieval_instructions</code>	A prompt for the LLM to determine whether a knowledge source should be in scope for a query, which is recommended when you have multiple knowledge sources. This field influences both knowledge source selection and query formulation. For example, instructions could append information or prioritize a knowledge source. Instructions are passed directly to the LLM, which means it's possible to provide instructions that break query planning, such as instructions that result in bypassing an essential knowledge source.	String	Yes
<code>answer_instructions</code>	Custom instructions to shape synthesized answers. The default is null. For more information, see Use answer synthesis for citation-backed responses .	String	Yes
<code>output_mode</code>	Valid values are <code>answer_synthesis</code> for an LLM-formulated answer or <code>extracted_data</code> for full search results that you can pass to an LLM as a downstream step.	String	Yes
<code>knowledge_sources</code>	One or more supported knowledge sources .	Array	Yes
<code>models</code>	A connection to a supported LLM used for answer formulation or query planning. In this preview, <code>models</code> can contain just one model, and the model provider must be Azure OpenAI. Obtain model information from the Foundry portal or a command-line request. You can use role-based access control instead of API keys for the Azure AI Search connection to the model. For more information, see How to deploy Azure OpenAI models with Foundry .	Object	No
<code>encryption_key</code>	A customer-managed key to encrypt sensitive information in both the knowledge base and the generated objects.	Object	No
<code>retrieval_reasoning_effort</code>	Determines the level of LLM-related query processing. Valid values are <code>minimal</code> , <code>low</code> (default),	Object	No

Name	Description	Type	Required
	and <code>medium</code> . For more information, see Set the retrieval reasoning effort .		

Query a knowledge base

Call the `retrieve` action on the knowledge base to verify the LLM connection and return results. For more information about the `retrieve` request and response schema, see [Retrieve data using a knowledge base in Azure AI Search](#).

Replace "Where does the ocean look green?" with a query string that's valid for your knowledge sources.

Python

```
# Send grounding request
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.knowledgebases import KnowledgeBaseRetrievalClient
from azure.search.documents.knowledgebases.models import KnowledgeBaseMessage,
KnowledgeBaseMessageTextContent, KnowledgeBaseRetrievalRequest,
RemoteSharePointKnowledgeSourceParams

kb_client = KnowledgeBaseRetrievalClient(endpoint = "search_url",
knowledge_base_name = "knowledge_base_name", credential =
AzureKeyCredential("api_key"))

request = KnowledgeBaseRetrievalRequest(
    messages=[
        KnowledgeBaseMessage(
            role = "assistant",
            content = [KnowledgeBaseMessageTextContent(text = "Use the earth at
night index to answer the question. If you can't find relevant content, say you
don't know.")]
        ),
        KnowledgeBaseMessage(
            role = "user",
            content = [KnowledgeBaseMessageTextContent(text = "Where does the ocean
look green?")]
        ),
    ],
    knowledge_source_params=[
        SearchIndexKnowledgeSourceParams(
            knowledge_source_name = "earth-at-night-ks",
            include_references = True,
            include_reference_source_data = True,
            always_query_source = False,
        )
    ],
    include_activity = True,
```

```
)  
  
result = kb_client.retrieve(request)  
print(result.response[0].content[0].text)
```

Key points:

- [messages](#) is required, but you can run this example using just the `user` role that provides the query.
- [knowledge_source_params](#) specifies one or more query targets. For each knowledge source, you can specify how much information to include in the output.

The response to the sample query might look like the following example:

HTTP

```
"response": [  
  {  
    "content": [  
      {  
        "type": "text",  
        "text": "The ocean appears green off the coast of Antarctica due to phytoplankton flourishing in the water, particularly in Granite Harbor near Antarctica's Ross Sea, where they can grow in large quantities during spring, summer, and even autumn under the right conditions [ref_id:0]. Additionally, off the coast of Namibia, the ocean can also look green due to blooms of phytoplankton and yellow-green patches of sulfur precipitating from bacteria in oxygen-depleted waters [ref_id:1]. In the Strait of Georgia, Canada, the waters turned bright green due to a massive bloom of coccolithophores, a type of phytoplankton [ref_id:5]. Furthermore, a milky green and blue bloom was observed off the coast of Patagonia, Argentina, where nutrient-rich waters from different currents converge [ref_id:6]. Lastly, a large bloom of cyanobacteria was captured in the Baltic Sea, which can also give the water a green appearance [ref_id:9]."  
      }  
    ]  
  }  
]
```

Delete a knowledge base

If you no longer need the knowledge base or need to rebuild it on your search service, use this request to delete the object.

Python

```
# Delete a knowledge base  
from azure.core.credentials import AzureKeyCredential  
from azure.search.documents.indexes import SearchIndexClient
```

```
index_client = SearchIndexClient(endpoint = "search_url", credential =  
AzureKeyCredential("api_key"))  
index_client.delete_knowledge_base("knowledge_base_name")  
print(f"Knowledge base deleted successfully.")
```

Use answer synthesis for citation-backed responses in Azure AI Search

(!) Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

By default, a [knowledge base](#) in Azure AI Search performs *data extraction*, which returns raw grounding chunks from your knowledge sources. Data extraction is useful for retrieving specific information but lacks the context and reasoning necessary for complex queries.

You can instead enable *answer synthesis*, which uses the LLM specified in your knowledge base to answer queries in natural language. Each answer includes citations to the retrieved sources and follows any instructions you provide, such as using bulleted lists.

You can enable answer synthesis in two ways:

- On the knowledge base (becomes the default for all queries)
- On individual retrieval requests (overrides the default)

(i) Important

- The `minimal` retrieval reasoning effort disables LLM processing, so it's incompatible with answer synthesis in both knowledge base definitions and retrieval requests. For more information, see [Set the retrieval reasoning effort](#).
- Answer synthesis incurs pay-as-you-go charges from Azure OpenAI, which is based on the number of input and output tokens. Charges appear under the LLM assigned to the knowledge base. For more information, see [Availability and pricing of agentic retrieval](#).

Prerequisites

- A knowledge base that uses the [2025-11-01-preview syntax](#).

- Visual Studio Code [with the REST Client extension](#) or a prerelease package of an Azure SDK that provides the knowledge base REST APIs.

! Note

Although you can use the Azure portal to configure answer synthesis, the portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Enable answer synthesis on a knowledge base

This section explains how to enable answer synthesis on an existing knowledge base. Although you can use this configuration for new knowledge bases, knowledge base creation is beyond the scope of this article.

To enable answer synthesis on a knowledge base:

1. Use the 2025-11-01-preview of [Knowledge Base - Create or Update \(REST API\)](#) to formulate the request.
2. In the body of the request, set `outputMode` to `answerSynthesis`.
3. (Optional) Use `answerInstructions` to customize the answer output. Our example instructs the knowledge base to `Use concise bulleted lists`.

HTTP

```
@search-url = <YOUR SEARCH SERVICE URL>
@api-key = <YOUR API KEY>
@knowledge-base-name = <YOUR KNOWLEDGE BASE NAME>

### Enable answer synthesis on a knowledge base
PUT {{search-url}}/knowledgebases/{{knowledge-base-name}}?api-version=2025-11-01-
preview HTTP/1.1
Content-Type: application/json
api-key: {{api-key}}

{
  "name": "{{knowledge-base-name}}",
  "knowledgeSources": [ ... // OMITTED FOR BREVITY ],
  "models": [ ... // OMITTED FOR BREVITY ],
  "outputMode": "answerSynthesis",
  "answerInstructions": "Use concise bulleted lists"
}
```

(!) Note

This example assumes that you're using key-based authentication for local proof-of-concept testing. We recommend role-based access control for production workloads. For more information, see [Connect to Azure AI Search using roles](#).

Enable answer synthesis on a retrieval request

For per-query control over the response format, you can enable answer synthesis at query time. This approach overrides the default output mode specified in the knowledge base.

To enable answer synthesis on a retrieval request:

1. Use the 2025-11-01-preview of [Knowledge Retrieval - Retrieve \(REST API\)](#) to formulate the request.
2. In the body of the request, set `outputMode` to `answerSynthesis`.

HTTP

```
@search-url = <YOUR SEARCH SERVICE URL>
@api-key = <YOUR API KEY>
@knowledge-base-name = <YOUR KNOWLEDGE BASE NAME>

### Enable answer synthesis on a retrieval request
POST {{search-url}}/knowledgebases/{{knowledge-base-name}}/retrieve?api-
version=2025-11-01-preview HTTP/1.1
Content-Type: application/json
api-key: {{api-key}}

{
  "messages": [
    {
      "role": "user",
      "content": [
        {
          "type": "text",
          "text": "What is healthcare?"
        }
      ]
    }
  ],
  "outputMode": "answerSynthesis"
}
```

(!) Note

This example assumes that you're using key-based authentication for local proof-of-concept testing. We recommend role-based access control for production workloads. For more information, see [Connect to Azure AI Search using roles](#).

Get a synthesized answer

When answer synthesis is enabled, [Knowledge Retrieval - Retrieve \(REST API\)](#) returns a natural-language answer based on the instructions you optionally specified in the knowledge base. Citations to your knowledge sources are formatted as `[ref_id:<number>]`.

For example, if your instructions are `Use concise bulleted lists` and your query is `What is healthcare?`, the response might look like this:

JSON

```
{  
  "response": [  
    {  
      "content": [  
        {  
          "type": "text",  
          "text": "- Healthcare encompasses various services provided to patients  
and the general population ... // TRIMMED FOR BREVITY"  
        }  
      ]  
    }  
  ]  
}
```

The full `text` output is as follows:

```
- Healthcare encompasses various services provided to patients and the general  
population, including primary health services, hospital care, dental care, mental  
health services, and alternative health services [ref_id:1].\n- It involves the  
delivery of safe, effective, patient-centered care through different modalities,  
such as in-person encounters, shared medical appointments, and group education  
sessions [ref_id:0].\n- Behavioral health is a significant aspect of healthcare,  
focusing on the connection between behavior and overall health, including mental  
health and substance use [ref_id:2].\n- The healthcare system aims to ensure quality  
of care, access to providers, and accountability for positive outcomes while  
managing costs effectively [ref_id:2].\n- The global health system is evolving to  
address complex health needs, emphasizing the importance of cross-sectoral  
collaboration and addressing social determinants of health [ref_id:4]."
```

Depending on your knowledge base's configuration, the response might include other information, such as activity logs and reference arrays. For more information, see [Create a knowledge base](#).

Set the retrieval reasoning effort

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In agentic retrieval, you can specify the level of large language model (LLM) processing for query planning and answer formulation. Use the `retrievalReasoningEffort` property to set LLM processing levels that affect costs and latency. Extra LLM processing improves relevancy, but it also takes longer and uses billable LLM resources. You can set this property in a knowledge base or on a retrieve request.

Levels of reasoning effort include:

[] Expand table

Level	Effort
<code>minimal</code>	No LLM processing. You provide the query.
<code>low</code>	Runs a single pass of LLM-based query planning and knowledge source selection. This is the default. The LLM analyzes the query and breaks it into component parts as needed.
<code>medium</code>	Adds deeper search and an enhanced retrieval stack to agentic retrieval to maximize completeness.

Prerequisites

- Azure AI Search in any [region that provides agentic retrieval](#).
- Familiarity with [agentic retrieval concepts and workflow](#).
- [A knowledge base](#) and a [knowledge source](#).
- [Visual Studio Code](#) with the [REST Client extension](#). You can also use a preview package of an Azure SDK that provides the latest knowledge source REST APIs.

Set `retrievalReasoningEffort` in a knowledge base

To establish the default behavior, set the property in the knowledge base.

1. Use [Create or Update Knowledge Base](#) to set the `retrievalReasoningEffort`.

2. Add the `retrievalReasoningEffort` property. The following JSON shows the syntax. For more information about knowledge bases, see [Create a knowledge base](#).

JSON

```
"retrievalReasoningEffort": { /* no other parameters when effort is minimal */
    "kind": "low"
}
```

Set `retrievalReasoningEffort` in a retrieve request

To override the default on a query-by-query basis, set the property in the retrieve request.

1. Modify a [retrieve action](#) to override the knowledge base `retrievalReasoningEffort` default.

2. Add the `retrievalReasoningEffort` property. A retrieve request might look similar to the following example.

JSON

```
{
  "messages": [ /* trimmed for brevity */ ],
  "retrievalReasoningEffort": { "kind": "low" },
  "outputMode": "answerSynthesis",
  "maxRuntimeInSeconds": 30,
  "maxOutputSize": 6000
}
```

Choose a retrieval reasoning effort

 Expand table

Level	Description	Recommendation	Limits
<code>minimal</code>	Disables LLM-based query planning to deliver the lowest cost and latency for agentic retrieval. It issues direct text and vector searches across the knowledge sources listed in the knowledge base, and returns the best-matching passages. Because all knowledge sources in the knowledge base are always searched and no query expansion is performed, behavior is predictable	Use "minimal" for migrations from the Search API or when you want to manage query planning yourself.	<code>outputMode</code> must be set to <code>extractiveData</code> . Answer synthesis and web knowledge aren't supported.

Level	Description	Recommendation	Limits
	and easy to control. It also means the <code>alwaysQueryKnowledgeSource</code> property on a retrieve request is ignored.		
low	The default mode of agentic retrieval, running a single pass of LLM-based query planning and knowledge source selection. The agentic retrieval engine generates subqueries and fans them out to the selected knowledge sources, then merges the results. You can enable answer synthesis to produce a grounded natural-language response with inline citations.	Use "low" when you want a balance between minimal latency and deeper processing.	5,000 answer tokens. Maximum three subqueries from a maximum of three knowledge sources. Maximum of 50 documents for semantic ranking, and 10 documents if the semantic ranker uses L3 classification.
medium	Adds deeper search and an enhanced retrieval stack to agentic retrieval to maximize completeness. After the first search is performed, a high-precision semantic classifier evaluates the retrieved documents to determine whether further processing and L3 ranking is required. If the initial results from the first pass are insufficiently relevant to the query, a follow-up iteration is performed using a revised query plan. This revised query plan takes the previous results into account and iterates by fine-tuning queries, broadening terms, or adding other knowledge sources such as the web. It also increases resource limits compared to low and minimal effort. This reasoning level optimizes for relevance rather than exhaustive recall.	Use "medium" to maximize the utility of LLM-assisted knowledge retrieval.	Medium isn't available in all agentic retrieval regions. See the list in the next section for available regions. 10,000 answer tokens. Maximum of five subqueries from a maximum of five knowledge sources. Maximum of 50 documents for semantic ranking, and 20 documents if the semantic ranker uses L3 classification.

Medium retrieval and iterative search

A medium retrieval reasoning effort provides iterative search if initial results aren't sufficiently relevant. An extra *semantic classifier model* is called to determine if a second iteration is

necessary.

The semantic classifier performs the following:

- Recognizes when there's enough context to answer the question.
- Retries on insufficient results, using existing information for context. New queries might drill down for more focused detail, or broaden the search. The activity log in the response shows the generated queries used for a more comprehensive answer.
- Rescores using L3 classification. The range is identical to L2 ranking, an absolute range of zero through 4.0.

There's only one retry. Each iteration adds latency and cost, so the system constrains retry to one pass. A second iteration adds input tokens to the query pipeline, which adds to the overall billable input token count.

Iteration can reuse or choose different sources. The second pass selects the most promising knowledge resource to provide the missing information.

Regions supporting medium retrieval reasoning effort

You can set a medium retrieval reasoning effort if your search service is in one of the following regions.

- East US 2
- East US
- South Central US
- West US 3
- West US 2
- West US
- Germany West Central
- North Europe
- Switzerland North
- Sweden Central
- Spain Central
- UK South
- Korea Central
- Japan East
- Southeast Asia

Retrieve data using a knowledge base in Azure AI Search

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In an agentic retrieval multi-query pipeline, query execution is through the [retrieve action](#) on a knowledge base that invokes parallel query processing. This request structure is updated for the new 2025-11-01-preview, which introduces breaking changes from previous previews. For help with breaking changes, see [Migrate your agentic retrieval code](#).

This article explains how to set up a retrieve action. It also covers the three components of the retrieval response:

- *extracted response for the LLM*
- *referenced results*
- *query activity*

A retrieve request can include instructions for query processing that override the default instructions set on the knowledge base. A retrieve action has core parameters that are supported on any request, plus parameters that are specific to a knowledge source.

Prerequisites

- A [supported knowledge source](#) that wraps a searchable index or points to an external source for native data retrieval.
- A [knowledge base](#) represents one or more knowledge sources, plus a chat completion model if you want intelligent query planning and answer formulation.
- Azure AI Search in any [region that provides agentic retrieval](#).
- Permissions on Azure AI Search. Roles for retrieving content include **Search Index Data Reader** for running queries. To support an outbound call from a search service to a chat completion model, you must configure a managed identity for the search service, and it must have **Cognitive Services User** permissions on the Azure OpenAI resource. For more

information about local testing and obtaining access tokens, see [Quickstart: Connect without keys](#).

- API version requirements. To create or use a knowledge base, use the [2025-11-01-preview](#) data plane REST API. Or, use a preview package of an Azure SDK that provides knowledge base APIs: [Python](#), [.NET](#), [Java](#).

To follow the steps in this guide, we recommend [Visual Studio Code](#) with a [REST client](#) for sending REST API calls to Azure AI Search.

 **Note**

Although you can use the Azure portal to retrieve data from knowledge bases, the portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Set up the retrieve action

A retrieve action is specified on a [knowledge base](#). The knowledge base has one or more knowledge sources. Retrieval can return a synthesized answer in natural language or raw grounding chunks from the knowledge sources.

- Review your knowledge base definition to understand which knowledge sources are in scope.
- Review your knowledge sources to understand their parameters and configuration.
- Use the [2025-11-01-preview](#) data plane REST API or an Azure SDK preview package to call retrieve.

For knowledge sources that have default retrieval instructions, you can override the defaults in the retrieve request.

Retrieval from a search index

For knowledge sources that target a search index, all `searchable` fields are in-scope for query execution. If the index includes vector fields, your index should have a valid [vectorizer definition](#) so that the agentic retrieval engine can vectorize the query inputs. Otherwise, vector fields are ignored. The implied query type is `semantic`, and there's no search mode.

The input for the retrieval route is chat conversation history in natural language, where the `messages` array contains the conversation. Messages are only supported if the [retrieval reasoning effort](#) is either low or medium.

HTTP

```
@search-url=<YOUR SEARCH SERVICE URL>
@accessToken=<YOUR PERSONAL ID>

# Send grounding request
POST https://{{search-url}}/knowledgebases/{{knowledge-base-name}}/retrieve?api-
version=2025-11-01-preview
Content-Type: application/json
Authorization: Bearer {{accessToken}}

{
  "messages" : [
    {
      "role" : "assistant",
      "content" : [
        { "type" : "text", "text" : "You can answer questions about the
Earth at night.
Sources have a JSON format with a ref_id that must be cited in
the answer.
If you do not have the answer, respond with 'I do not know'." }
      ]
    },
    {
      "role" : "user",
      "content" : [
        { "type" : "text", "text" : "Why is the Phoenix nighttime street
grid is so sharply visible from space, whereas large stretches of the interstate
between midwestern cities remain comparatively dim?" }
      ]
    }
  ],
  "knowledgeSourceParams": [
    {
      "filterAddOn": null,
      "knowledgeSourceName": "earth-at-night-blob-ks",
      "kind": "searchIndex"
    }
  ]
}
```

Responses

Successful retrieval returns a `200 OK` status code. If the knowledge base fails to retrieve from one or more knowledge sources, a `206 Partial Content` status code is returned, and the

response only includes results from sources that succeeded. Details about the partial response appear as [errors in the activity array](#).

Retrieve parameters

 [Expand table](#)

Name	Description	Type	Editable	Required
<code>messages</code>	Articulates the messages sent to a chat completion model. The message format is similar to Azure OpenAI APIs.	Object	Yes	No
<code>role</code>	Defines where the message came from, for example either <code>assistant</code> or <code>user</code> . The model you use determines which roles are valid.	String	Yes	No
<code>content</code>	The message or prompt sent to the LLM. It must be text in this preview.	String	Yes	No
<code>knowledgeSourceParams</code>	Specifies parameters for each knowledge source if you want to customize the query or response at query time.	Object	Yes	No

Examples

Retrieve requests vary depending on the knowledge sources and whether you want to override a default configuration. Here are several examples that illustrate a range of requests.

Example: Override default reasoning effort and set request limits

This example specifies [answer formulation](#), so `retrievalReasoningEffort` must be "low" or "medium".

HTTP

```
POST {{url}}/knowledgebases/kb-override/retrieve?api-version={{api-version}}
api-key: {{key}}
Content-Type: application/json
```

```
{
  "messages": [
    {
```

```

        "role": "user",
        "content": [
            { "type": "text", "text": "What companies are in the financial
sector?" }
        ]
    },
    "retrievalReasoningEffort": { "kind": "low" },
    "outputMode": "answerSynthesis",
    "maxRuntimeInSeconds": 30,
    "maxOutputSize": 6000
}

```

Example: Set references for each knowledge source

This example uses the default reasoning effort specified in the knowledge base. The focus of this example is specification of how much information to include in the response.

HTTP

```

POST {{url}}/knowledgebases/kb-medium-example/retrieve?api-version={{api-version}}
api-key: {{key}}
Content-Type: application/json

{
    "messages": [
        {
            "role": "user",
            "content": [
                { "type": "text", "text": "What companies are in the financial
sector?" }
            ]
        }
    ],
    "includeActivity": true,
    "knowledgeSourceParams": [
        {
            "knowledgeSourceName": "demo-financials-ks",
            "kind": "searchIndex",
            "includeReferences": true,
            "includeReferenceSourceData": true
        },
        {
            "knowledgeSourceName": "demo-communicationservices-ks",
            "kind": "searchIndex",
            "includeReferences": false,
            "includeReferenceSourceData": false
        },
        {
            "knowledgeSourceName": "demo-healthcare-ks",
            "kind": "searchIndex",
            "includeReferences": true,

```

```
        "includeReferenceSourceData": false,
        "alwaysQuerySource": true
    }
]
}
```

⚠ Note

If you're retrieving content from a OneLake or indexed SharePoint knowledge source, set `includeReferenceSourceData` to `true` to include the source document URL in the citation.

Example: minimal reasoning effort

In this example, there's no chat completion model for intelligent query planning or answer formulation. The query string is passed to the agentic retrieval engine for keyword search or hybrid search.

HTTP

```
POST {{url}}/knowledgebases/kb-minimal/retrieve?api-version={{api-version}}
api-key: {{key}}
Content-Type: application/json

{
    "intents": [
        {
            "type": "semantic",
            "search": "what is a brokerage"
        }
    ]
}
```

Review the extracted response

The *extracted response* is single unified string that's typically passed to an LLM that consumes it as grounding data, using it to formulate a response. Your API call to the LLM includes the unified string and instructions for model, such as whether to use the grounding exclusively or as a supplement.

The body of the response is also structured in the chat message style format. Currently in this preview release, the content is serialized JSON.

HTTP

```
"response": [
  {
    "role": "assistant",
    "content": [
      {
        "type": "text",
        "text": "[{\\"ref_id\\":0,\\\"title\\\":\\\"Urban
Structure\\\",\\\"terms\\\":\\\"Location of Phoenix, Grid of City Blocks, Phoenix
Metropolitan Area at Night\\\",\\\"content\\\":\\\"<content chunk redacted>\\\"}]"
      }
    ]
  }
]
```

Key points:

- `content.text` is a JSON array. It's a single string composed of the most relevant documents (or chunks) found in the search index, given the query and chat history inputs. This array is your grounding data that a chat completion model uses to formulate a response to the user's question.

This portion of the response consists of the 200 chunks or less, excluding any results that fail to meet the minimum threshold of a 2.5 reranker score.

The string starts with the reference ID of the chunk (used for citation purposes), and any fields specified in the semantic configuration of the target index. In this example, you should assume the semantic configuration in the target index has a "title" field, a "terms" field, and a "content" field.

- `content.type` has one valid value in this preview: `text`.

ⓘ Note

The `maxOutputSize` property on the [knowledge base](#) determines the length of the string.

Review the activity array

The activity array outputs the query plan, which helps you track the operations performed when executing the request. It also provides operational transparency so you can understand the billing implications and frequency of resource invocations.

The output includes the following components.

[] Expand table

Section	Description
modelQueryPlanning	For knowledge bases that use an LLM for query planning, this section reports on the token counts used for input, and the token count for the subqueries.
source-specific activity	For each knowledge source included in the query, report on elapsed time and which arguments were used in the query, including the semantic ranker. Knowledge source types include <code>searchIndex</code> , <code>azureBlob</code> , and other supported knowledge sources .
agenticReasoningEffort	For each retrieve action, you can specify the degree of LLM support. Use minimal to bypass an LLM, low for constrained LLM processing, and medium for full LLM processing.
modelAnswerSynthesis	For knowledge bases that specify answer formulation, this section reports on the token count for formulating the answer, and the token count of the answer output.

Output reports on the token consumption for agentic reasoning during retrieval at the specified [retrieval reasoning effort](#).

Output also includes the following information:

- Subqueries sent to the retrieval pipeline.
- Errors for any retrieval failures, such as inaccessible knowledge sources.

Here's an example of an activity array.

JSON

```

"activity": [
  {
    "type": "modelQueryPlanning",
    "id": 0,
    "inputTokens": 2302,
    "outputTokens": 109,
    "elapsedMs": 2396
  },
  {
    "type": "searchIndex",
    "id": 1,
    "knowledgeSourceName": "demo-financials-ks",
    "queryTime": "2025-11-04T19:25:23.683Z",
    "count": 26,
    "elapsedMs": 1137,
    "searchIndexArguments": {
      "search": "List of companies in the financial sector according to SEC GICS classification",
      "filter": null,
      "sourceDataFields": [ ],
      "searchFields": [ ]
    }
  }
]

```

```

        "semanticConfigurationName": "en-semantic-config"
    }
},
{
    "type": "searchIndex",
    "id": 2,
    "knowledgeSourceName": "demo-healthcare-ks",
    "queryTime": "2025-11-04T19:25:24.186Z",
    "count": 17,
    "elapsedMs": 494,
    "searchIndexArguments": {
        "search": "List of companies in the financial sector according to SEC GICS classification",
        "filter": null,
        "sourceDataFields": [ ],
        "searchFields": [ ],
        "semanticConfigurationName": "en-semantic-config"
    }
},
{
    "type": "agenticReasoning",
    "id": 3,
    "retrievalReasoningEffort": {
        "kind": "low"
    },
    "reasoningTokens": 103368
},
{
    "type": "modelAnswerSynthesis",
    "id": 4,
    "inputTokens": 5821,
    "outputTokens": 344,
    "elapsedMs": 3837
}
]

```

Review the references array

The `references` array is a direct reference from the underlying grounding data and includes the `sourceData` used to generate the response. It consists of every single document that was found and semantically ranked by the agentic retrieval engine. Fields in the `sourceData` include an `id` and semantic fields: `title`, `terms`, `content`.

The `id` is a reference ID for an item within a specific response. It's not the document key in the search index. It's used for providing citations.

The purpose of this array is to provide a chat message style structure for easy integration. For example, if you want to serialize the results into a different structure or you require some programmatic manipulation of the data before you returned it to the user.

You can also get the structured data from the source data object in the references array to manipulate it however you see fit.

Here's an example of the references array.

JSON

```
"references": [
  {
    "type": "AzureSearchDoc",
    "id": "0",
    "activitySource": 2,
    "docKey": "earth_at_night_508_page_104_verbalized",
    "sourceData": null
  },
  {
    "type": "AzureSearchDoc",
    "id": "1",
    "activitySource": 2,
    "docKey": "earth_at_night_508_page_105_verbalized",
    "sourceData": null
  }
]
```

ⓘ Note

If you're retrieving content from a OneLake or indexed SharePoint knowledge source, set `includeReferenceSourceData` to `true` on the retrieve request to get the source document URL in the citation.

Migrate agentic retrieval code to the latest version

Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

If you wrote [agentic retrieval](#) code using an early preview REST API, this article explains when and how to migrate to a newer version. It also describes breaking and nonbreaking changes for all REST API versions that support agentic retrieval.

Migration instructions are intended to help you run an existing solution on a newer API version. The instructions in this article help you address breaking changes at the API level so that your app runs as before. For help with adding new functionality, start with [What's new](#).

Tip

Using Azure SDKs instead of REST? Read this article to learn about breaking changes, and then install a newer preview package to begin your updates. Before you start, check the SDK change logs to confirm API updates: [Python](#), [.NET](#), [JavaScript](#), [Java](#).

When to migrate

Each new API version that supports agentic retrieval has introduced breaking changes, from the original [2025-05-01-preview](#) to [2025-08-01-preview](#), to the latest [2025-11-01-preview](#).

You can continue to run older code with no updates if you retain the API version value. However, to benefit from bug fixes, improvements, and newer functionality, you must update your code.

How to migrate

- The supported migration path is incremental. If your code targets 2025-05-01-preview, first migrate to 2025-08-01-preview, and then migrate to 2025-11-01-preview.

- To understand the scope of changes, review [breaking and nonbreaking changes](#) for each version.
- "Migration" means creating new, uniquely named objects that implement the behaviors of the previous version. You can't overwrite an existing object if properties are added or deleted on the API. One advantage of creating new objects is the ability to preserve existing objects while new ones are developed and tested.
- For each object that you migrate, start by getting the current definition from the search service so that you can review existing properties before specifying the new one.
- Delete older versions only after your migration is fully tested and deployed.

2025-11-01-preview

If you're migrating from [2025-08-01-preview](#), *knowledge agent* is renamed to *knowledge base*, and multiple properties are relocated to different objects and levels within an object definition.

1. [Update searchIndex knowledge sources.](#)
2. [Update azureBlob knowledge sources.](#)
3. Replace knowledge agent with knowledge base.
4. Update the retrieval request and send a query to test your updates.
5. [Update client code.](#)

Update a searchIndex knowledge source

This procedure creates a new 2025-11-01-preview `searchIndex` knowledge source at the same functional level as the previous 2025-08-01 version. The underlying index itself requires no updates.

1. List all knowledge sources by name to find your knowledge source.

HTTP

```
### List all knowledge sources by name
GET {{search-endpoint}}/knowledge-sources?api-version=2025-08-01-
preview&$select=name
api-key: {{api-key}}
Content-Type: application/json
```

2. [Get the current definition](#) to review existing properties.

HTTP

```
### Get a specific knowledge source
GET {{search-endpoint}}/knowledge-sources/search-index-ks?api-version=2025-08-01-preview
api-key: {{api-key}}
Content-Type: application/json
```

The response should look similar to the following example.

JSON

```
{  
    "name": "search-index-ks",  
    "kind": "searchIndex",  
    "description": "This knowledge source pulls from a search index created using the 2025-08-01-preview.",  
    "encryptionKey": null,  
    "searchIndexParameters": {  
        "searchIndexName": "earth-at-night-idx",  
        "sourceDataSelect": "id, page_chunk, page_number"  
    },  
    "azureBlobParameters": null  
}
```

3. Formulate a [Create Knowledge Source](#) request as the basis for your migration.

Start with the 08-01-preview JSON.

HTTP

```
POST {{url}}/knowledge-sources/search-index-ks?api-version=2025-08-01-preview
api-key: {{key}}
Content-Type: application/json

{  
    "name": "search-index-ks",  
    "kind": "searchIndex",  
    "description": "A sample search index knowledge source",  
    "encryptionKey": null,  
    "searchIndexParameters": {  
        "searchIndexName": "my-search-index",  
        "sourceDataSelect": "id, page_chunk, page_number"  
    }  
}
```

Make the following updates for a 2025-11-01-preview migration:

- Give the knowledge source a new name.
- Change the API version to 2025-11-01-preview.

- Rename `sourceDataSelect` to `sourceDataFields` and change the string to an array with name-value pairs for each retrievable field you want to query. These are the fields to return in the search results, similar to a `select` clause in a classic query.

4. Review your updates and then send the request to create the object.

HTTP

```
PUT {{url}}/knowledge-sources/search-index-ks-11-01?api-version=2025-11-01-preview
api-key: {{key}}
Content-Type: application/json

{
    "name": "search-index-ks-11-01",
    "kind": "searchIndex",
    "description": "knowledge source migrated to 2025-11-01-preview",
    "encryptionKey": null,
    "searchIndexParameters": {
        "searchIndexName": "my-search-index",
        "sourceDataFields": [
            { "name": "id" }, { "name": "page_chunk" }, { "name": "page_number" }
        ]
    }
}
```

You now have a migrated `searchIndex` knowledge source is backwards compatible with the previous version, using the correct property specifications for the 2025-11-01-preview.

The response includes the full definition of the new object. For more information about new properties available to this knowledge source type, which you can now do through updates, see [How to create a search index knowledge source](#).

Update an azureBlob knowledge source

This procedure creates a new 2025-11-01-preview `azureBlob` knowledge source at the same functional level as the previous 2025-08-01 version. It creates a new set of generated objects: data source, skillset, indexer, index.

1. List all knowledge sources by name to find your knowledge source.

HTTP

```
### List all knowledge sources by name
GET {{search-endpoint}}/knowledge-sources?api-version=2025-08-01-preview&$select=name
```

```
api-key: {{api-key}}
Content-Type: application/json
```

2. Get the current definition to review existing properties.

HTTP

```
### Get a specific knowledge source
GET {{search-endpoint}}/knowledge-sources/azure-blob-ks?api-version=2025-08-01-preview
api-key: {{api-key}}
Content-Type: application/json
```

The response might look similar to the following example if your workflow includes a model. Notice that a response includes the names of the generated objects. These objects are fully independent of the knowledge source and remain operational even if you update or delete their knowledge source.

JSON

```
{
  "name": "azure-blob-ks",
  "kind": "azureBlob",
  "description": "A sample azure blob knowledge source.",
  "encryptionKey": null,
  "searchIndexParameters": null,
  "azureBlobParameters": {
    "connectionString": "<redacted>",
    "containerName": "blobcontainer",
    "folderPath": null,
    "disableImageVerbalization": false,
    "identity": null,
    "embeddingModel": {
      "name": "embedding-model",
      "kind": "azureOpenAI",
      "azureOpenAIParameters": {
        "resourceUri": "<redacted>",
        "deploymentId": "text-embedding-3-large",
        "apiKey": "<redacted>",
        "modelName": "text-embedding-3-large",
        "authIdentity": null
      },
      "customWebApiParameters": null,
      "aiServicesVisionParameters": null,
      "amlParameters": null
    },
    "chatCompletionModel": {
      "kind": "azureOpenAI",
      "azureOpenAIParameters": {
        "resourceUri": "<redacted>",
        "deploymentId": "gpt-4o-mini",
        "modelType": "chat"
      }
    }
}
```

```

        "apiKey": "<redacted>",
        "modelName": "gpt-4o-mini",
        "authIdentity": null
    }
},
"ingestionSchedule": null,
"createdResources": {
    "datasource": "azure-blob-ks-datasource",
    "indexer": "azure-blob-ks-indexer",
    "skillset": "azure-blob-ks-skillset",
    "index": "azure-blob-ks-index"
}
}
}

```

3. Formulate a [Create Knowledge Source](#) request as the basis for your migration.

Start with the 08-01-preview JSON.

HTTP

```

POST {{url}}/knowledge-sources/azure-blob-ks?api-version=2025-08-01-preview
api-key: {{key}}
Content-Type: application/json

{
    "name": "azure-blob-ks",
    "kind": "azureBlob",
    "description": "A sample azure blob knowledge source.",
    "encryptionKey": null,
    "azureBlobParameters": {
        "connectionString": "<redacted>",
        "containerName": "blobcontainer",
        "folderPath": null,
        "disableImageVerbalization": false,
        "identity": null,
        "embeddingModel": {
            "name": "embedding-model",
            "kind": "azureOpenAI",
            "azureOpenAIParameters": {
                "resourceUri": "<redacted>",
                "deploymentId": "text-embedding-3-large",
                "apiKey": "<redacted>",
                "modelName": "text-embedding-3-large",
                "authIdentity": null
            },
            "customWebApiParameters": null,
            "aiServicesVisionParameters": null,
            "amlParameters": null
        },
        "chatCompletionModel": null,
        "ingestionSchedule": null
    }
}
```

```
}
```

Make the following updates for a 2025-11-01-preview migration:

- Give the knowledge source a new name.
- Change the API version to `2025-11-01-preview`.
- Add `ingestionParameters` as a container for the following child properties:
`"embeddingModel"`, `"chatCompletionModel"`, `"ingestionSchedule"`,
`"contentExtractionMode"`.

4. Review your updates and then send the request to create the object. New generated objects are created for the indexer pipeline.

HTTP

```
PUT {{url}}/knowledge-sources/azure-blob-ks-11-01?api-version=2025-11-01-
preview
api-key: {{key}}
Content-Type: application/json

{
    "name": "azure-blob-ks",
    "kind": "azureBlob",
    "description": "A sample azure blob knowledge source",
    "encryptionKey": null,
    "azureBlobParameters": {
        "connectionString": "{{blob-connection-string}}",
        "containerName": "blobcontainer",
        "folderPath": null,
        "ingestionParameters": {
            "embeddingModel": {
                "kind": "azureOpenAI",
                "azureOpenAIParameters": {
                    "deploymentId": "text-embedding-3-large",
                    "modelName": "text-embedding-3-large",
                    "resourceUri": "{{aoai-endpoint}}",
                    "apiKey": "{{aoai-key}}"
                }
            },
            "chatCompletionModel": null,
            "disableImageVerbalization": false,
            "ingestionSchedule": null,
            "contentExtractionMode": "minimal"
        }
    }
}
```

You now have a migrated `azureBlob` knowledge source that is backwards compatible with the previous version, using the correct property specifications for the 2025-11-01-preview.

The response includes the full definition of the new object. For more information about new properties available to this knowledge source type, which you can now do through updates, see [How to create an Azure Blob knowledge source](#).

Replace knowledge agent with knowledge base

1. Knowledge bases require a knowledge source. Make sure you have a knowledge source that targets 2025-11-01-preview before you start.
2. [Get the current definition](#) to review existing properties.

HTTP

```
### Get a knowledge agent by name
GET {{search-endpoint}}/agents/earth-at-night?api-version=2025-08-01-
preview
api-key: {{api-key}}
Content-Type: application/json
```

The response might look similar to the following example.

JSON

```
{
  "name": "earth-at-night",
  "description": "A sample knowledge agent that retrieves from the earth-
at-night knowledge source.",
  "retrievalInstructions": null,
  "requestLimits": null,
  "encryptionKey": null,
  "knowledgeSources": [
    {
      "name": "earth-at-night",
      "alwaysQuerySource": null,
      "includeReferences": null,
      "includeReferenceSourceData": null,
      "maxSubQueries": null,
      "rerankerThreshold": 2.5
    }
  ],
  "models": [
    {
      "kind": "azureOpenAI",
      "azureOpenAIParameters": {
        "resourceUri": "<redacted>",
        "deploymentId": "gpt-5-mini",
        "temperature": 0.5
      }
    }
  ]
}
```

```

        "apiKey": "<redacted>",
        "modelName": "gpt-5-mini",
        "authIdentity": null
    }
},
],
"outputConfiguration": {
    "modality": "answerSynthesis",
    "answerInstructions": null,
    "attemptFastPath": false,
    "includeActivity": null
}
}

```

3. Formulate a [Create Knowledge Base](#) request as the basis for your migration.

Start with the 08-01-preview JSON.

HTTP

```

PUT {{url}}/knowledgebases/earth-at-night?api-version=2025-08-01-preview
HTTP/1.1
api-key: {{key}}
Content-Type: application/json

{
    "name": "earth-at-night",
    "description": "A sample knowledge agent that retrieves from the earth-at-night knowledge source.",
    "retrievalInstructions": null,
    "encryptionKey": null,
    "knowledgeSources": [
        {
            "name": "earth-at-night",
            "alwaysQuerySource": null,
            "includeReferences": null,
            "includeReferenceSourceData": null,
            "maxSubQueries": null,
            "rerankerThreshold": 2.5
        }
    ],
    "models": [
        {
            "kind": "azureOpenAI",
            "azureOpenAIParameters": {
                "resourceUri": "<redacted>",
                "apiKey": "<redacted>",
                "deploymentId": "gpt-5-mini",
                "modelName": "gpt-5-mini"
            }
        }
    ],
    "outputConfiguration": {

```

```
        "modality": "answerSynthesis"
    }
}
```

Make the following updates for a 2025-11-01-preview migration:

- Replace the endpoint: `/knowledgebases/{{your-object-name}}`. Give the knowledge base a unique name.
 - Change the API version to `2025-11-01-preview`.
 - Delete `requestLimits`. The `maxRuntimeInSeconds` and `maxOutputSize` properties are now specified on the retrieval request object directly
 - Update `knowledgeSources`:
 - Delete `maxSubQueries` and replace with a `retrievalReasoningEffort`` (see [Set the retrieval reasoning effort](#)).
 - Move `alwaysQuerySource`, `includeReferenceSourceData`, `includeReferences`, and `rerankerThreshold` to the `knowledgeSourcesParams` section of a [retrieve action](#).
 - No changes for `models`.
 - Update `outputConfiguration`:
 - Replace `outputConfiguration` with `outputMode`.
 - Delete `attemptFastPath`. It no longer exists. Equivalent behavior is implemented through `retrievalReasoningEffort` set to minimum (see [Set the retrieval reasoning effort](#)).
 - If modality is set to `answerSynthesis`, make sure you set the retrieval reasoning effort to low (default) or medium.
 - Add `ingestionParameters` as a requirement for creating a 2025-11-01-preview `azureBlob` knowledge source.
4. Review your updates and then send the request to create the object. New generated objects are created for the indexer pipeline.

HTTP

```
PUT {{url}}/knowledgebases/earth-at-night-11-01?api-version={{api-version}}
```

```
api-key: {{key}}
Content-Type: application/json

{
    "name": "earth-at-night-11-01",
    "description": "A sample knowledge base at the same functional level as the previous knowledge agent.",
    "retrievalInstructions": null,
    "encryptionKey": null,
    "knowledgeSources": [
        {
            "name": "earth-at-night-ks"
        }
    ],
    "models": [
        {
            "kind": "azureOpenAI",
            "azureOpenAIParameters": {
                "resourceUri": "<redacted>",
                "apiKey": "<redacted>",
                "deploymentId": "gpt-5-mini",
                "modelName": "gpt-5-mini"
            }
        }
    ],
    "retrievalReasoningEffort": null,
    "outputMode": "answerSynthesis",
    "answerInstructions": "Provide a concise and accurate answer based on the retrieved information."
}

}
```

You now have a knowledge base instead of a knowledge agent, and the object is backwards compatible with the previous version

The response includes the full definition of the new object. For more information about new properties available to a knowledge base, which you can now do through updates, see [How to create a knowledge base](#).

Update and test the retrieval for 2025-11-01-preview updates

The retrieval request is modified for the 2025-11-01-preview to support more shapes, including a simpler request that minimizes LLM processing. For more information about retrieval in this preview, see [Retrieve data using a knowledge base](#). This section explains how to update your code.

1. Change the `/agents/retrieve` endpoint to `/knowledgebases/retrieve`.
2. Change the API version to `2025-11-01-preview`.

3. No changes to `messages` are required if you are using a `low` or `medium` `retrievalReasoningEffort`. Replace `messages` with `intent` if you use `minimal` reasoning (see [Set the retrieval reasoning effort](#)).
4. Modify `knowledgeSourceParams` to include any properties that were removed from the agent: `rerankerThreshold`, `alwaysQuerySource`, `includeReferenceSourceData`, `includeReferences`.
5. Add `retrievalReasoningEffort` set to `minimum` if you were using `attemptFastPath`. If you were using `maxSubQueries`, it no longer exists. Use the `retrievalReasoningEffort` setting to specify subquery processing (see [Set the retrieval reasoning effort](#)).

To test your knowledge base's output with a query, use the 2025-11-01-preview of [Knowledge Retrieval - Retrieve \(REST API\)](#).

HTTP

```
### Send a query to the knowledge base
POST {{url}}/knowledgebases/earth-at-night-11-01/retrieve?api-version=2025-11-01-preview
api-key: {{key}}
Content-Type: application/json

{
  "messages": [
    {
      "role": "user",
      "content": [
        { "type": "text", "text": "What are some light sources on the ocean at night" }
      ]
    }
  ],
  "includeActivity": true,
  "retrievalReasoningEffort": { "kind": "medium" },
  "outputMode": "answerSynthesis",
  "maxRuntimeInSeconds": 30,
  "maxOutputSize": 6000
}
```

If the response has a `200 OK` HTTP code, your knowledge base successfully retrieved content from the knowledge source.

Update code and clients for 2025-11-01-preview

To complete your migration, follow these cleanup steps:

1. For Azure Blob knowledge sources only, update clients to use the new index. If you have code or script that runs an indexer or references a data source, index, or skillset, make sure you update the references to the new objects.
2. Replace all agent references with `knowledgeBases` in configuration files, code, scripts, and tests.
3. Update client calls to use the 2025-11-01-preview.
4. Clear or regenerate cached definitions that were created using the old shapes.

Version-specific changes

This section covers breaking and nonbreaking changes for the following REST API versions:

- [2025-11-01-preview](#)
- [2025-08-01-preview](#)
- [2025-05-01-preview](#)

2025-11-01-preview

To review the [REST API reference documentation](#) for this version, make sure the 2025-11-01-preview API version is selected in the filter at the top of the page.

Breaking changes

- Knowledge agent is renamed to knowledge base.

 [Expand table](#)

Previous Route	New Route
<code>/agents</code>	<code>/knowledgebases</code>
<code>/agents/agent-name</code>	<code>/knowledgebases/knowledge-base-name</code>
<code>/agents/agent-name/retrieve</code>	<code>/knowledgebases/knowledge-base-name/retrieve</code>

- Knowledge agent (base) `outputConfiguration` is renamed to `outputMode` and changed from an object to a string enumerator. Several properties are impacted:

- `includeActivity` is moved from `outputConfiguration` onto the retrieval request object directly.
- `attemptFastPath` in `outputConfiguration` is removed entirely. The new `minimal` reasoning effort is the replacement.
- Knowledge agent (base) `requestLimits` is removed. Its child properties of `maxRuntimeInSeconds` and `maxOutputSize` are moved onto the retrieval request object directly.
- Knowledge agent (base) `knowledgeSources` parameters now only list the names of knowledge source used by a knowledge base. Other child properties that used to be under `knowledgeSources` are moved to the `knowledgeSourceParams` properties of the retrieval request object:
 - `rerankerThreshold`
 - `alwaysQuerySource`
 - `includeReferenceSourceData`
 - `includeReferences`

The `maxSubQueries` property is gone. Its replacement is the new retrieval reasoning effort property.

- Knowledge agent (base) retrieval request object: The `semanticReranker` activity record is replaced with the `agenticReasoning` activity record type.
- Knowledge sources for both `azureBlob` and `searchIndex`: top-level properties for `identity`, `embeddingModel`, `chatCompletionModel`, `disableImageVerbalization`, and `ingestionSchedule` are now part of an `ingestionParameters` object on the knowledge source. All knowledge sources that pull from a search index have an `ingestionParameters` object.
- For `searchIndex` knowledge sources only: `sourceDataSelect` is renamed to `sourceDataFields` and is an array that accepts `fieldName` and `fieldToSearch`.

2025-08-01-preview

To review the [REST API reference documentation](#) for this version, make sure the 2025-08-01-preview API version is selected in the filter at the top of the page.

- Introduces knowledge sources as the new way to define data sources, supporting both `searchIndex` (one or multiple indexes) and `azureBlob` kinds. For more information, see [Create a search index knowledge source](#) and [Create a blob knowledge source](#).
- Requires `knowledgeSources` instead of `targetIndexes` in agent definitions. For migration steps, see [How to migrate](#).
- Removes `defaultMaxDocsForReranker` support. This property previously existed in `targetIndexes`, but there's no replacement in `knowledgeSources`.

2025-05-01-preview

This REST API version introduces agentic retrieval and knowledge agents. Each agent definition requires a `targetIndexes` array that specifies a single index and optional properties, such as `defaultRerankerThreshold` and `defaultIncludeReferenceSourceData`.

To review the [REST API reference documentation](#) for this version, make sure the 2025-05-01-preview API version is selected in the filter at the top of the page.

Create a vector query in Azure AI Search

09/29/2025

If you have a [vector index](#) in Azure AI Search, this article explains how to:

- ✓ [Query vector fields](#)
- ✓ [Query multiple vector fields at once](#)
- ✓ [Set vector weights](#)
- ✓ [Query with integrated vectorization](#)
- ✓ [Set thresholds to exclude low-scoring results \(preview\)](#)

This article uses REST for illustration. After you understand the basic workflow, continue with the Azure SDK code samples in the [azure-search-vector-samples](#) repo, which provides end-to-end solutions that include vector queries.

You can also use [Search Explorer](#) in the Azure portal.

Prerequisites

- An [Azure AI Search service](#) in any region and on any tier.
- A [vector index](#). Check for a `vectorSearch` section in your index to confirm its presence.
- Optionally, [add a vectorizer](#) to your index for built-in text-to-vector or image-to-vector conversion during queries.
- Visual Studio Code with a [REST client](#) and sample data if you want to run these examples on your own. To get started with the REST client, see [Quickstart: Full-text search using REST](#).

Convert a query string input into a vector

To query a vector field, the query itself must be a vector.

One approach for converting a user's text query string into its vector representation is to call an embedding library or API in your application code. As a best practice, *always use the same embedding models used to generate embeddings in the source documents*. You can find code samples showing [how to generate embeddings](#) in the [azure-search-vector-samples](#) repo.

A second approach is to [use integrated vectorization](#), now generally available, to have Azure AI Search handle your query vectorization inputs and outputs.

Here's a REST API example of a query string submitted to a deployment of an Azure OpenAI embedding model:

HTTP

```
POST https://{{openai-service-name}}.openai.azure.com/openai/deployments/{{openai-deployment-name}}/embeddings?api-version={{openai-api-version}}
Content-Type: application/json
api-key: {{admin-api-key}}
{
    "input": "what azure services support generative AI"
}
```

The expected response is 202 for a successful call to the deployed model.

The `embedding` field in the body of the response is the vector representation of the query string `input`. For testing purposes, you would copy the value of the `embedding` array into `vectorQueries.vector` in a query request, using the syntax shown in the next several sections.

The actual response to this POST call to the deployed model includes 1,536 embeddings. For readability, this example only shows the first few vectors.

JSON

```
{
    "object": "list",
    "data": [
        {
            "object": "embedding",
            "index": 0,
            "embedding": [
                -0.009171937,
                0.018715322,
                ...
                -0.0016804502
            ]
        }
    ],
    "model": "ada",
    "usage": {
        "prompt_tokens": 7,
        "total_tokens": 7
    }
}
```

In this approach, your application code is responsible for connecting to a model, generating embeddings, and handling the response.

Vector query request

This section shows you the basic structure of a vector query. You can use the Azure portal, REST APIs, or the Azure SDKs to formulate a vector query.

If you're migrating from [2023-07-01-PublicPreview](#), there are breaking changes. For more information, see [Upgrade to the latest REST API](#).

2025-09-01

The stable version supports:

- `vectorQueries` is the construct for vector search.
- `vectorQueries.kind` set to `vector` for a vector array or `text` if the input is a string and if you [have a vectorizer](#).
- `vectorQueries.vector` is the query (a vector representation of text or an image).
- `vectorQueries.exhaustive` (optional) invokes exhaustive KNN at query time, even if the field is indexed for HNSW.
- `vectorQueries.fields` (optional) targets specific fields for query execution (up to 10 per query).
- `vectorQueries.weight` (optional) specifies the relative weight of each vector query included in search operations. For more information, see [Vector weighting](#).
- `vectorQueries.k` is the number of matches to return.

In the following example, the vector is a representation of this string: `"what Azure services support full text search"`. The query targets the `contentVector` field and returns `k` results. The actual vector has 1,536 embeddings, which are trimmed in this example for readability.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
Content-Type: application/json
api-key: {{admin-api-key}}
{
    "count": true,
    "select": "title, content, category",
    "vectorQueries": [
        {
            "kind": "vector",
            "vector": [
                -0.009154141,
                0.018708462,
                ...
            ]
        }
    ]
}
```

```
        -0.02178128,
        -0.00086512347
    ],
    "exhaustive": true,
    "fields": "contentVector",
    "weight": 0.5,
    "k": 5
}
]
}
```

Vector query response

In Azure AI Search, query responses consist of all `retrievable` fields by default. However, it's common to limit search results to a subset of `retrievable` fields by listing them in a `select` statement.

In a vector query, carefully consider whether you need to vector fields in a response. Vector fields aren't human readable, so if you're pushing a response to a web page, you should choose nonvector fields that represent the result. For example, if the query executes against `contentVector`, you could return `content` instead.

If you want vector fields in the result, here's an example of the response structure. `contentVector` is a string array of embeddings, which are trimmed in this example for readability. The search score indicates relevance. Other nonvector fields are included for context.

JSON

```
{
    "@odata.count": 3,
    "value": [
        {
            "@search.score": 0.80025613,
            "title": "Azure Search",
            "category": "AI + Machine Learning",
            "contentVector": [
                -0.0018343845,
                0.017952163,
                0.0025753193,
                ...
            ]
        },
        {
            "@search.score": 0.78856903,
            "title": "Azure Application Insights",
            "category": "Management + Governance",
        }
    ]
}
```

```

    "contentVector": [
        -0.016821077,
        0.0037742127,
        0.016136652,
        ...
    ],
},
{
    "@search.score": 0.78650564,
    "title": "Azure Media Services",
    "category": "Media",
    "contentVector": [
        -0.025449317,
        0.0038463024,
        -0.02488436,
        ...
    ]
}
]
}

```

Key points:

- `k` determines how many nearest neighbor results are returned, in this case, three. Vector queries always return `k` results, assuming at least `k` documents exist, even if some documents have poor similarity. This is because the algorithm finds any `k` nearest neighbors to the query vector.
- The [vector search algorithm](#) determines the `@search.score`.
- Fields in search results are either all `retrievable` fields or fields in a `select` clause. During vector query execution, matching is made on vector data alone. However, a response can include any `retrievable` field in an index. Because there's no facility for decoding a vector field result, the inclusion of nonvector text fields is helpful for their human-readable values.

Multiple vector fields

You can set the `vectorQueries.fields` property to multiple vector fields. The vector query executes against each vector field that you provide in the `fields` list. You can specify up to 10 fields.

When querying multiple vector fields, ensure that each one contains embeddings from the same embedding model. The query should also be generated from the same embedding model.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
Content-Type: application/json
api-key: {{admin-api-key}}
{
  "count": true,
  "select": "title, content, category",
  "vectorQueries": [
    {
      "kind": "vector",
      "vector": [
        -0.009154141,
        0.018708462,
        . . .
        -0.02178128,
        -0.00086512347
      ],
      "exhaustive": true,
      "fields": "contentVector, titleVector",
      "k": 5
    }
  ]
}
```

Multiple vector queries

Multi-query vector search sends multiple queries across multiple vector fields in your search index. This type of query is commonly used with models such as [CLIP](#) for multimodal search, where the same model can vectorize both text and images.

The following query example looks for similarity in both `myImageVector` and `myTextVector` but sends two respective query embeddings, each executing in parallel. The result of this query is scored using [reciprocal rank fusion](#) (RRF).

- `vectorQueries` provides an array of vector queries.
- `vector` contains the image vectors and text vectors in the search index. Each instance is a separate query.
- `fields` specifies which vector field to target.
- `k` is the number of nearest neighbor matches to include in results.

JSON

```
{
  "count": true,
  "select": "title, content, category",
```

```
"vectorQueries": [
  {
    "kind": "vector",
    "vector": [
      -0.009154141,
      0.018708462,
      ...
      -0.02178128,
      -0.00086512347
    ],
    "fields": "myimagevector",
    "k": 5
  },
  {
    "kind": "vector"
    "vector": [
      -0.002222222,
      0.018708462,
      -0.013770515,
      ...
    ],
    "fields": "mytextvector",
    "k": 5
  }
]
```

Search indexes can't store images. Assuming that your index includes a field for the image file, the search results would include a combination of text and images.

Query with integrated vectorization

This section shows a vector query that invokes the [integrated vectorization](#) to convert a text or [image query](#) into a vector. We recommend the stable [2025-09-01](#) REST API, Search Explorer, or newer Azure SDK packages for this feature.

A prerequisite is a search index that has a [vectorizer configured and assigned](#) to a vector field. The vectorizer provides connection information to an embedding model used at query time.

Azure portal

Search Explorer supports integrated vectorization at query time. If your index contains vector fields and has a vectorizer, you can use the built-in text-to-vector conversion.

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. From the left menu, select **Search management > Indexes**, and then select your index.

3. Select the **Vector profiles** tab to confirm that you have a vectorizer.

The screenshot shows the Azure AI Search interface for an index named 'vector-20240531'. The 'Vector profiles' tab is selected. A table lists a single profile:

Profile name	Algorithm	Vectorizer	Compression
vector-20240531-azureOpenAi-text-...	vector-20240531-algorithm	vector-20240531-azureOpenAi-text-...	

4. Select the **Search explorer** tab. Using the default query view, you can enter a text string into the search bar. The built-in vectorizer converts your string into a vector, performs the search, and returns results.

Alternatively, you can select **View > JSON view** to view or modify the query. If vectors are present, Search Explorer sets up a vector query automatically. You can use the JSON view to select fields for use in the search and response, add filters, and construct more advanced queries, such as [hybrid queries](#). To see a JSON example, select the REST API tab in this section.

Number of ranked results in a vector query response

A vector query specifies the `k` parameter, which determines how many matches are returned in the results. The search engine always returns `k` number of matches. If `k` is larger than the number of documents in the index, the number of documents determines the upper limit of what can be returned.

If you're familiar with full-text search, you know to expect zero results if the index doesn't contain a term or phrase. However, in vector search, the search operation identifies nearest neighbors and always return `k` results, even if the nearest neighbors aren't that similar. It's possible to get results for nonsensical or off-topic queries, especially if you aren't using prompts to set boundaries. Less relevant results have a worse similarity score, but they're still the "nearest" vectors if there isn't anything closer. Therefore, a response with no meaningful results can still return `k` results, but each result's similarity score would be low.

A [hybrid approach](#) that includes full-text search can mitigate this problem. Another solution is to set a minimum threshold on the search score, but only if the query is a pure single vector query. Hybrid queries aren't conducive to minimum thresholds because the RRF ranges are much smaller and more volatile.

Query parameters that affect result count include:

- `"k": n` results for vector-only queries.
- `"top": n` results for hybrid queries that include a `search` parameter.

Both `k` and `top` are optional. When unspecified, the default number of results in a response is 50. You can set `top` and `skip` to [page through more results](#) or change the default.

Ranking algorithms used in a vector query

The ranking of results is computed by either:

- The similarity metric.
- RRF if there are multiple sets of search results.

Similarity metric

The similarity metric specified in the index `vectorSearch` section for a vector-only query. Valid values are `cosine`, `euclidean`, and `dotProduct`.

Azure OpenAI embedding models use cosine similarity, so if you're using Azure OpenAI embedding models, `cosine` is the recommended metric. Other supported ranking metrics include `euclidean` and `dotProduct`.

RRF

Multiple sets are created if the query targets multiple vector fields, runs multiple vector queries in parallel, or is a hybrid of vector and full-text search, with or without [semantic ranking](#).

During query execution, a vector query can only target one internal vector index. For [multiple vector fields](#) and [multiple vector queries](#), the search engine generates multiple queries that target the respective vector indexes of each field. The output is a set of ranked results for each query, which are fused using RRF. For more information, see [Relevance scoring using Reciprocal Rank Fusion](#).

Vector weighting

Add a `weight` query parameter to specify the relative weight of each vector query included in search operations. This value is used when combining the results of multiple ranking lists produced by two or more vector queries in the same request, or from the vector portion of a hybrid query.

The default is 1.0, and the value must be a positive number larger than zero.

Weights are used when calculating the [RRF scores](#) of each document. The calculation is a multiplier of the `weight` value against the rank score of the document within its respective result set.

The following example is a hybrid query with two vector query strings and one text string. Weights are assigned to the vector queries. The first query is 0.5 or half the weight, reducing its importance in the request. The second vector query is twice as important.

HTTP

```
POST https://[service-name].search.windows.net/indexes/[index-name]/docs/search?  
api-version=2025-09-01  
  
{  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [1.0, 2.0, 3.0],  
            "fields": "my_first_vector_field",  
            "k": 10,  
            "weight": 0.5  
        },  
        {  
            "kind": "vector",  
            "vector": [4.0, 5.0, 6.0],  
            "fields": "my_second_vector_field",  
            "k": 10,  
            "weight": 2.0  
        }  
    ],  
    "search": "hello world"  
}
```

Vector weighting applies to vectors only. The text query in this example, `"hello world"`, has an implicit neutral weight of 1.0. However, in a hybrid query, you can increase or decrease the importance of text fields by setting [maxTextRecallSize](#).

Set thresholds to exclude low-scoring results (preview)

Because nearest neighbor search always returns the requested `k` neighbors, it's possible to get multiple low-scoring matches as part of meeting the `k` number requirement on search results. To exclude low-scoring search results, you can add a `threshold` query parameter that filters out results based on a minimum score. Filtering occurs before [fusing results](#) from different recall sets.

This parameter is in preview. We recommend the [2024-05-01-preview](#) REST API version.

In this example, all matches that score below 0.8 are excluded from vector search results, even if the number of results falls below `k`.

HTTP

```
POST https://[service-name].search.windows.net/indexes/[index-name]/docs/search?  
api-version=2024-05-01-preview  
Content-Type: application/json  
api-key: [admin key]  
  
{  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [1.0, 2.0, 3.0],  
            "fields": "my-cosine-field",  
            "threshold": {  
                "kind": "vectorSimilarity",  
                "value": 0.8  
            }  
        }  
    ]  
}
```

Next steps

As a next step, review vector query code examples in [Python](#), [C#](#) or [JavaScript](#).

Multi-vector field support in Azure AI Search

08/27/2025

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

The multi-vector field support feature in Azure AI Search enables you to index multiple child vectors within a single document field. This feature is valuable for use cases like multimodal data or long-form documents, where representing the content with a single vector would lead to loss of important detail.

Understanding multi-vector field support

Traditionally, vector types, for example `Collection(Edm.Single)` could only be used in top-level fields. With the introduction of multi-vector field support, you can now use vector types in nested fields of complex collections, effectively allowing multiple vectors to be associated with a single document.

A single document can include up to 100 vectors in total, across all complex collection fields. Vector fields can only be nested one level deep.

Index definition with multi-vector field

No new index properties are needed for this feature. Here's a sample index definition:

JSON

```
{  
  "name": "multivector-index",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true,  
      "searchable": true  
    },
```

```
{  
    "name": "title",  
    "type": "Edm.String",  
    "searchable": true  
},  
{  
    "name": "description",  
    "type": "Edm.String",  
    "searchable": true  
},  
{  
    "name": "descriptionEmbedding",  
    "type": "Collection(Edm.Single)",  
    "dimensions": 3,  
    "searchable": true,  
    "retrievable": true,  
    "vectorSearchProfile": "hnsw"  
},  
{  
    "name": "scenes",  
    "type": "Collection(Edm.ComplexType)",  
    "fields": [  
        {  
            "name": "embedding",  
            "type": "Collection(Edm.Single)",  
            "dimensions": 3,  
            "searchable": true,  
            "retrievable": true,  
            "vectorSearchProfile": "hnsw"  
        },  
        {  
            "name": "timestamp",  
            "type": "Edm.Int32",  
            "retrievable": true  
        },  
        {  
            "name": "description",  
            "type": "Edm.String",  
            "searchable": true,  
            "retrievable": true  
        },  
        {  
            "name": "framePath",  
            "type": "Edm.String",  
            "retrievable": true  
        }  
    ]  
}  
]
```

Sample ingest document

Here's a sample document that illustrates how you might use multi-vector fields in practice:

JSON

```
{  
  "id": "123",  
  "title": "Non-Existent Movie",  
  "description": "A fictional movie for demonstration purposes.",  
  "descriptionEmbedding": [1, 2, 3],  
  "releaseDate": "2025-08-01",  
  "scenes": [  
    {  
      "embedding": [4, 5, 6],  
      "timestamp": 120,  
      "description": "A character is introduced.",  
      "framePath": "nonexistentmovie\\scenes\\scene120.png"  
    },  
    {  
      "embedding": [7, 8, 9],  
      "timestamp": 2400,  
      "description": "The climax of the movie.",  
      "framePath": "nonexistentmovie\\scenes\\scene2400.png"  
    }  
  ]  
}
```

In this example, the scenes field is a complex collection containing multiple vectors (the embedding fields), along with other associated data. Each vector represents a scene from the movie and could be used to find similar scenes in other movies, among other potential use cases.

Querying with multi-vector field support

The multi-vector field support feature introduces some changes to the query mechanism in Azure AI Search. However, the main querying process remains largely the same. Previously, `vectorQueries` could only target vector fields defined as top-level index fields. With this feature, we're relaxing this restriction and allowing `vectorQueries` to target fields that are nested within a collection of complex types (up to one level deep). Additionally, a new query time parameter is available: `perDocumentVectorLimit`.

- Setting `perDocumentVectorLimit` to `1` ensures that at most one vector per document is matched, guaranteeing that results come from distinct documents.
- Setting `perDocumentVectorLimit` to `0` (unlimited) allows multiple relevant vectors from the same document to be matched.

JSON

```
{  
  "vectorQueries": [  
    {  
      "kind": "text",  
      "text": "whales swimming",  
      "K": 50,  
      "fields": "scenes/embedding",  
      "perDocumentVectorLimit": 0  
    }  
  ],  
  "select": "title, scenes/timestamp, scenes/framePath"  
}
```

Ranking across multiple vectors in a single field

When multiple vectors are associated with a single document, Azure AI Search uses the maximum score among them for ranking. The system uses the most relevant vector to score each document, which prevents dilution by less relevant ones.

Retrieving the relevant elements in a collection

When a collection of complex types is included in the `$select` parameter, only the elements that matched the vector query are returned. This is useful for retrieving associated metadata such as timestamps, text descriptions, or image paths.

 **Note**

To reduce payload size, avoid including the vector values themselves in the `$select` parameter. Consider omitting vector storage entirely if unnecessary.

Limitations

- Semantic ranker isn't supported for nested chunks within a complex field. Therefore, the semantic ranker doesn't support nested vectors in multi-vector fields.

Debugging multi-vector queries (Preview)

When a document includes multiple embedded vectors, such as text and image embeddings in different subfields, the system uses the highest vector score across all elements to rank the document.

To debug how each vector contributed, use the `innerHits` debug mode (available in the latest preview REST API).

JSON

```
POST /indexes/my-index/docs/search?api-version=2025-08-01-preview
{
  "vectorQueries": [
    {
      "kind": "vector",
      "field": "keyframes.imageEmbedding",
      "kNearestNeighborsCount": 5,
      "vector": [ /* query vector */ ]
    }
  ],
  "debug": "innerHits"
}
```

Example response shape

JSON

```
"@search.documentDebugInfo": {
  "innerHits": {
    "keyframes": [
      {
        "ordinal": 0,
        "vectors": [
          {
            "imageEmbedding": {
              "searchScore": 0.958,
              "vectorSimilarity": 0.956
            },
            "textEmbedding": {
              "searchScore": 0.958,
              "vectorSimilarity": 0.956
            }
          }
        ]
      },
      {
        "ordinal": 1,
        "vectors": [
          {
            "imageEmbedding": null,
            "textEmbedding": {
              "searchScore": 0.872,
              "vectorSimilarity": 0.869
            }
          }
        ]
      }
    ]
  }
}
```

```
        }
    ]
}
```

Field descriptions

[Expand table](#)

Field	Description
<code>ordinal</code>	Zero-based index of the element inside the collection.
<code>vectors</code>	One entry per searchable vector field contained in the element.
<code>searchScore</code>	Final score for that field, after any rescaling and boosts.
<code>vectorSimilarity</code>	Raw similarity returned by the distance function.

 Note

`innerHits` currently reports only vector fields.

Relationship to debug=vector

Here are some facts about this property:

- The existing `debug=vector` switch remains unchanged.
- When used with multi-vector fields, `@search.document DebugInfo.vector.subscore` shows the maximum score used to rank the parent document, but not per-element detail.
- Use `innerHits` to gain insight into how individual elements contributed to the score.

Configure a vectorizer in a search index

In Azure AI Search, a *vectorizer* is a component that performs vectorization using a deployed embedding model on Azure OpenAI or Azure Vision in Foundry Tools. It converts text (or images) to vectors during query execution.

It's defined in a [search index](#), it applies to searchable vector fields, and it's used at query time to generate an embedding for a text or image query input. If instead you need to vectorize content as part of the indexing process, refer to [integrated vectorization](#). For built-in vectorization during indexing, you can configure an indexer and skillset that calls an embedding model for your raw text or image content.

To add a vectorizer to search index, you can use the index designer in Azure portal, or call the [Create or Update Index REST API](#), or use any Azure SDK package that's updated to provide this feature.

Vectorizers are now generally available as long as you use a generally available skill-vectorizer pair. [AzureOpenAIEmbedding vectorizer](#) and [AzureOpenAIEmbedding skill](#) are generally available. The custom [Web API vectorizer](#) is also generally available.

[Azure Vision vectorizer](#), [Microsoft Foundry model catalog vectorizer](#), and their equivalent skills are still in preview. Your skillset must specify [2024-05-01-preview REST API](#) to use preview skills and vectorizers.

Prerequisites

- An [index with searchable vector fields](#) on Azure AI Search.
- A deployed embedding model (see the next section).
- Permissions to use the embedding model. On Azure OpenAI, the caller must have [Cognitive Services OpenAI User](#) permissions. Or, you can provide an API key.
- [Visual Studio Code](#) with a [REST client](#) to send the query and accept a response.

We recommend that you [enable diagnostic logging](#) on your search service to confirm vector query execution.

Supported embedding models

The following table lists the embedding models that can be used with a vectorizer. Because you must use the [same embedding model for indexing and queries](#), vectorizers are paired with

skills that generate embeddings during indexing. The table lists the skill associated with a particular vectorizer.

[] [Expand table](#)

Vectorizer kind	Model names	Model provider	Associated skill
azureOpenAI	text-embedding-ada-002	Azure OpenAI	AzureOpenAIEmbedding skill
	text-embedding-3		
aml	Cohere-embed-v3 Cohere-embed-v4 ¹	Foundry model catalog	AML skill
aiServicesVision	Multimodal embeddings 4.0 API	Azure Vision (through a Foundry resource)	Azure Vision multimodal embeddings skill
customWebApi	Any embedding model	Hosted externally	Custom Web API skill

¹ At this time, you can only specify `embed-v-4-0` programmatically through the [AML skill](#) or [Microsoft Foundry model catalog vectorizer](#), not through the Azure portal. However, you can use the portal to manage the skillset or vectorizer afterward.

Try a vectorizer with sample data

The [Import data \(new\) wizard](#) reads files from Azure Blob storage, creates an index with chunked and vectorized fields, and adds a vectorizer. By design, the vectorizer that's created by the wizard is set to the same embedding model used to index the blob content.

1. Upload sample data files to a container on Azure Storage. We used some [small text files from NASA's earth book](#) to test these instructions on a free search service.
2. Run the [Import data \(new\) wizard](#), choosing the blob container for the data source.

Configure your Azure Blob Storage

Connect to Azure Blob Storage to access your structured and unstructured data files, including PDFs. [Learn more](#)

Subscription *	my-subscription

[Previous](#) [Next](#) 

4. After the wizard is finished and all indexer processing is complete, you should have an index with a searchable vector field. The field's JSON definition looks like this:

JSON

```
{  
  "name": "vector",  
  "type": "Collection(Edm.Single)",  
  "searchable": true,
```

```
        "retrievable": true,  
        "dimensions": 1536,  
        "vectorSearchProfile": "vector-nasa-ebook-text-profile"  
    }  
}
```

5. You should also have a vector profile and a vectorizer, similar to the following example:

JSON

```
"profiles": [  
    {  
        "name": "vector-nasa-ebook-text-profile",  
        "algorithm": "vector-nasa-ebook-text-algorithm",  
        "vectorizer": "vector-nasa-ebook-text-vectorizer"  
    }  
,  
    "vectorizers": [  
        {  
            "name": "vector-nasa-ebook-text-vectorizer",  
            "kind": "azureOpenAI",  
            "azureOpenAIParameters": {  
                "resourceUri": "https://my-fake-azure-openai-resource.openai.azure.com",  
                "deploymentId": "text-embedding-ada-002",  
                "modelName": "text-embedding-ada-002",  
                "apiKey": "00000000000000000000000000000000",  
                "authIdentity": null  
            },  
            "customWebApiParameters": null  
        }  
    ]  
]
```

6. Skip ahead to [test your vectorizer](#) for text-to-vector conversion during query execution.

Define a vectorizer and vector profile

This section explains the modifications to an index schema for defining a vectorizer manually.

1. Use [Create or Update Index](#) to add `vectorizers` to a search index.
2. Add the following JSON to your index definition. The vectorizers section provides connection information to a deployed embedding model. This step shows two vectorizer examples so that you can compare an Azure OpenAI embedding model and a custom web API side by side.

JSON

```
"vectorizers": [  
    {  
        "name": "my_azure_open_ai_vectorizer",  
        "kind": "azureOpenAI",  
        "azureOpenAIParameters": {  
            "resourceUri": "https://my-fake-azure-openai-resource.openai.azure.com",  
            "deploymentId": "text-embedding-ada-002",  
            "modelName": "text-embedding-ada-002",  
            "apiKey": "00000000000000000000000000000000",  
            "authIdentity": null  
        },  
        "customWebApiParameters": null  
    }  
]
```

```

    "kind": "azureOpenAI",
    "azureOpenAIParameters": {
        "resourceUri": "https://url.openai.azure.com",
        "deploymentId": "text-embedding-ada-002",
        "modelName": "text-embedding-ada-002",
        "apiKey": "mytopsecretkey"
    }
},
{
    "name": "my_custom_vectorizer",
    "kind": "customWebApi",
    "customVectorizerParameters": {
        "uri": "https://my-endpoint",
        "authResourceId": " ",
        "authIdentity": " "
    }
}
]

```

3. In the same index, add a vector profiles section that specifies one of your vectorizers.

Vector profiles also require a [vector search algorithm](#) used to create navigation structures.

JSON

```

"profiles": [
    {
        "name": "my_vector_profile",
        "algorithm": "my_hnsw_algorithm",
        "vectorizer": "my_azure_open_ai_vectorizer"
    }
]

```

4. Assign a vector profile to a vector field. The following example shows a fields collection with the required key field, a title string field, and two vector fields with a vector profile assignment.

JSON

```

"fields": [
    {
        "name": "ID",
        "type": "Edm.String",
        "key": true,
        "sortable": true,
        "analyzer": "keyword"
    },
    {
        "name": "title",
        "type": "Edm.String"
    },
    {

```

```
        "name": "vector",
        "type": "Collection(Edm.Single)",
        "dimensions": 1536,
        "vectorSearchProfile": "my_vector_profile",
        "searchable": true,
        "retrievable": true
    },
    {
        "name": "my-second-vector",
        "type": "Collection(Edm.Single)",
        "dimensions": 1024,
        "vectorSearchProfile": "my_vector_profile",
        "searchable": true,
        "retrievable": true
    }
]
```

Test a vectorizer

Use a search client to send a query through a vectorizer. This example assumes Visual Studio Code with a REST client and a [sample index](#).

1. In Visual Studio Code, provide a search endpoint and [search query API key](#):

```
HTTP
```

```
@baseUrl:
@queryApiKey: 00000000000000000000000000000000
```

2. Paste in a [vector query request](#).

```
HTTP
```

```
### Run a query
POST {{baseUrl}}/indexes/vector-nasa-ebook-txt/docs/search?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{queryApiKey}}

{
    "count": true,
    "select": "title,chunk",
    "vectorQueries": [
        {
            "kind": "text",
            "text": "what cloud formations exists in the troposphere",
            "fields": "vector",
            "k": 3,
            "exhaustive": true
        }
    ]
}
```

```
        ]  
    }
```

Key points about the query include:

- `"kind": "text"` tells the search engine that the input is a text string, and to use the vectorizer associated with the search field.
- `"text": "what cloud formations exists in the troposphere"` is the text string to vectorize.
- `"fields": "vector"` is the name of the field to query over. If you use the sample index produced by the wizard, the generated vector field is named `vector`.

3. Send the request. You should get three `k` results, where the first result is the most relevant.

Notice that there are no vectorizer properties to set at query time. The query reads the vectorizer properties, as per the vector profile field assignment in the index.

Check logs

If you enabled diagnostic logging for your search service, run a Kusto query to confirm query execution on your vector field:

```
Kusto
```

```
OperationEvent  
| where TIMESTAMP > ago(30m)  
| where Name == "Query.Search" and AdditionalInfo["QueryMetadata"]["Vectors"] has  
"TextLength"
```

Best practices

If you're setting up an Azure OpenAI vectorizer, consider the same [best practices](#) that we recommend for the Azure OpenAI embedding skill.

Add a filter to a vector query in Azure AI Search

09/16/2025

! Note

`strictPostFilter` is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

`prefilter` and `postfilter` are generally available in the [latest stable REST API version](#).

In Azure AI Search, you can use a [filter expression](#) to add inclusion or exclusion criteria to a [vector query](#). You can also specify a filtering mode that applies the filter:

- Before query execution, known as *prefiltering*.
- After query execution, known as *postfiltering*.
- After the global top-`k` results are identified, known as *strict postfiltering* (preview).

This article uses REST for illustration. For code samples in other languages and end-to-end solutions that include vector queries, see the [azure-search-vector-samples](#) GitHub repository.

You can also use [Search Explorer](#) in the Azure portal to query vector content. In the JSON view, you can add filters and specify the filter mode.

How filtering works in vector queries

Azure AI Search uses the Hierarchical Navigable Small World (HNSW) algorithm for Approximate Nearest Neighbor (ANN) search, storing HNSW graphs across multiple shards. Each shard contains a portion of the entire index.

Filters apply to `filterable nonvector` fields, either string or numeric, to include or exclude search documents based on filter criteria. Vector fields themselves aren't filterable, but you can use filters on other fields in the same index to narrow the documents considered for vector search. If your index lacks suitable text or numeric fields, check for document metadata that might help with filtering, such as `LastModified` or `CreatedBy` properties.

The `vectorFilterMode` parameter controls where filter operations are applied during the stages of search, which affects how the results are filtered to a subset of items (such as by category, tag, or other attributes) and impacts latency, recall, and throughput. There are three modes:

- `preFilter` applies the filter *during* HNSW traversal on each shard. This mode maximizes recall but can traverse more of the graph, increasing CPU and latency for highly selective filters.
- `postFilter` runs HNSW traversal and filtering on each shard independently, intersects results at the shard level, and then aggregates the top `k` from each shard into a global top `k`. This mode can create false negatives for highly selective filters or small `k` values.
- `strictPostFilter` (preview) finds the unfiltered global top `k` *before* applying the filter. This mode has the highest risk of returning false negatives for highly selective filters and small `k` values.

For more information about these modes, see [Set the filter mode](#).

Define a filter

Filters determine the scope of vector queries and are defined using [Documents - Search Post \(REST API\)](#). Unless you want to use a preview feature, use the latest stable version of the [Search Service REST APIs](#) to formulate the request.

This REST API provides:

- `filter` for the criteria.
- `vectorFilterMode` to specify when the filter is applied during the vector query. For supported modes, see [Set the filter mode](#).

HTTP

```
POST https://{{search-endpoint}}/indexes/{{index-name}}/docs/search?api-version={{api-version}}
Content-Type: application/json
api-key: {{admin-api-key}}

{  
    "count": true,  
    "select": "title, content, category",  
    "filter": "category eq 'Databases'",  
    "vectorFilterMode": "preFilter",  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [  
                {{vector}}  
            ]  
        }  
    ]  
}
```

```
-0.009154141,  
0.018708462,  
. . . // Trimmed for readability  
-0.02178128,  
-0.00086512347  
],  
"fields": "contentVector",  
"k": 50  
}  
]  
}
```

In this example, the vector embedding targets the `contentVector` field, and the filter criteria apply to `category`, a filterable text field. Because the `preFilter` mode is used, the filter is applied before the search engine runs the query, so only documents in the `Databases` category are considered during the vector search.

Set the filter mode

The `vectorFilterMode` parameter determines when and how the filter is applied relative to vector query execution. You can use the following modes:

- `preFilter` (recommended)
- `postFilter`
- `strictPostFilter` (preview)

(!) Note

`preFilter` is the default for indexes created after approximately October 15, 2023. For indexes created before this date, `postFilter` is the default. To use `preFilter` and other advanced vector features, such as vector compression, you must recreate your index.

You can test compatibility by sending a vector query with `"vectorFilterMode": "preFilter"` on the `2023-10-01-preview` REST API version or later. If the query fails, your index doesn't support `preFilter`.

preFilter

Prefiltering applies filters before query execution, which reduces the candidate set for the vector search algorithm. The top-`k` results are then selected from this filtered set.

In a vector query, `prefilter` is the default mode because it favors recall and quality over latency.

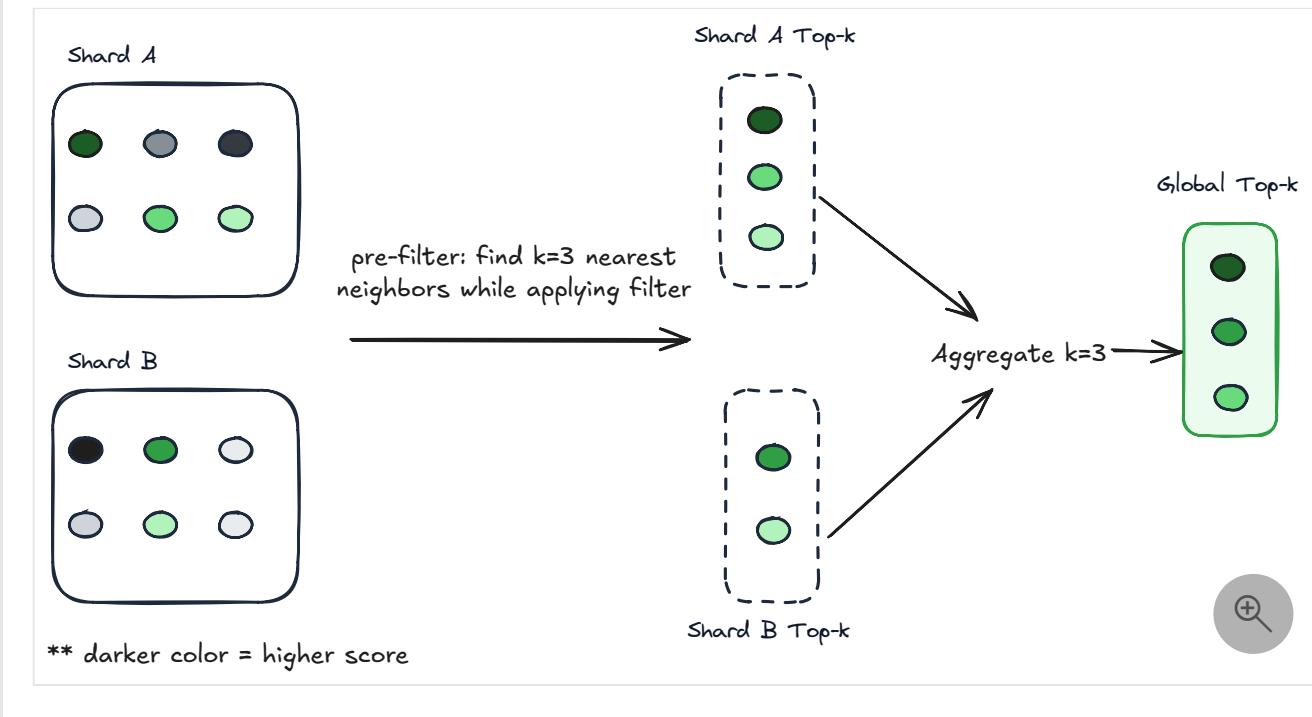

How this mode works

1. On each shard, apply the filter predicate *during* HNSW traversal, expanding the graph until `k` candidates are found.
2. Produce the prefiltered local top-`k` results per shard.
3. Aggregate the filtered results into a global top-`k` result set.

Effect of this mode

Traversal expands the search surface to find more filtered candidates, especially if the filter is selective. This produces the most similar top-`k` results across all shards. Each shard identifies the `k` results that satisfy the filter predicate.

Prefiltering guarantees that `k` results are returned if they exist in the index. For highly selective filters, this can cause a significant portion of the graph to be traversed, increasing computation cost and latency while reducing throughput. If your filter is highly selective (has very few matches), consider using `exhaustive: true` to perform exhaustive search.

Comparison table

Mode	Recall (filtered results)	Computational cost	Risk of false negatives	When to use
preFilter	Very high	Higher (increases with filter selectivity and complexity)	No risk	Recommended default for all scenarios, especially when recall is critical (sensitive search domains), when using selective filters, or when using small k .
postFilter	Medium to high (decreases with filter selectivity)	Similar to unfiltered but increases with filter complexity	Moderate (can miss matches per shard)	An option for filters that aren't too selective and for higher- k queries.
strictPostFilter	Lowest (decreases most quickly with filter selectivity)	Similar to unfiltered	Highest (can return zero results for selective filters or small k)	An option for faceted search applications where surfacing more results after filter application impacts the user experience more than the risk of false negatives. Don't use with small k .

Benchmark testing of prefiltering and postfiltering

ⓘ Important

This section applies to prefiltering and postfiltering, not strict postfiltering.

To understand the conditions under which one filter mode performs better than the other, we ran a series of tests to evaluate query outcomes over small, medium, and large indexes.

- Small (100,000 documents, 2.5-GB index, 1,536 dimensions)
- Medium (1 million documents, 25-GB index, 1,536 dimensions)
- Large (1 billion documents, 1.9-TB index, 96 dimensions)

For the small and medium workloads, we used a Standard 2 (S2) service with one partition and one replica. For the large workload, we used a Standard 3 (S3) service with 12 partitions and one replica.

Indexes had an identical construction: one key field, one vector field, one text field, and one numeric filterable field. The following index is defined using the 2023-11-03 syntax.

Python

```
def get_index_schema(self, index_name, dimensions):
    return {
        "name": index_name,
        "fields": [
            {"name": "id", "type": "Edm.String", "key": True, "searchable": True},
            {"name": "content_vector", "type": "Collection(Edm.Single)"}
        ],
        "dimensions": dimensions,
        "searchable": True, "retrievable": True, "filterable": False,
        "facetable": False, "sortable": False,
        "vectorSearchProfile": "defaulthnsw"},
        {"name": "text", "type": "Edm.String", "searchable": True,
        "filterable": False, "retrievable": True,
        "sortable": False, "facetable": False},
        {"name": "score", "type": "Edm.Double", "searchable": False,
        "filterable": True,
        "retrievable": True, "sortable": True, "facetable": True}
    ],
    "vectorSearch": {
        "algorithms": [
            {
                "name": "defaulthnsw",
                "kind": "hnsw",
                "hnswParameters": { "metric": "euclidean" }
            }
        ],
        "profiles": [
            {
                "name": "defaulthnsw",
                "algorithm": "defaulthnsw"
            }
        ]
    }
}
```

In queries, we used an identical filter for both prefilter and postfilter operations. We used a simple filter to ensure that variations in performance were due to filtering mode, not filter complexity.

Outcomes were measured in queries per second (QPS).

Takeaways

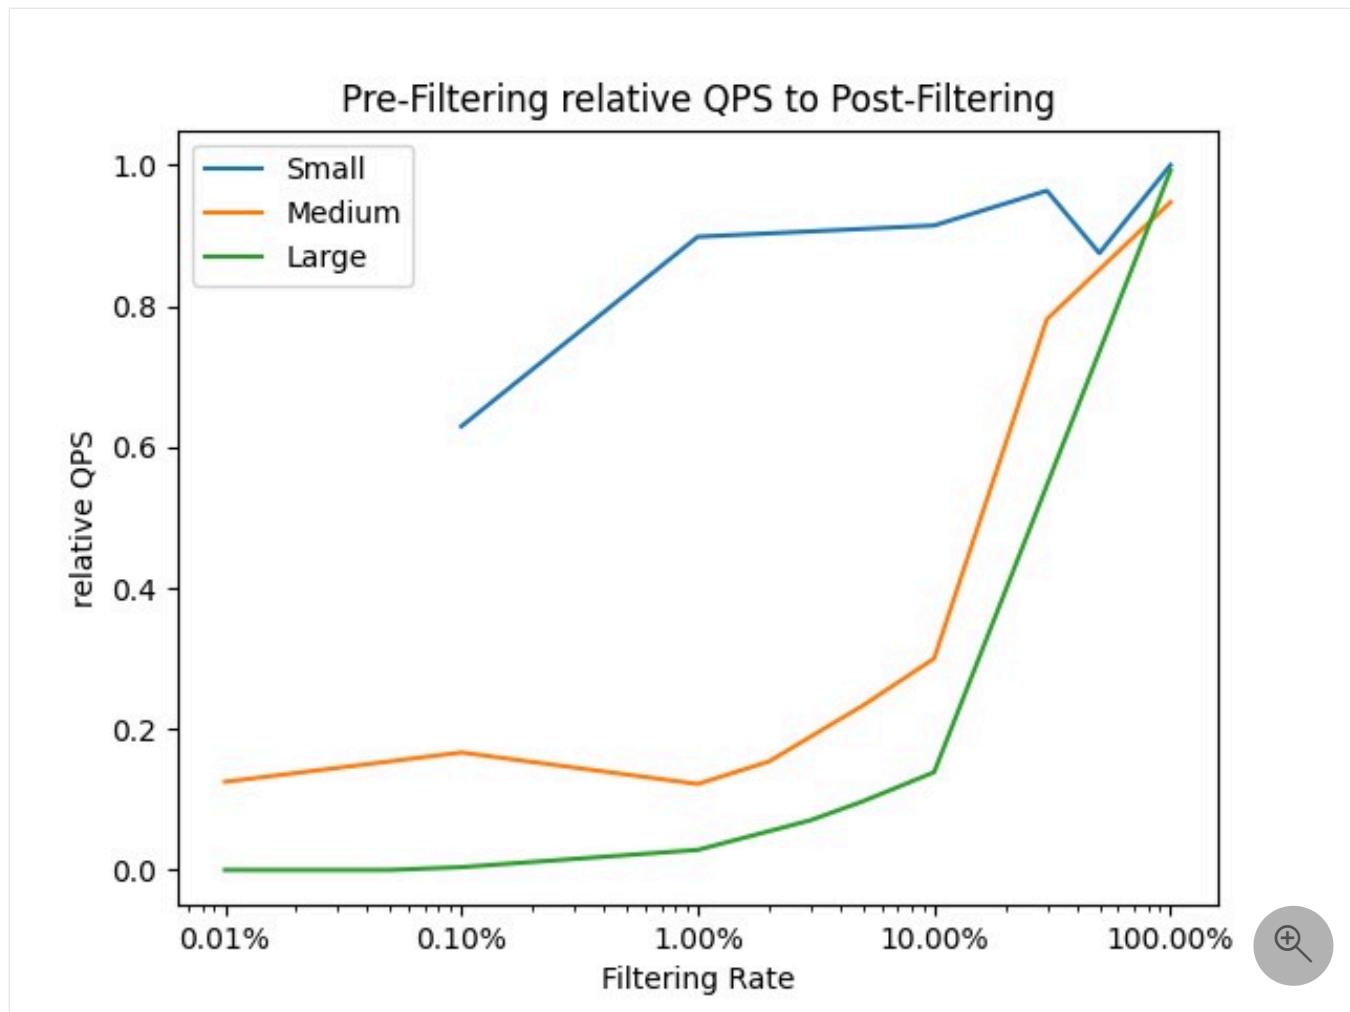

- Prefiltering is almost always slower than postfiltering, except on small indexes where performance is approximately equal.

- On larger datasets, prefiltering is orders of magnitude slower.
- Why is prefilter the default if it's almost always slower? Prefiltering guarantees that k results are returned if they exist in the index, where the bias favors recall and precision over speed.
- Use postfiltering if you:
 - Value speed over selection (postfiltering can return fewer than k results).
 - Use filters that aren't overly selective.
 - Have indexes of sufficient size such that prefiltering performance is unacceptable.

Details

- Given a dataset with 100,000 vectors at 1,536 dimensions:
 - When filtering more than 30% of the dataset, prefiltering and postfiltering were comparable.
 - When filtering less than 0.1% of the dataset, prefiltering was about 50% slower than postfiltering.
- Given a dataset with 1 million vectors at 1,536 dimensions:
 - When filtering more than 30% of the dataset, prefiltering was about 30% slower.
 - When filtering less than 2% of the dataset, prefiltering was about seven times slower.
- Given a dataset with 1 billion vectors at 96 dimensions:
 - When filtering more than 5% of the dataset, prefiltering was about 50% slower.
 - When filtering less than 10% of the dataset, prefiltering was about seven times slower.

The following graph shows prefilter relative QPS, computed as prefilter QPS divided by postfilter QPS.

The vertical axis represents the relative performance of prefiltering compared to postfiltering, expressed as a ratio of QPS (queries per second). For example:

- A value of `0.0` means prefiltering is 100% slower than postfiltering.
- A value of `0.5` means prefiltering is 50% slower.
- A value of `1.0` means prefiltering and post filtering are equivalent.

The horizontal axis represents the filtering rate, or the percentage of candidate documents after applying the filter. For example, a rate of `1.00%` means the filter criteria selected one percent of the search corpus.

Create a full text query in Azure AI Search

10/03/2025

If you're building a query for [full text search](#), this article provides steps for setting up the request. It also introduces a query structure, and explains how field attributes and linguistic analyzers can affect query outcomes.

Prerequisites

- A [search index](#) with string fields attributed as *searchable*. You can also use an [index alias](#) as the endpoint of your query request.
- Read permissions on the search index. For read access, include a [query API key](#) on the request, or give the caller [Search Index Data Reader](#) permissions.

Example of a full text query request

In Azure AI Search, a query is a read-only request against the docs collection of a single search index, with parameters that both inform query execution and shape the response coming back.

A full text query is specified in a `search` parameter and consists of terms, quote-enclosed phrases, and operators. Other parameters add more definition to the request.

The following [Search POST REST API](#) call illustrates a query request using `search` and other parameters.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2025-09-01
{
    "search": "NY +view",
    "queryType": "simple",
    "searchMode": "all",
    "searchFields": "HotelName, Description, Address/City, Address/StateProvince,
Tags",
    "select": "HotelName, Description, Address/City, Address/StateProvince, Tags",
    "top": 10,
    "count": true
}
```

Key points

- `search` provides the match criteria, usually whole terms or phrases, with or without operators. Any field that is attributed as *searchable* in the index schema is within scope for a search operation.
- `queryType` sets the parser: *simple*, *full*. The [default simple query parser](#) is optimal for full text search. The [full Lucene query parser](#) is for advanced query constructs like regular expressions, proximity search, fuzzy and wildcard search. This parameter can also be set to *semantic* for [semantic ranking](#) for advanced semantic modeling on the query response.
- `searchMode` specifies whether matches are based on *all* criteria (favors precision) or *any* criteria (favors recall) in the expression. The default is *any*. If you anticipate heavy use of Boolean operators, which is more likely in indexes that contain large text blocks (a content field or long descriptions), be sure to test queries with the `searchMode=Any|All` parameter to evaluate the impact of that setting on Boolean search.
- `searchFields` constrains query execution to specific searchable fields. During development, it's helpful to use the same field list for select and search. Otherwise a match might be based on field values that you can't see in the results, creating uncertainty as to why the document was returned.

Parameters used to shape the response:

- `select` specifies which fields to return in the response. Only fields marked as *retrievable* in the index can be used in a select statement.
- `top` returns the specified number of best-matching documents. In this example, only 10 hits are returned. You can use top and skip (not shown) to page the results.
- `count` tells you how many documents in the entire index match overall, which can be more than what are returned. Valid values are "true" or "false". Defaults to "false". Count is accurate if the index is stable, but will under or over-report any documents that are actively added, updated, or deleted. If you'd like to get only the count without any documents, you can use \$top=0.
- `orderby` is used if you want to sort results by a value, such as a rating or location. Otherwise, the default is to use the relevance score to rank results. A field must be attributed as *sortable* to be a candidate for this parameter.

Choose a client

For early development and proof-of-concept testing, start with the Azure portal or a REST client or a Jupyter notebook. These approaches are interactive, useful for targeted testing, and

help you assess the effects of different properties without having to write any code.

To call search from within an app, use the `Azure.Document.Search` client libraries in the Azure SDKs for .NET, Java, JavaScript, and Python.

Azure portal

In the Azure portal, when you open an index, you can work with Search Explorer alongside the index JSON definition in side-by-side tabs for easy access to field attributes. Check the **Fields** table to see which ones are searchable, sortable, filterable, and facetable while testing queries.

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. In your service, select **Indexes** and choose an index.
3. An index opens to the **Search explorer** tab so that you can query right away. Switch to **JSON view** to specify query syntax.

Here's a full text search query expression that works for the Hotels sample index:

```
JSON

{
    "search": "pool spa +airport",
    "queryType": "simple",
    "searchMode": "any",
    "searchFields": "Description, Tags",
    "select": "HotelName, Description, Tags",
    "top": 10,
    "count": true
}
```

The following screenshot illustrates the query and response:

The screenshot shows the Microsoft Azure AI Search interface for a project named "hotels-sample-index". At the top, there are navigation links for "Home", "Search explorer", "Fields", "CORS", "Scoring profiles", "Semantic configurations", and "Vector profiles". Below this, the "Search explorer" tab is selected. A JSON query editor window is open, displaying the following code:

```
2 |   "search": "pool spa +airport",
3 |   "queryType": "simple",
4 |   "searchMode": "any",
5 |   "searchFields": "Description, Tags",
6 |   "select": "HotelName, Description, Tags",
7 |   "top": 10,
8 |   "count": true
```

To the right of the query editor, a dropdown menu titled "View" is open, showing options: "Query view" (selected), "Image view", and "JSON view". The "Results" section below the query editor displays the search results in JSON format, showing four hotel entries. On the far right, there is a small preview pane showing thumbnail images of the hotel results.

Choose a query type: simple | full

If your query is full text search, a query parser is used to process any text that's passed as search terms and phrases. Azure AI Search offers two query parsers.

- The simple parser understands the [simple query syntax](#). This parser was selected as the default for its speed and effectiveness in free form text queries. The syntax supports common search operators (AND, OR, NOT) for term and phrase searches, and prefix (*) search (as in `sea*` for Seattle and Seaside). A general recommendation is to try the simple parser first, and then move on to full parser if application requirements call for more powerful queries.
- The [full Lucene query syntax](#), enabled when you add `queryType=full` to the request, is based on the [Apache Lucene Parser](#).

Full syntax and simple syntax overlap to the extent that both support the same prefix and Boolean operations, but the full syntax provides more operators. In full, there are more

operators for Boolean expressions, and more operators for advanced queries such as fuzzy search, wildcard search, proximity search, and regular expressions.

Choose query methods

Search is fundamentally a user-driven exercise, where terms or phrases are collected from a search box, or from click events on a page. The following table summarizes the mechanisms by which you can collect user input, along with the expected search experience.

 Expand table

Input	Experience
Search method	A user types the terms or phrases into a search box, with or without operators, and selects Search to send the request. Search can be used with filters on the same request, but not with autocomplete or suggestions.
Autocomplete method	A user types a few characters, and queries are initiated after each new character is typed. The response is a completed string from the index. If the string provided is valid, the user selects Search to send that query to the service.
Suggestions method	As with autocomplete, a user types a few characters and incremental queries are generated. The response is a dropdown list of matching documents, typically represented by a few unique or descriptive fields. If any of the selections are valid, the user selects one and the matching document is returned.
Faceted navigation	A page shows clickable navigation links or breadcrumbs that narrow the scope of the search. A faceted navigation structure is composed dynamically based on an initial query. For example, <code>search=*</code> to populate a faceted navigation tree composed of every possible category. A faceted navigation structure is created from a query response, but it's also a mechanism for expressing the next query. In REST API reference, <code>facets</code> is documented as a query parameter of a Search Documents operation, but it can be used without the <code>search</code> parameter.
Filter method	Filters are used with facets to narrow results. You can also implement a filter behind the page, for example to initialize the page with language-specific fields. In REST API reference, <code>\$filter</code> is documented as a query parameter of a Search Documents operation, but it can be used without the <code>search</code> parameter.

Effect of field attributes on queries

If you're familiar with [query types and composition](#), you might remember that the parameters on a query request depend on field attributes in an index. For example, only fields marked as *searchable* and *retrievable* can be used in queries and search results. When setting the `search`,

`filter`, and `orderby` parameters in your request, you should check attributes to avoid unexpected results.

In the following screenshot of the [hotels sample index](#), only the last two fields **LastRenovationDate** and **Rating** are *sortable*, a requirement for use in an `"$orderby"` only clause.

FIELD NAME	TYPE	RETRIEVABLE	FILTERABLE	SORTABLE	FACTETABLE	SEARCHABLE
霆 HotelId	Edm.String	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>	<input type="checkbox"/>
HotelName	Edm.String	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>
Description	Edm.String	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>
Description_fr	Edm.String	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>
Category	Edm.String	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>
Tags	Collection(E...	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>		<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>
ParkingIncluded	Edm.Boolean	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>	
LastRenovationDate	Edm.DateTi...	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>		<input type="checkbox"/>
Rating	Edm.Double	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>		<input checked="" type="checkbox"/>

For field attribute definitions, see [Create Index \(REST API\)](#).

Effect of tokens on queries

During indexing, the search engine uses a text analyzer on strings to maximize the potential for finding a match at query time. At a minimum, strings are lower-cased, but depending on the analyzer, might also undergo lemmatization and stop word removal. Larger strings or compound words are typically broken up by whitespace, hyphens, or dashes, and indexed as separate tokens.

The key point is that what you think your index contains, and what's actually in it, can be different. If queries don't return expected results, you can inspect the tokens created by the analyzer through the [Analyze Text \(REST API\)](#). For more information about tokenization and the effect on queries, see [Partial term search and patterns with special characters](#).

Add autocomplete and search suggestions in client apps

Article • 04/14/2025

Search-as-you-type is a common technique for improving query productivity. In Azure AI Search, this experience is supported through *autocomplete*, which finishes a term or phrase based on partial input (for example, completing *micro* with *microchip*, *microscope*, *microsoft*, and any other micro matches). A second user experience is *suggestions*, which produces a short list of matching documents (for example, returning book titles with an ID so that you can link to a detail page about that book). Both autocomplete and suggestions are predicated on a match in the index. The service doesn't offer autocompleted queries or suggestions that return zero results.

To implement these experiences in Azure AI Search:

- Add a `suggester` to an index schema.
- Build a query that calls the [Autocomplete API](#) or [Suggestions API](#) on the request.
- Add a UI control to handle search-as-you-type interactions in your client app. We recommend using an existing JavaScript library for this purpose.

In Azure AI Search, autocompleted queries and suggested results are retrieved from the search index, from selected fields that you register with a suggester. A suggester is part of the index, and it specifies which fields provide content that either completes a query, suggests a result, or does both. When the index is created and loaded, a suggester data structure is created internally to store prefixes used for matching on partial queries. For suggestions, choosing suitable fields that are unique, or at least not repetitive, is essential to the experience. For more information, see [Configure a suggester](#).

The remainder of this article is focused on queries and client code. It uses JavaScript and C# to illustrate key points. REST API examples are used to concisely present each operation. For end-to-end code samples, see [Add search to a web site with .NET](#).

Set up a request

Elements of a request include one of the search-as-you-type APIs, a partial query, and a suggester. The following script illustrates components of a request, using the Autocomplete REST API as an example.

HTTP

```
POST /indexes/myboxgames/docs/autocomplete?search&api-version=2024-07-01
{
```

```
"search": "minecraf",
"suggesterName": "sg"
}
```

The `suggesterName` parameter gives you the suggester-aware fields used to complete terms or suggestions. For suggestions in particular, the field list should be composed of suggestions that offer clear choices among matching results. On a site that sells computer games, the field might be the game title.

The `search` parameter provides the partial query, where characters are fed to the query request through the jQuery Autocomplete control. In the previous example, *minecraf* is a static illustration of what the control might pass in.

The APIs don't impose minimum length requirements on the partial query; it can be as little as one character. However, jQuery Autocomplete provides a minimum length. A minimum of two or three characters is typical.

Matches are on the beginning of a term anywhere in the input string. Given *the quick brown fox*, both autocomplete and suggestions match on partial versions of *the*, *quick*, *brown*, or *fox* but not on partial infix terms like *rown* or *ox*. Furthermore, each match sets the scope for downstream expansions. A partial query of *quick br* matches on *quick brown* or *quick bread*, but neither *brown* or *bread* by themselves would be a match unless *quick** precedes them.

APIs for search-as-you-type

Follow these links for the REST and .NET SDK reference pages:

- [Suggestions REST API](#)
- [Autocomplete REST API](#)
- [SuggestAsync method](#)
- [AutocompleteAsync method](#)

Structure a response

Responses for autocomplete and suggestions are what you might expect for the pattern: [Autocomplete](#) returns a list of terms, [Suggestions](#) returns terms plus a document ID so that you can fetch the document (use the [Lookup Document API](#) to fetch the specific document for a detail page).

Responses are shaped by the parameters on the request:

- For autocomplete, set the `autocompleteMode` to determine whether text completion occurs on one or two terms.

- For suggestions, set `$select` to return fields containing unique or differentiating values, such as names and description. Avoid fields that contain duplicate values (such as a category or city).

The following parameters apply to both autocomplete and suggestions, but are more applicable to suggestions, especially when a suggester includes multiple fields.

 [Expand table](#)

Parameter	Usage
searchFields	Constrain the query to specific fields.
\$filter	Apply match criteria on the result set (<code>\$filter=Category eq 'ActionAdventure'</code>).
\$top	Limit the results to a specific number (<code>\$top=5</code>).

Add user interaction code

Autofilling a query term or dropping down a list of matching links requires user interaction code, typically JavaScript, that can consume requests from external sources, such as autocomplete or suggestion queries against an Azure Search Cognitive index.

Although you could write this code natively, it's easier to use functions from existing JavaScript library, such as one of the following.

- [Autocomplete widget \(jQuery UI\)](#) appears in the suggestion code snippet. You can create a search box, and then reference it in a JavaScript function that uses the autocomplete widget. Properties on the widget set the source (an autocomplete or suggestions function), minimum length of input characters before action is taken, and positioning.
- [XDSOFT Autocomplete plug-in](#) appears in the autocomplete code snippet.
- [Suggestions](#) appears in the [Add search to web sites tutorial](#) and code sample.

Use these libraries in the client to create a search box that supports both suggestions and autocomplete. Inputs collected in the search box can then be paired with suggestions and autocomplete actions on the search service.

Suggestions

This section walks you through an implementation of suggested results, starting with the search box definition. It also shows how and script that invokes the first JavaScript

autocomplete library referenced in this article.

Create a search box

Assuming the [jQuery UI Autocomplete library](#) and an MVC project in C#, you could define the search box using JavaScript in the *Index.cshtml* file. The library adds the search-as-you-type interaction to the search box by making asynchronous calls to the MVC controller to retrieve suggestions.

In *Index.cshtml* inside the folder *\Views\Home*, a line to create a search box might be as follows:

HTML

```
<input class="searchBox" type="text" id="searchbox1" placeholder="search">
```

This example is a simple input text box with a class for styling, an ID to be referenced by JavaScript, and placeholder text.

Within the same file, embed JavaScript that references the search box. The following function calls the Suggest API, which requests suggested matching documents based on partial term inputs:

JavaScript

```
$(function () {
    $("#searchbox1").autocomplete({
        source: "/home/suggest?highlights=false&fuzzy=false&",
        minLength: 3,
        position: {
            my: "left top",
            at: "left-23 bottom+10"
        }
    });
});
```

The `source` tells the jQuery UI Autocomplete function where to get the list of items to show under the search box. Since this project is an MVC project, it calls the `Suggest` function in *HomeController.cs* that contains the logic for returning query suggestions. This function also passes a few parameters to control highlights, fuzzy matching, and term. The autocomplete JavaScript API adds the term parameter.

The `minLength: 3` ensures that recommendations are only shown when there are at least three characters in the search box.

Enable fuzzy matching

Fuzzy search allows you to get results based on close matches even if the user misspells a word in the search box. The edit distance is 1, which means there can be a maximum discrepancy of one character between the user input and a match.

```
JavaScript
```

```
source: "/home/suggest?highlights=false&fuzzy=true&" ,
```

Enable highlighting

Highlighting applies font style to the characters in the result that correspond to the input. For example, if the partial input is *micro*, the result would appear as **microsoft**, **microscope**, and so forth. Highlighting is based on the `HighlightPreTag` and `HighlightPostTag` parameters, defined inline with the `Suggest` function.

```
JavaScript
```

```
source: "/home/suggest?highlights=true&fuzzy=true&" ,
```

Suggest function

If you're using C# and an MVC application, the `HomeController.cs` file in the `Controllers` directory is where you might create a class for suggested results. In .NET, a `Suggest` function is based on the [SuggestAsync method](#). For more information about the .NET SDK, see [How to use Azure AI Search from a .NET Application](#).

The `InitSearch` method creates an authenticated HTTP index client to the Azure AI Search service. Properties on the `SuggestOptions` class determine which fields are searched and returned in the results, the number of matches, and whether fuzzy matching is used.

For autocomplete, fuzzy matching is limited to one edit distance (one omitted or misplaced character). Fuzzy matching in autocomplete queries can sometimes produce unexpected results depending on index size and [how it's sharded](#).

```
C#
```

```
public async Task<ActionResult> SuggestAsync(bool highlights, bool fuzzy, string term)
{
    InitSearch();
```

```

var options = new SuggestOptions()
{
    UseFuzzyMatching = fuzzy,
    Size = 8,
};

if (highlights)
{
    options.HighlightPreTag = "<b>";
    options.HighlightPostTag = "</b>";
}

// Only one suggester can be specified per index.
// The suggester for the Hotels index enables autocomplete/suggestions on the
HotelName field only.
// During indexing, HotelNames are indexed in patterns that support
autocomplete and suggested results.
var suggestResult = await _searchClient.SuggestAsync<Hotel>(term, "sg",
options).ConfigureAwait(false);

// Convert the suggest query results to a list that can be displayed in the
client.
List<string> suggestions = suggestResult.Value.Results.Select(x =>
x.Text).ToList();

// Return the list of suggestions.
return new JsonResult(suggestions);
}

```

The `SuggestAsync` function takes two parameters that determine whether hit highlights are returned or fuzzy matching is used in addition to the search term input. Up to eight matches can be included in suggested results. The method creates a `SuggestOptions object`, which is then passed to the Suggest API. The result is then converted to JSON so it can be shown in the client.

Autocomplete

So far, the search UX code has been centered on suggestions. The next code block shows autocomplete, using the XDSOFT jQuery UI Autocomplete function, passing in a request for Azure AI Search autocomplete. As with the suggestions, in a C# application, code that supports user interaction goes in *index.cshtml*.

JavaScript

```

$(function () {
    // using modified jQuery Autocomplete plugin v1.2.8
    https://xdsoft.net/jqplugins/autocomplete/
    // $.autocomplete -> $.autocompleteInline
    $("#searchbox1").autocompleteInline({

```

```

appendMethod: "replace",
source: [
    function (text, add) {
        if (!text) {
            return;
        }

        $.getJSON("/home/autocomplete?term=" + text, function (data) {
            if (data && data.length > 0) {
                currentSuggestion2 = data[0];
                add(data);
            }
        });
    }
],
});

// complete on TAB and clear on ESC
$("#searchbox1").keydown(function (evt) {
    if (evt.keyCode === 9 /* TAB */ && currentSuggestion2) {
        $("#searchbox1").val(currentSuggestion2);
        return false;
    } else if (evt.keyCode === 27 /* ESC */) {
        currentSuggestion2 = "";
        $("#searchbox1").val("");
    }
});
});

```

Autocomplete function

Autocomplete is based on the [AutocompleteAsync method](#). As with suggestions, this code block would go in the *HomeController.cs* file.

C#

```

public async Task<ActionResult> AutoCompleteAsync(string term)
{
    InitSearch();

    // Setup the autocomplete parameters.
    var ap = new AutocompleteOptions()
    {
        Mode = AutocompleteMode.OneTermWithContext,
        Size = 6
    };
    var autocompleteResult = await _searchClient.AutocompleteAsync(term, "sg",
ap).ConfigureAwait(false);

    // Convert the autocompleteResult results to a list that can be displayed in
    // the client.
    List<string> autocomplete = autocompleteResult.Value.Results.Select(x =>

```

```
x.Text).ToList();  
  
    return new JsonResult(autocomplete);  
}
```

The Autocomplete function takes the search term input. The method creates an [AutoCompleteParameters object](#). The result is then converted to JSON so it can be shown in the client.

Next step

The following tutorial demonstrates a search-as-you-type experience.

[Add search to a web site \(C#\)](#)

Examples of *simple* search queries in Azure AI Search

Article • 04/14/2025

In Azure AI Search, the [simple query syntax](#) invokes the default query parser for full text search. The parser is fast and handles common scenarios, including full text search, filtered and faceted search, and prefix search. This article uses examples to illustrate simple syntax usage in a [Search Documents \(REST API\)](#) request.

ⓘ Note

An alternative query syntax is [Lucene](#), which supports more complex query structures, such as fuzzy and wildcard search. For more information, see [Examples of full Lucene search syntax](#).

Hotels sample index

The following queries are based on the hotels-sample-index, which you can create by following the instructions in [Quickstart: Create a search index in the Azure portal](#).

Example queries are articulated using the REST API and POST requests. You can paste and run them in a [REST client](#). Or, use the JSON view of [Search explorer](#) in the Azure portal. In JSON view, you can paste in the query examples shown here in this article.

Request headers must have the following values:

[+] [Expand table](#)

Key	Value
Content-Type	application/json
api-key	<your-search-service-api-key>, either query or admin key

URI parameters must include your search service endpoint with the index name, docs collections, search command, and API version, similar to the following example:

HTTP

```
https://{{service-name}}.search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2024-07-01
```

The request body should be formed as valid JSON:

JSON

```
{  
  "search": "*",  
  "queryType": "simple",  
  "select": "HotelId, HotelName, Category, Tags, Description",  
  "count": true  
}
```

- `search` set to `*` is an unspecified query, equivalent to null or empty search. It's not especially useful, but it's the simplest search you can do, and it shows all retrievable fields in the index, with all values.
- `queryType` set to `simple` is the default and can be omitted, but it's included to emphasize that the query examples in this article are expressed in the simple syntax.
- `select` set to a comma-delimited list of fields is used for search result composition, including just those fields that are useful in the context of search results.
- `count` returns the number of documents matching the search criteria. On an empty search string, the count is all documents in the index (50 in the hotels-sample-index).

Example 1: Full text search

Full text search can be any number of standalone terms or quote-enclosed phrases, with or without Boolean operators.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01  
{  
  "search": "pool spa +airport",  
  "searchMode": "any",  
  "queryType": "simple",  
  "select": "HotelId, HotelName, Category, Description",  
  "count": true  
}
```

A keyword search that's composed of important terms or phrases tend to work best. String fields undergo text analysis during indexing and querying, dropping nonessential words like `the`, `and`, `it`. To see how a query string is tokenized in the index, pass the string in an [Analyze Text](#) call to the index.

The `searchMode` parameter controls precision and recall. If you want more recall, use the default `any` value, which returns a result if any part of the query string is matched. If you favor precision, where all parts of the string must be matched, change `searchMode` to `all`. Try the preceding query both ways to see how `searchMode` changes the outcome.

The response for the `pool spa +airport` query should look similar to the following example.

JSON

```
"@odata.count": 4,
"value": [
{
    "@search.score": 6.090657,
    "HotelId": "12",
    "HotelName": "Winter Panorama Resort",
    "Description": "Plenty of great skiing, outdoor ice skating, sleigh rides, tubing and snow biking. Yoga, group exercise classes and outdoor hockey are available year-round, plus numerous options for shopping as well as great spa services. Newly-renovated with large rooms, free 24-hr airport shuttle & a new restaurant. Rooms/suites offer mini-fridges & 49-inch HDTVs.",
    "Category": "Resort and Spa"
},
{
    "@search.score": 4.314683,
    "HotelId": "21",
    "HotelName": "Good Business Hotel",
    "Description": "1 Mile from the airport. Free WiFi, Outdoor Pool, Complimentary Airport Shuttle, 6 miles from Lake Lanier & 10 miles from downtown. Our business center includes printers, a copy machine, fax, and a work area.",
    "Category": "Suite"
},
{
    "@search.score": 3.575948,
    "HotelId": "27",
    "HotelName": "Starlight Suites",
    "Description": "Complimentary Airport Shuttle & WiFi. Book Now and save - Spacious All Suite Hotel, Indoor Outdoor Pool, Fitness Center, Florida Green certified, Complimentary Coffee, HDTV",
    "Category": "Suite"
},
{
    "@search.score": 2.6926985,
    "HotelId": "25",
    "HotelName": "Waterfront Scottish Inn",
    "Description": "Newly Redesigned Rooms & airport shuttle. Minutes from the airport, enjoy lakeside amenities, a resort-style pool & stylish new guestrooms with Internet TVs.",
    "Category": "Suite"
}
]
```

Notice the search score in the response. This is the relevance score of the match. By default, a search service returns the top 50 matches based on this score.

Uniform scores of *1.0* occur when there's no rank, either because the search wasn't full text search, or because no criteria were provided. For example, in an empty search (`search=*`), rows come back in arbitrary order. When you include actual criteria, you'll see search scores evolve into meaningful values.

Example 2: Look up by ID

After search results are returned, a logical next step is to provide a details page that includes more fields from the document. This example shows you how to return a single document using [Get Document](#) by passing in the document ID.

HTTP

```
GET /indexes/hotels-sample-index/docs/41?api-version=2024-07-01
```

All documents have a unique identifier. If you're using the Azure portal, select the index from the **Indexes** tab and then look at the field definitions to determine which field is the key. In the REST API, the [GET Index](#) call returns the index definition in the response body.

The response for the preceding query consists of the document whose key is *41*. Any field that is marked as *retrievable* in the index definition can be returned in search results and rendered in your app.

JSON

```
{
    "HotelId": "41",
    "HotelName": "Windy Ocean Motel",
    "Description": "Oceanfront hotel overlooking the beach features rooms with a private balcony and 2 indoor and outdoor pools. Inspired by the natural beauty of the island, each room includes an original painting of local scenes by the owner. Rooms include a mini fridge, Keurig coffee maker, and flatscreen TV. Various shops and art entertainment are on the boardwalk, just steps away.",
    "Description_fr": "Cet hôtel en bord de mer donnant sur la plage propose des chambres dotées d'un balcon privé et de 2 piscines intérieure et extérieure. Inspiré par la beauté naturelle de l'île, chaque chambre comprend une peinture originale de scènes locales par le propriétaire. Les chambres comprennent un mini-réfrigérateur, une cafetière Keurig et une télévision à écran plat. Divers magasins et divertissements artistiques se trouvent sur la promenade, à quelques pas.",
    "Category": "Suite",
    "Tags": [
        "pool",
        "air conditioning",
```

```

    "bar",
  ],
  "ParkingIncluded": true,
  "LastRenovationDate": "2021-05-10T00:00:00Z",
  "Rating": 3.5,
  "Location": {
    "type": "Point",
    "coordinates": [
      -157.846817,
      21.295841
    ],
    "crs": {
      "type": "name",
      "properties": {
        "name": "EPSG:4326"
      }
    }
  },
  "Address": {
    "StreetAddress": "1450 Ala Moana Blvd 2238 Ala Moana Ctr",
    "City": "Honolulu",
    "StateProvince": "HI",
    "PostalCode": "96814",
    "Country": "USA"
  }
}

```

Example 3: Filter on text

[Filter syntax](#) is an OData expression that you can use by itself or with `search`. When used together in the same request, `filter` is applied first to the entire index, and then the `search` is performed on the results of the filter. Filters can therefore be a useful technique to improve query performance since they reduce the set of documents that the search query needs to process.

Filters can be defined on any field marked as `filterable` in the index definition. For `hotels-sample-index`, filterable fields include `Category`, `Tags`, `ParkingIncluded`, `Rating`, and most `Address` fields.

HTTP

```

POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "art tours",
  "queryType": "simple",
  "filter": "Category eq 'Boutique'",
  "searchFields": "HotelName,Description,Category",
  "select": "HotelId,HotelName,Description,Category",

```

```
    "count": true
}
```

The response for the preceding query is scoped to only those hotels categorized as *Boutique*, and that include the terms *art* or *tours*. In this case, there's just one match.

JSON

```
"value": [
{
  "@search.score": 1.2814453,
  "HotelId": "2",
  "HotelName": "Old Century Hotel",
  "Description": "The hotel is situated in a nineteenth century plaza, which has been expanded and renovated to the highest architectural standards to create a modern, functional and first-class hotel in which art and unique historical elements coexist with the most modern comforts. The hotel also regularly hosts events like wine tastings, beer dinners, and live music.",
  "Category": "Boutique"
}
]
```

Example 4: Filter functions

Filter expressions can include [search.ismatch](#) and [search.ismatchscoring](#) functions, allowing you to build a search query within the filter. This filter expression uses a wildcard on *free* to select amenities including free wifi, free parking, and so forth.

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "",
  "filter": "search.ismatch('free*', 'Tags', 'full', 'any')",
  "select": "HotelName, Tags, Description",
  "count": true
}
```

The response for the preceding query matches on 27 hotels that offer free amenities. Notice that the search score is a uniform *1* throughout the results. This is because the search expression is null or empty, resulting in verbatim filter matches, but no full text search. Relevance scores are only returned on full text search. If you're using filters without `search`, make sure you have sufficient sortable fields so that you can control search rank.

JSON

```

"@odata.count": 27,
"value": [
  {
    "@search.score": 1,
    "HotelName": "Country Residence Hotel",
    "Description": "All of the suites feature full-sized kitchens stocked with cookware, separate living and sleeping areas and sofa beds. Some of the larger rooms have fireplaces and patios or balconies. Experience real country hospitality in the heart of bustling Nashville. The most vibrant music scene in the world is just outside your front door.",
    "Tags": [
      "laundry service",
      "restaurant",
      "free parking"
    ]
  },
  {
    "@search.score": 1,
    "HotelName": "Downtown Mix Hotel",
    "Description": "Mix and mingle in the heart of the city. Shop and dine, mix and mingle in the heart of downtown, where fab lake views unite with a cheeky design.",
    "Tags": [
      "air conditioning",
      "laundry service",
      "free wifi"
    ]
  },
  {
    "@search.score": 1,
    "HotelName": "Starlight Suites",
    "Description": "Complimentary Airport Shuttle & WiFi. Book Now and save - Spacious All Suite Hotel, Indoor Outdoor Pool, Fitness Center, Florida Green certified, Complimentary Coffee, HDTV",
    "Tags": [
      "pool",
      "coffee in lobby",
      "free wifi"
    ]
  },
  ...

```

Example 5: Range filters

Range filtering is supported through filters expressions for any data type. The following examples illustrate numeric and string ranges. Data types are important in range filters and work best when numeric data is in numeric fields, and string data in string fields. Numeric data in string fields isn't suitable for ranges because numeric strings aren't comparable.

The following query is a numeric range. In hotels-sample-index, the only filterable numeric field is `Rating`.

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "*",
  "filter": "Rating ge 2 and Rating lt 4",
  "select": "HotelId, HotelName, Rating",
  "orderby": "Rating desc",
  "count": true
}
```

The response for this query should look similar to the following example, trimmed for brevity.

JSON

```
"@odata.count": 27,
"value": [
  {
    "@search.score": 1,
    "HotelId": "22",
    "HotelName": "Lion's Den Inn",
    "Rating": 3.9
  },
  {
    "@search.score": 1,
    "HotelId": "25",
    "HotelName": "Waterfront Scottish Inn",
    "Rating": 3.8
  },
  {
    "@search.score": 1,
    "HotelId": "2",
    "HotelName": "Old Century Hotel",
    "Rating": 3.6
  },
  ...
]
```

The next query is a range filter over a string field (`Address/StateProvince`):

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "*",
  "filter": "Address/StateProvince ge 'A*' and Address/StateProvince lt 'D*'",
  "select": "HotelId, HotelName, Address/StateProvince",
```

```
    "count": true
}
```

The response for this query should look similar to the following example, trimmed for brevity. In this example, it's not possible to sort by `StateProvince` because the field isn't attributed as *sortable* in the index definition.

JSON

```
{
  "@odata.count": 9,
  "value": [
    {
      "@search.score": 1,
      "HotelId": "39",
      "HotelName": "White Mountain Lodge & Suites",
      "Address": {
        "StateProvince": "CO"
      }
    },
    {
      "@search.score": 1,
      "HotelId": "9",
      "HotelName": "Smile Up Hotel",
      "Address": {
        "StateProvince": "CA "
      }
    },
    {
      "@search.score": 1,
      "HotelId": "7",
      "HotelName": "Roach Motel",
      "Address": {
        "StateProvince": "CA "
      }
    },
    {
      "@search.score": 1,
      "HotelId": "34",
      "HotelName": "Lakefront Captain Inn",
      "Address": {
        "StateProvince": "CT"
      }
    },
    {
      "@search.score": 1,
      "HotelId": "37",
      "HotelName": "Campus Commander Hotel",
      "Address": {
        "StateProvince": "CA "
      }
    }
  ]
}
```

```
 },  
 . . .
```

Example 6: Geospatial search

The hotels-sample-index includes a *Location* field with latitude and longitude coordinates. This example uses the [geo.distance function](#) that filters on documents within the circumference of a starting point, out to an arbitrary distance (in kilometers) that you provide. You can adjust the last value in the query (10) to reduce or enlarge the surface area of the query.

HTTP

```
POST /indexes/v/docs/search?api-version=2024-07-01  
{  
  "search": "*",  
  "filter": "geo.distance(Location, geography'POINT(-122.335114 47.612839)' ) le  
10",  
  "select": "HotelId, HotelName, Address/City, Address/StateProvince",  
  "count": true  
}
```

The response for this query returns all hotels within a 10-kilometer distance of the coordinates provided:

JSON

```
{  
  "@odata.count": 3,  
  "value": [  
    {  
      "@search.score": 1,  
      "HotelId": "45",  
      "HotelName": "Happy Lake Resort & Restaurant",  
      "Address": {  
        "City": "Seattle",  
        "StateProvince": "WA"  
      }  
    },  
    {  
      "@search.score": 1,  
      "HotelId": "24",  
      "HotelName": "Uptown Chic Hotel",  
      "Address": {  
        "City": "Seattle",  
        "StateProvince": "WA"  
      }  
    },  
    {  
      "@search.score": 1,
```

```
        "HotelId": "16",
        "HotelName": "Double Sanctuary Resort",
        "Address": {
            "City": "Seattle",
            "StateProvince": "WA"
        }
    }
]
```

Example 7: Booleans with searchMode

Simple syntax supports Boolean operators in the form of characters (+, -, |) to support AND, OR, and NOT query logic. Boolean search behaves as you might expect, with a few noteworthy exceptions.

In a Boolean search, consider adding the `searchMode` parameter as a mechanism for influencing precision and recall. Valid values include `"searchMode": "any"` favoring recall (a document that satisfies any of the criteria is considered a match), and `"searchMode": "all"` favoring precision (all criteria must be matched in a document).

In the context of a Boolean search, the default `"searchMode": "any"` can be confusing if you're stacking a query with multiple operators and getting broader instead of narrower results. This is particularly true with NOT, where results include all documents *not containing* a specific term or phrase.

The following example provides an illustration. The query looks for matches on *restaurant* that exclude the phrase *air conditioning*. If you run the following query with `searchMode` (any), 43 documents are returned: those containing the term *restaurant*, plus all documents that *don't* have the phrase **air conditioning*.

Notice that there's no space between the boolean operator (-) and the phrase *air conditioning*. The quotation marks are escaped (\").

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
    "search": "restaurant -\"air conditioning\",
    "searchMode": "any",
    "searchFields": "Tags",
    "select": "HotelId, HotelName, Tags",
    "count": true
}
```

Changing to `"searchMode": "all"` enforces a cumulative effect on criteria and returns a smaller result set (seven matches) consisting of documents containing the term *restaurant*, minus those containing the phrase *air conditioning*.

The response for this query would now look similar to the following example, trimmed for brevity.

```
JSON

{
  "@odata.count": 14,
  "value": [
    {
      "@search.score": 3.1383743,
      "HotelId": "18",
      "HotelName": "Ocean Water Resort & Spa",
      "Tags": [
        "view",
        "pool",
        "restaurant"
      ],
    },
    {
      "@search.score": 2.028083,
      "HotelId": "22",
      "HotelName": "Lion's Den Inn",
      "Tags": [
        "laundry service",
        "free wifi",
        "restaurant"
      ],
    },
    {
      "@search.score": 2.028083,
      "HotelId": "34",
      "HotelName": "Lakefront Captain Inn",
      "Tags": [
        "restaurant",
        "laundry service",
        "coffee in lobby"
      ],
    },
    ...
  ]
}
```

Example 8: Paging results

In previous examples, you learned about parameters that affect search results composition, including `select` that determines which fields are in a result, sort orders, and how to include a count of all matches. This example is a continuation of search result composition in the form of

paging parameters that allow you to batch the number of results that appear in any given page.

By default, a search service returns the top 50 matches. To control the number of matches in each page, use `top` to define the size of the batch, and then use `skip` to pick up subsequent batches.

The following example uses a filter and sort order on the `Rating` field (Rating is both filterable and sortable) because it's easier to see the effects of paging on sorted results. In a regular full search query, the top matches are ranked and paged by `@search.score`.

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "*",
  "filter": "Rating gt 4",
  "select": "HotelName, Rating",
  "orderby": "Rating desc",
  "top": 5,
  "count": true
}
```

The query finds 21 matching documents, but because you specified `top`, the response returns just the top five matches, with ratings starting at 4.9, and ending at 4.7 with *Lakeside B & B*.

To get the next five, skip the first batch:

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "*",
  "filter": "Rating gt 4",
  "select": "HotelName, Rating",
  "orderby": "Rating desc",
  "top": 5,
  "skip": 5,
  "count": true
}
```

The response for the second batch skips the first five matches, returning the next five, starting with *Pull'r Inn Motel*. To continue with more batches, you would keep `top` at five, and then increment `skip` by five on each new request (`skip=5`, `skip=10`, `skip=15`, and so forth).

JSON

```
{  
    "@odata.count": 21,  
    "value": [  
        {  
            "@search.score": 1,  
            "HotelName": "Head Wind Resort",  
            "Rating": 4.7  
        },  
        {  
            "@search.score": 1,  
            "HotelName": "Sublime Palace Hotel",  
            "Rating": 4.6  
        },  
        {  
            "@search.score": 1,  
            "HotelName": "City Skyline Antiquity Hotel",  
            "Rating": 4.5  
        },  
        {  
            "@search.score": 1,  
            "HotelName": "Nordick's Valley Motel",  
            "Rating": 4.5  
        },  
        {  
            "@search.score": 1,  
            "HotelName": "Winter Panorama Resort",  
            "Rating": 4.5  
        }  
    ]  
}
```

Add spell check to queries in Azure AI Search

08/27/2025

ⓘ Important

Spell correction is in public preview under [supplemental terms of use](#). It's available through the Azure portal, preview REST APIs, and beta versions of Azure SDK libraries.

You can improve recall by spell-correcting words in a query before they reach the search engine. The `speller` parameter is supported for all text (non-vector) query types.

Prerequisites

- A search service at the Basic tier or higher, in any region.
- An existing search index with content in a [supported language](#).
- [A query request](#) that has `speller=lexicon` and `queryLanguage` set to a [supported language](#). Spell check works on strings passed in the `search` parameter. It's not supported for filters, fuzzy search, wildcard search, regular expressions, or vector queries.

Use a search client that supports preview APIs on the query request. You can use a [REST client](#) or beta releases of the Azure SDKs.

[] [Expand table](#)

Client library	Versions
REST API	Versions 2020-06-30-Preview and later. We recommend the latest preview API: 2025-08-01-preview
Azure SDK for .NET	version 11.7.0-beta.4
Azure SDK for Java	version 11.8.0-beta.7
Azure SDK for JavaScript	version 11.3.0-beta.8
Azure SDK for Python	version 11.6.0b12

Spell correction with simple search

The following example uses the built-in hotels-sample index to demonstrate spell correction on a simple text query. Without spell correction, the query returns zero results. With correction, the query returns one result for Johnson's family-oriented resort.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2025-08-01-preview
{
    "search": "famly acitvites",
    "speller": "lexicon",
    "queryLanguage": "en-us",
    "queryType": "simple",
    "select": "HotelId,HotelName,Description,Category,Tags",
    "count": true
}
```

Spell correction with full Lucene

Spelling correction occurs on individual query terms that undergo text analysis, which is why you can use the speller parameter with some Lucene queries, but not others.

- Incompatible query forms that bypass text analysis include: wildcard, regex, fuzzy
- Compatible query forms include: fielded search, proximity, term boosting

This example uses fielded search over the Category field, with full Lucene syntax, and a misspelled query term. By including speller, the typo in "Suiite" is corrected and the query succeeds.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2025-08-01-preview
{
    "search": "Category:(Resort and Spa) OR Category:Suiite",
    "queryType": "full",
    "speller": "lexicon",
    "queryLanguage": "en-us",
    "select": "Category",
    "count": true
}
```

Spell correction with semantic ranking

This query, with typos in every term except one, undergoes spelling corrections to return relevant results. To learn more, see [Configure semantic ranker](#).

HTTP

```

{
    "search": "hisotoric hotell wiht great restraint nad wiifi",
    "queryType": "semantic",
    "speller": "lexicon",
    "queryLanguage": "en-us",
    "searchFields": "HotelName,Tags,Description",
    "select": "HotelId,HotelName,Description,Category,Tags",
    "count": true
}
```

Supported languages

Valid values for `queryLanguage` can be found in the following table, copied from the list of [supported languages \(REST API reference\)](#).

[] Expand table

Language	queryLanguage
English [EN]	EN, EN-US (default)
Spanish [ES]	ES, ES-ES (default)
French [FR]	FR, FR-FR (default)
German [DE]	DE, DE-DE (default)
Dutch [NL]	NL, NL-BE, NL-NL (default)

!Note

Previously, while semantic ranker was in public preview, the `queryLanguage` parameter was also used for semantic ranking. Semantic ranker is now language-agnostic.

Language analyzer considerations

Indexes that contain non-English content often use [language analyzers](#) on non-English fields to apply the linguistic rules of the native language.

When adding spell check to content that also undergoes language analysis, you can achieve better results using the same language for each indexing and query processing step. For example, if a field's content was indexed using the "fr.microsoft" language analyzer, then queries and spell check should all use a French lexicon or language library of some form.

To recap how language libraries are used in Azure AI Search:

- Language analyzers can be invoked during indexing and query execution, and are either Apache Lucene (for example, "de.lucene") or Microsoft ("de.microsoft").
- Language lexicons invoked during spell check are specified using one of the language codes in the [supported language table](#).

In a query request, the value assigned to `queryLanguage` applies to `speller`.

 **Note**

Language consistency across various property values is only a concern if you are using language analyzers. If you are using language-agnostic analyzers (such as keyword, simple, standard, stop, whitespace, or `standardasciifolding.lucene`), then the `queryLanguage` value can be whatever you want.

While content in a search index can be composed in multiple languages, the query input is most likely in one. The search engine doesn't check for compatibility of `queryLanguage`, language analyzer, and the language in which content is composed, so be sure to scope queries accordingly to avoid producing incorrect results.

Filters in keyword search

Article • 03/11/2025

A *filter* provides value-based criteria for including or excluding content before query execution for keyword search, or before or after query execution for vector search.

Filters are applied to nonvector fields, but can be used in vector search if documents include nonvector fields. For example, for indexes organized around chunked content, you might have parent-level fields or metadata fields that can be filtered.

This article explains filtering for keyword search. For more information about vectors, see [Add a filter in a vector query](#).

A filter is specified using [OData filter expression syntax](#). In contrast with keyword and vector search, a filter succeeds only if the match is exact.

When to use a filter

Filters are foundational to several search experiences, including "find near me" geospatial search, faceted navigation, and security filters that show only those documents a user is allowed to see. If you implement any one of these experiences, a filter is required. It's the filter attached to the search query that provides the geolocation coordinates, the facet category selected by the user, or the security ID of the requestor.

Common scenarios include:

- Slice search results based on content in the index. Given a schema with hotel location, categories, and amenities, you might create a filter to explicitly match on criteria (in Seattle, on the water, with a view).
- Implement a search experience comes with a filter dependency:
 - [Faceted navigation](#) uses a filter to pass back the facet category selected by the user.
 - [Geospatial search](#) uses a filter to pass coordinates of the current location in "find near me" apps and functions that match within an area or by distance.
 - [Security filters](#) pass security identifiers as filter criteria, where a match in the index serves as a proxy for access rights to the document.
- Do a "numbers search". Numeric fields are retrievable and can appear in search results, but they aren't searchable (subject to full text search) individually. If you need selection criteria based on numeric data, use a filter.

How filters are executed

At query time, a filter parser accepts criteria as input, converts the expression into atomic Boolean expressions represented as a tree, and then evaluates the filter tree over filterable fields in an index.

Filtering occurs in tandem with search, qualifying which documents to include in downstream processing for document retrieval and relevance scoring. When paired with a search string, the filter effectively reduces the recall set of the subsequent search operation. When used alone (for example, when the query string is empty where `search=*`), the filter criteria is the sole input.

How filters are defined

Filters apply to text and numeric (nonvector) content on fields that are attributed as `filterable`.

Filters are OData expressions, articulated in the [filter syntax](#) supported by Azure AI Search.

You can specify one filter for each `search` operation, but the filter itself can include multiple fields, multiple criteria, and if you use an `ismatch` function, multiple full-text search expressions. In a multi-part filter expression, you can specify predicates in any order (subject to the rules of operator precedence). There's no appreciable gain in performance if you try to rearrange predicates in a particular sequence.

One of the limits on a filter expression is the maximum size limit of the request. The entire request, inclusive of the filter, can be a maximum of 16 MB for POST, or 8 KB for GET. There's also a limit on the number of clauses in your filter expression. A good rule of thumb is that if you have hundreds of clauses, you are at risk of running into the limit. We recommend designing your application in such a way that it doesn't generate filters of unbounded size.

The following examples represent prototypical filter definitions in several APIs.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels/docs/search?  
api-version=2024-07-01  
{  
    "search": "*",  
    "filter": "Rooms/any(room: room/BaseRate lt 150.0)",
```

```
        "select": "HotelId, HotelName, Rooms/Description, Rooms/BaseRate"  
    }  
  
C#
```

```
options = new SearchOptions()  
{  
    Filter = "Rating gt 4",  
    OrderBy = { "Rating desc" }  
};
```

Filter patterns

The following examples illustrate several usage patterns for filter scenarios. For more ideas, see [OData expression syntax > Examples](#).

- Standalone **\$filter**, without a query string, useful when the filter expression is able to fully qualify documents of interest. Without a query string, there's no lexical or linguistic analysis, no scoring, and no ranking. Notice the search string is just an asterisk, which means "match all documents".

JSON

```
{  
    "search": "*",  
    "filter": "Rooms/any(room: room/BaseRate ge 60 and room/BaseRate lt  
300) and Address/City eq 'Honolulu'"  
}
```

- Combination of query string and **\$filter**, where the filter creates the subset, and the query string provides the term inputs for full text search over the filtered subset. The addition of terms (walking distance theaters) introduces search scores in the results, where documents that best match the terms are ranked higher. Using a filter with a query string is the most common usage pattern.

JSON

```
{  
    "search": "walking distance theaters",  
    "filter": "Rooms/any(room: room/BaseRate ge 60 and room/BaseRate lt  
300) and Address/City eq 'Seattle'"  
}
```

- Compound queries, separated by "or", each with its own filter criteria (for example, 'beagles' in 'dog' or 'siamese' in 'cat'). Expressions combined with `or` are evaluated individually, with the union of documents matching each expression sent back in the response. This usage pattern is achieved through the `search.ismatchscoring` function. You can also use the nonscoring version, `search.ismatch`.

HTTP

```
# Match on hostels rated higher than 4 OR 5-star motels.
$filter=search.ismatchscoring('hostel') and Rating ge 4 or
search.ismatchscoring('motel') and Rating eq 5

# Match on 'luxury' or 'high-end' in the description field OR on
category exactly equal to 'Luxury'.
$filter=search.ismatchscoring('luxury | high-end', 'Description') or
Category eq 'Luxury'&$count=true
```

It's also possible to combine full-text search via `search.ismatchscoring` with filters using `and` instead of `or`, but this is functionally equivalent to using the `search` and `$filter` parameters in a search request. For example, the following two queries produce the same result:

HTTP

```
$filter=search.ismatchscoring('pool') and Rating ge 4

search=pool&$filter=Rating ge 4
```

Field requirements for filtering

In the REST API, filterable is *on* by default for simple fields. Filterable fields increase index size; be sure to set `"filterable": false` for fields that you don't plan to actually use in a filter. For more information about settings for field definitions, see [Create Index](#).

In the Azure SDKs, filterable is *off* by default. You can make a field filterable by setting the [IsFilterable property](#) of the corresponding [SearchField](#) object to `true`. In the next example, the attribute is set on the `Rating` property of a model class that maps to the index definition.

C#

```
[SearchField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
public double? Rating { get; set; }
```

Making an existing field filterable

You can't modify existing fields to make them filterable. Instead, you need to add a new field, or rebuild the index. For more information about rebuilding an index or repopulating fields, see [How to rebuild an Azure AI Search index](#).

Text filter fundamentals

Text filters match string fields against literal strings that you provide in the filter:

```
$filter=Category eq 'Resort and Spa'
```

Unlike full-text search, there's no lexical analysis or word-breaking for text filters, so comparisons are for exact matches only. For example, assume a field *f* contains "sunny day", `$filter=f eq 'sunny'` doesn't match, but `$filter=f eq 'sunny day'` will.

Text strings are case-sensitive, which means text filters are case sensitive by default. For example, `$filter=f eq 'Sunny day'` won't find "sunny day". However, you can use a [normalizer](#) to make it so filtering isn't case sensitive.

Approaches for filtering on text

[+] [Expand table](#)

Approach	Description	When to use
<code>search.in</code>	A function that matches a field against a delimited list of strings.	Recommended for security filters and for any filters where many raw text values need to be matched with a string field. The <code>search.in</code> function is designed for speed and is much faster than explicitly comparing the field against each string using <code>eq</code> and <code>or</code> .
<code>search.ismatch</code>	A function that allows you to mix full-text search operations with strictly Boolean filter operations in the same filter expression.	Use <code>search.ismatch</code> (or its scoring equivalent, <code>search.ismatchscoring</code>) when you want multiple search-filter combinations in one request. You can also use it for a <i>contains</i> filter to filter on a partial string within a larger string.
<code>\$filter=field operator string</code>	A user-defined expression composed of fields, operators, and values.	Use this when you want to find exact matches between a string field and a string value.

Numeric filter fundamentals

Numeric fields aren't `searchable` in the context of full text search. Only strings are subject to full text search. For example, if you enter 99.99 as a search term, you won't get back items priced at \$99.99. Instead, you would see items that have the number 99 in string fields of the document. Thus, if you have numeric data, the assumption is that you'll use them for filters, including ranges, facets, groups, and so forth.

Documents that contain numeric fields (price, size, SKU, ID) provide those values in search results if the field is marked `retrievable`. The point here's that full text search itself isn't applicable to numeric field types.

Next steps

First, try **Search explorer** in the Azure portal to submit queries with `$filter` parameters. The [real-estate-sample index](#) provides interesting results for the following filtered queries when you paste them into the search bar:

```
HTTP

# Geo-filter returning documents within 5 kilometers of Redmond, Washington state
# Use $count=true to get a number of hits returned by the query
# Use $select to trim results, showing values for named fields only
# Use search=* for an empty query string. The filter is the sole input

search=*&$count=true&$select=description,city,postCode&$filter=geo.distance(location,geography'POINT(-122.121513 47.673988)') le 5

# Numeric filters use comparison like greater than (gt), less than (lt), not equal (ne)
# Include "and" to filter on multiple fields (baths and bed)
# Full text search is on John Leclerc, matching on John or Leclerc

search=John
Leclerc&$count=true&$select=source,city,postCode,baths,beds&$filter=baths gt 3 and beds gt 4

# Text filters can also use comparison operators
# Wrap text in single or double quotes and use the correct case
# Full text search is on John Leclerc, matching on John or Leclerc

search=John
Leclerc&$count=true&$select=source,city,postCode,baths,beds&$filter=city gt 'Seattle'
```

To work with more examples, see [OData Filter Expression Syntax > Examples](#).

Understand how OData collection filters work in Azure AI Search

05/29/2025

This article provides background for developers who are writing advanced filters with complex lambda expressions. The article explains why the rules for collection filters exist by exploring how Azure AI Search executes these filters.

When you build a [filter](#) on collection fields in Azure AI Search, you can use the [any and all operators](#) together with [lambda expressions](#). Lambda expressions are Boolean expressions that refer to a [range variable](#). In filters that use a lambda expression, the `any` and `all` operators are analogous to a `for` loop in most programming languages, with the range variable taking the role of loop variable, and the lambda expression as the body of the loop. The range variable takes on the "current" value of the collection during iteration of the loop.

At least that's how it works conceptually. In reality, Azure AI Search implements filters in a very different way to how `for` loops work. Ideally, this difference would be invisible to you, but in certain situations it isn't. The end result is that there are rules you have to follow when writing lambda expressions.

ⓘ Note

For information on what the rules for collection filters are, including examples, see [Troubleshooting OData collection filters in Azure AI Search](#).

Why collection filters are limited

There are three underlying reasons why filter features aren't fully supported for all types of collections:

1. Only certain operators are supported for certain data types. For example, it doesn't make sense to compare the Boolean values `true` and `false` using `lt`, `gt`, and so on.
2. Azure AI Search doesn't support *correlated search* on fields of type `Collection(Edm.ComplexType)`.
3. Azure AI Search uses inverted indexes to execute filters over all types of data, including collections.

The first reason is just a consequence of how the OData language and EDM type system are defined. The last two are explained in more detail in the rest of this article.

Correlated versus uncorrelated search

When you apply multiple filter criteria over a collection of complex objects, the criteria are correlated because they apply to *each object in the collection*. For example, the following filter returns hotels that have at least one deluxe room with a rate less than 100:

odata-filter-expr

```
Rooms/any(room: room/Type eq 'Deluxe Room' and room/BaseRate lt 100)
```

If filtering was *uncorrelated*, the above filter might return hotels where one room is deluxe and a different room has a base rate less than 100. That wouldn't make sense, since both clauses of the lambda expression apply to the same range variable, namely `room`. This is why such filters are correlated.

However, for full-text search, there's no way to refer to a specific range variable. If you use fielded search to issue a [full Lucene query](#) like this one:

odata-filter-expr

```
Rooms/Type:deluxe AND Rooms/Description:"city view"
```

you might get hotels back where one room is deluxe, and a different room mentions "city view" in the description. For example, the document below with `Id` of `1` would match the query:

JSON

```
{
  "value": [
    {
      "Id": "1",
      "Rooms": [
        { "Type": "deluxe", "Description": "Large garden view suite" },
        { "Type": "standard", "Description": "Standard city view room" }
      ]
    },
    {
      "Id": "2",
      "Rooms": [
        { "Type": "deluxe", "Description": "Courtyard motel room" }
      ]
    }
  ]
}
```

The reason is that `Rooms/Type` refers to all the analyzed terms of the `Rooms/Type` field in the entire document, and similarly for `Rooms/Description`, as shown in the tables below.

How `Rooms/Type` is stored for full-text search:

 Expand table

Term in <code>Rooms/Type</code>	Document IDs
deluxe	1, 2
standard	1

How `Rooms/Description` is stored for full-text search:

 Expand table

Term in <code>Rooms/Description</code>	Document IDs
courtyard	2
city	1
garden	1
large	1
motel	2
room	1, 2
standard	1
suite	1
view	1

So unlike the filter above, which basically says "match documents where a room has `Type` equal to 'Deluxe Room' and **that same room** has `BaseRate` less than 100", the search query says "match documents where `Rooms/Type` has the term "deluxe" and `Rooms/Description` has the phrase "city view". There's no concept of individual rooms whose fields can be correlated in the latter case.

Inverted indexes and collections

You might have noticed that there are far fewer restrictions on lambda expressions over complex collections than there are for simple collections like `Collection(Edm.Int32)`, `Collection(Edm.GeographyPoint)`, and so on. This is because Azure AI Search stores complex collections as actual collections of subdocuments, while simple collections aren't stored as collections at all.

For example, consider a filterable string collection field like `seasons` in an index for an online retailer. Some documents uploaded to this index might look like this:

```
JSON

{
  "value": [
    {
      "id": "1",
      "name": "Hiking boots",
      "seasons": ["spring", "summer", "fall"]
    },
    {
      "id": "2",
      "name": "Rain jacket",
      "seasons": ["spring", "fall", "winter"]
    },
    {
      "id": "3",
      "name": "Parka",
      "seasons": ["winter"]
    }
  ]
}
```

The values of the `seasons` field are stored in a structure called an **inverted index**, which looks something like this:

[Expand table](#)

Term	Document IDs
spring	1, 2
summer	1
fall	1, 2
winter	2, 3

This data structure is designed to answer one question with great speed: In which documents does a given term appear? Answering this question works more like a plain equality check than

a loop over a collection. In fact, this is why for string collections, Azure AI Search only allows `eq` as a comparison operator inside a lambda expression for `any`.

Next, we look at how it's possible to combine multiple equality checks on the same range variable with `or`. It works thanks to algebra and [the distributive property of quantifiers](#). This expression:

```
odata-filter-expr
```

```
seasons/any(s: s eq 'winter' or s eq 'fall')
```

is equivalent to:

```
odata-filter-expr
```

```
seasons/any(s: s eq 'winter') or seasons/any(s: s eq 'fall')
```

and each of the two `any` sub-expressions can be efficiently executed using the inverted index. Also, thanks to [the negation law of quantifiers](#), this expression:

```
odata-filter-expr
```

```
seasons/all(s: s ne 'winter' and s ne 'fall')
```

is equivalent to:

```
odata-filter-expr
```

```
not seasons/any(s: s eq 'winter' or s eq 'fall')
```

which is why it's possible to use `all` with `ne` and `and`.

⚠ Note

Although the details are beyond the scope of this document, these same principles extend to [distance and intersection tests for collections of geo-spatial points](#) as well. This is why, in `any`:

- `geo.intersects` cannot be negated
- `geo.distance` must be compared using `lt` or `le`
- expressions must be combined with `or`, not `and`

The converse rules apply for `all`.

A wider variety of expressions are allowed when filtering on collections of data types that support the `lt`, `gt`, `le`, and `ge` operators, such as `Collection(Edm.Int32)` for example. Specifically, you can use `and` as well as `or` in `any`, as long as the underlying comparison expressions are combined into **range comparisons** using `and`, which are then further combined using `or`. This structure of Boolean expressions is called [Disjunctive Normal Form \(DNF\)](#), otherwise known as "ORs of ANDs". Conversely, lambda expressions for `all` for these data types must be in [Conjunctive Normal Form \(CNF\)](#), otherwise known as "ANDs of ORs". Azure AI Search allows such range comparisons because it can execute them using inverted indexes efficiently, just like it can do fast term lookup for strings.

In summary, here are the rules of thumb for what's allowed in a lambda expression:

- Inside `any`, *positive checks* are always allowed, like equality, range comparisons, `geo.intersects`, or `geo.distance` compared with `lt` or `le` (think of "closeness" as being like equality when it comes to checking distance).
- Inside `any`, `or` is always allowed. You can use `and` only for data types that can express range checks, and only if you use ORs of ANDs (DNF).
- Inside `all`, the rules are reversed. Only *negative checks* are allowed, you can use `and` always, and you can use `or` only for range checks expressed as ANDs of ORs (CNF).

In practice, these are the types of filters you're most likely to use anyway. It's still helpful to understand the boundaries of what's possible though.

For specific examples of which kinds of filters are allowed and which aren't, see [How to write valid collection filters](#).

Troubleshooting OData collection filters in Azure AI Search

05/29/2025

To [filter](#) on collection fields in Azure AI Search, you can use the [any and all operators](#) together with **lambda expressions**. A lambda expression is a subfilter that is applied to each element of a collection.

Not every feature of filter expressions is available inside a lambda expression. Which features are available differs depending on the data type of the collection field that you want to filter. This can result in an error if you try to use a feature in a lambda expression that isn't supported in that context. If you're encountering such errors while trying to write a complex filter over collection fields, this article will help you troubleshoot the problem.

Common collection filter errors

The following table lists errors that you might encounter when trying to execute a collection filter. These errors happen when you use a feature of filter expressions that isn't supported inside a lambda expression. Each error gives some guidance on how you can rewrite your filter to avoid the error. The table also includes a link to the relevant section of this article that provides more information on how to avoid that error.

[Expand table](#)

Error message	Situation	Details
The function <code>ismatch</code> has no parameters bound to the range variable 's'. Only bound field references are supported inside lambda expressions ('any' or 'all'). However, you can change your filter so that the <code>ismatch</code> function is outside the lambda expression and try again.	Using <code>search.ismatch</code> or <code>search.ismatchscoring</code> inside a lambda expression	Rules for filtering complex collections

How to write valid collection filters

The rules for writing valid collection filters are different for each data type. The following sections describe the rules by showing examples of which filter features are supported and

which aren't:

- Rules for filtering string collections
- Rules for filtering Boolean collections
- Rules for filtering GeographyPoint collections
- Rules for filtering comparable collections
- Rules for filtering complex collections

Rules for filtering string collections

Inside lambda expressions for string collections, the only comparison operators that can be used are `eq` and `ne`.

(!) Note

Azure AI Search does not support the `lt`/`le`/`gt`/`ge` operators for strings, whether inside or outside a lambda expression.

The body of an `any` can only test for equality while the body of an `all` can only test for inequality.

It's also possible to combine multiple expressions via `or` in the body of an `any`, and via `and` in the body of an `all`. Since the `search.in` function is equivalent to combining equality checks with `or`, it's also allowed in the body of an `any`. Conversely, `not search.in` is allowed in the body of an `all`.

For example, these expressions are allowed:

- `tags/any(t: t eq 'books')`
- `tags/any(t: search.in(t, 'books, games, toys'))`
- `tags/all(t: t ne 'books')`
- `tags/all(t: not (t eq 'books'))`
- `tags/all(t: not search.in(t, 'books, games, toys'))`
- `tags/any(t: t eq 'books' or t eq 'games')`
- `tags/all(t: t ne 'books' and not (t eq 'games'))`

While these expressions aren't allowed:

- `tags/any(t: t ne 'books')`
- `tags/any(t: not search.in(t, 'books, games, toys'))`
- `tags/all(t: t eq 'books')`

- `tags/all(t: search.in(t, 'books, games, toys'))`
- `tags/any(t: t eq 'books' and t ne 'games')`
- `tags/all(t: t ne 'books' or not (t eq 'games'))`

Rules for filtering Boolean collections

The type `Edm.Boolean` supports only the `eq` and `ne` operators. As such, it doesn't make much sense to allow combining such clauses that check the same range variable with `and`/`or` since that would always lead to tautologies or contradictions.

Here are some examples of filters on Boolean collections that are allowed:

- `flags/any(f: f)`
- `flags/all(f: f)`
- `flags/any(f: f eq true)`
- `flags/any(f: f ne true)`
- `flags/all(f: not f)`
- `flags/all(f: not (f eq true))`

Unlike string collections, Boolean collections have no limits on which operator can be used in which type of lambda expression. Both `eq` and `ne` can be used in the body of `any` or `all`.

Expressions such as the following aren't allowed for Boolean collections:

- `flags/any(f: f or not f)`
- `flags/any(f: f or f)`
- `flags/all(f: f and not f)`
- `flags/all(f: f and f eq true)`

Rules for filtering GeographyPoint collections

Values of type `Edm.GeographyPoint` in a collection can't be compared directly to each other. Instead, they must be used as parameters to the `geo.distance` and `geo.intersects` functions. The `geo.distance` function in turn must be compared to a distance value using one of the comparison operators `lt`, `le`, `gt`, or `ge`. These rules also apply to noncollection `Edm.GeographyPoint` fields.

Like string collections, `Edm.GeographyPoint` collections have some rules for how the geo-spatial functions can be used and combined in the different types of lambda expressions:

- Which comparison operators you can use with the `geo.distance` function depends on the type of lambda expression. For `any`, you can use only `lt` or `le`. For `all`, you can use only `gt` or `ge`. You can negate expressions involving `geo.distance`, but you have to change the comparison operator (`geo.distance(...)` `lt` `x` becomes `not (geo.distance(...)` `ge` `x)` and `geo.distance(...)` `le` `x` becomes `not (geo.distance(...)` `gt` `x)).`
- In the body of an `all`, the `geo.intersects` function must be negated. Conversely, in the body of an `any`, the `geo.intersects` function must not be negated.
- In the body of an `any`, geo-spatial expressions can be combined using `or`. In the body of an `all`, such expressions can be combined using `and`.

The above limitations exist for similar reasons as the equality/inequality limitation on string collections. See [Understanding OData collection filters in Azure AI Search](#) for a deeper look at these reasons.

Here are some examples of filters on `Edm.GeographyPoint` collections that are allowed:

- `locations/any(l: geo.distance(l, geography'POINT(-122 49)') lt 10)`
- `locations/any(l: not (geo.distance(l, geography'POINT(-122 49)') ge 10) or geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`
- `locations/all(l: geo.distance(l, geography'POINT(-122 49)') ge 10 and not geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`

Expressions such as the following aren't allowed for `Edm.GeographyPoint` collections:

- `locations/any(l: l eq geography'POINT(-122 49)')`
- `locations/any(l: not geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`
- `locations/all(l: geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`
- `locations/any(l: geo.distance(l, geography'POINT(-122 49)') gt 10)`
- `locations/all(l: geo.distance(l, geography'POINT(-122 49)') lt 10)`
- `locations/any(l: geo.distance(l, geography'POINT(-122 49)') lt 10 and geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`
- `locations/all(l: geo.distance(l, geography'POINT(-122 49)') le 10 or not geo.intersects(l, geography'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581)))')`

Rules for filtering comparable collections

This section applies to all the following data types:

- `Collection(Edm.DateTimeOffset)`
- `Collection(Edm.Double)`
- `Collection(Edm.Int32)`
- `Collection(Edm.Int64)`

Types such as `Edm.Int32` and `Edm.DateTimeOffset` support all six of the comparison operators: `eq`, `ne`, `lt`, `le`, `gt`, and `ge`. Lambda expressions over collections of these types can contain simple expressions using any of these operators. This applies to both `any` and `all`. For example, these filters are allowed:

- `ratings/any(r: r ne 5)`
- `dates/any(d: d gt 2017-08-24T00:00:00Z)`
- `not margins/all(m: m eq 3.5)`

However, there are limitations on how such comparison expressions can be combined into more complex expressions inside a lambda expression:

- Rules for `any`:
 - Simple inequality expressions can't be usefully combined with any other expressions.
For example, this expression is allowed:
 - `ratings/any(r: r ne 5)`but this expression isn't:
 - `ratings/any(r: r ne 5 and r gt 2)`and while this expression is allowed, it isn't useful because the conditions overlap:
 - `ratings/any(r: r ne 5 or r gt 7)`
 - Simple comparison expressions involving `eq`, `lt`, `le`, `gt`, or `ge` can be combined with `and` / `or`. For example:
 - `ratings/any(r: r gt 2 and r le 5)`
 - `ratings/any(r: r le 5 or r gt 7)`
 - Comparison expressions combined with `and` (conjunctions) can be further combined using `or`. This form is known in Boolean logic as "[Disjunctive Normal Form](#)" (DNF).
For example:
 - `ratings/any(r: (r gt 2 and r le 5) or (r gt 7 and r lt 10))`

- Rules for `all`:
 - Simple equality expressions can't be usefully combined with any other expressions. For example, this expression is allowed:
 - `ratings/all(r: r eq 5)`
 - but this expression isn't:
 - `ratings/all(r: r eq 5 or r le 2)`
 - and while this expression is allowed, it isn't useful because the conditions overlap:
 - `ratings/all(r: r eq 5 and r le 7)`
 - Simple comparison expressions involving `ne`, `lt`, `le`, `gt`, or `ge` can be combined with `and` / `or`. For example:
 - `ratings/all(r: r gt 2 and r le 5)`
 - `ratings/all(r: r le 5 or r gt 7)`
 - Comparison expressions combined with `or` (disjunctions) can be further combined using `and`. This form is known in Boolean logic as "[Conjunctive Normal Form](#)" (CNF). For example:
 - `ratings/all(r: (r le 2 or gt 5) and (r lt 7 or r ge 10))`

Rules for filtering complex collections

Lambda expressions over complex collections support a much more flexible syntax than lambda expressions over collections of primitive types. You can use any filter construct inside such a lambda expression that you can use outside one, with only two exceptions.

First, the functions `search.ismatch` and `search.ismatchscoring` aren't supported inside lambda expressions. For more information, see [Understanding OData collection filters in Azure AI Search](#).

Second, referencing fields that aren't *bound* to the range variable (so-called *free variables*) isn't allowed. For example, consider the following two equivalent OData filter expressions:

1. `stores/any(s: s/amenities/any(a: a eq 'parking')) and details/margin gt 0.5`
2. `stores/any(s: s/amenities/any(a: a eq 'parking' and details/margin gt 0.5))`

The first expression is allowed, while the second form is rejected because `details/margin` isn't bound to the range variable `s`.

This rule also extends to expressions that have variables bound in an outer scope. Such variables are free with respect to the scope in which they appear. For example, the first

expression is allowed, while the second equivalent expression isn't allowed because `s/name` is free with respect to the scope of the range variable `a`:

1. `stores/any(s: s/amenities/any(a: a eq 'parking') and s/name ne 'Flagship')`
2. `stores/any(s: s/amenities/any(a: a eq 'parking' and s/name ne 'Flagship'))`

This limitation shouldn't be a problem in practice since it's always possible to construct filters such that lambda expressions contain only bound variables.

Cheat sheet for collection filter rules

The following table summarizes the rules for constructing valid filters for each collection data type.

[Expand table](#)

Data type	Features allowed in lambda expressions with <code>any</code>	Features allowed in lambda expressions with <code>all</code>
<code>Collection(Edm.ComplexType)</code>	Everything except <code>search.ismatch</code> and <code>search.ismatchscoring</code>	Same
<code>Collection(Edm.String)</code>	Comparisons with <code>eq</code> or <code>search.in</code>	Comparisons with <code>ne</code> or <code>not search.in()</code>
	Combining sub-expressions with <code>or</code>	Combining sub-expressions with <code>and</code>
<code>Collection(Edm.Boolean)</code>	Comparisons with <code>eq</code> or <code>ne</code>	Same
<code>Collection(Edm.GeographyPoint)</code>	Using <code>geo.distance</code> with <code>lt</code> or <code>le</code> <code>geo.intersects</code>	Using <code>geo.distance</code> with <code>gt</code> or <code>ge</code> <code>not geo.intersects(...)</code>
	Combining sub-expressions with <code>or</code>	Combining sub-expressions with <code>and</code>
<code>Collection(Edm.DateTimeOffset),</code> <code>Collection(Edm.Double),</code> <code>Collection(Edm.Int32),</code> <code>Collection(Edm.Int64)</code>	Comparisons using <code>eq</code> , <code>ne</code> , <code>lt</code> , <code>gt</code> , <code>le</code> , or <code>ge</code>	Comparisons using <code>eq</code> , <code>ne</code> , <code>lt</code> , <code>gt</code> , <code>le</code> , or <code>ge</code>
	Combining comparisons with other sub-expressions using <code>or</code>	Combining comparisons with other sub-expressions using <code>and</code>

Data type	Features allowed in lambda expressions with <code>any</code>	Features allowed in lambda expressions with <code>all</code>
	<p>Combining comparisons except <code>ne</code> with other sub-expressions using <code>and</code></p> <p>Expressions using combinations of <code>and</code> and <code>or</code> in Disjunctive Normal Form (DNF) ↴</p>	<p>Combining comparisons except <code>eq</code> with other sub-expressions using <code>or</code></p> <p>Expressions using combinations of <code>and</code> and <code>or</code> in Conjunctive Normal Form (CNF) ↴</p>

For examples of how to construct valid filters for each case, see [How to write valid collection filters](#).

If you write filters often, and understanding the rules from first principles would help you more than just memorizing them, see [Understanding OData collection filters in Azure AI Search](#).

Text normalization for case-insensitive filtering, faceting and sorting

09/28/2025

In Azure AI Search, a *normalizer* is a component that pre-processes text for keyword matching over fields marked as "filterable", "facetable", or "sortable". In contrast with full text "searchable" fields that are paired with [text analyzers](#), content that's created for filter-facet-sort operations doesn't undergo analysis or tokenization. Omission of text analysis can produce unexpected results when casing and character differences show up, which is why you need a normalizer to homogenize variations in your content.

By applying a normalizer, you can achieve light text transformations that improve results:

- Consistent casing (such as all lowercase or uppercase)
- Normalize accents and diacritics like ö or ê to ASCII equivalent characters "o" and "e"
- Map characters like - and whitespace into a user-specified character

Benefits of normalizers

Searching and retrieving documents from a search index requires matching the query input to the contents of the document. Matching is either over tokenized content, as is the case when you invoke "search", or over non-tokenized content if the request is a [filter](#), [facet](#), or [orderby](#) operation.

Because non-tokenized content is also not analyzed, small differences in the content are evaluated as distinctly different values. Consider the following examples:

- `$filter=City eq 'Las Vegas'` will only return documents that contain the exact text "Las Vegas" and exclude documents with "LAS VEGAS" and "las vegas", which is inadequate when the use-case requires all documents regardless of the casing.
- `search=*&facet=City,count:5` will return "Las Vegas", "LAS VEGAS" and "las vegas" as distinct values despite being the same city.
- `search=usa&$orderby=City` will return the cities in lexicographical order: "Las Vegas", "Seattle", "las vegas", even if the intent is to order the same cities together irrespective of the case.

A normalizer, which is invoked during indexing and query execution, adds light transformations that smooth out minor differences in text for filter, facet, and sort scenarios. In the previous

examples, the variants of "Las Vegas" would be processed according to the normalizer you select (for example, all text is lower-cased) for more uniform results.

How to specify a normalizer

Normalizers are specified in an index definition, on a per-field basis, on text fields (`Edm.String` and `Collection(Edm.String)`) that have at least one of "filterable", "sortable", or "facetable" properties set to true. Setting a normalizer is optional and is null by default. We recommend evaluating predefined normalizers before configuring a custom one.

Normalizers can only be specified when you add a new field to the index, so if possible, try to assess the normalization needs upfront and assign normalizers in the initial stages of development when dropping and recreating indexes is routine.

1. When creating a field definition in the [index](#), set the "normalizer" property to one of the following values: a [predefined normalizer](#) such as "lowercase", or a custom normalizer (defined in the same index schema).

JSON

```
"fields": [
{
  "name": "Description",
  "type": "Edm.String",
  "retrievable": true,
  "searchable": true,
  "filterable": true,
  "analyzer": "en.microsoft",
  "normalizer": "lowercase"
  ...
}
]
```

2. Custom normalizers are defined in the "normalizers" section of the index first, and then assigned to the field definition as shown in the previous step. For more information, see [Create Index](#) and also [Add custom normalizers](#).

JSON

```
"fields": [
{
  "name": "Description",
  "type": "Edm.String",
  "retrievable": true,
  "searchable": true,
  "analyzer": null,
}
```

```
    "normalizer": "my_custom_normalizer"  
},
```

!**Note**

To change the normalizer of an existing field, [rebuild the index](#) entirely (you cannot rebuild individual fields).

A good workaround for production indexes, where rebuilding indexes is costly, is to create a new field identical to the old one but with the new normalizer, and use it in place of the old one. Use [Update Index](#) to incorporate the new field and [mergeOrUpload](#) to populate it. Later, as part of planned index servicing, you can clean up the index to remove obsolete fields.

Predefined and custom normalizers

Azure AI Search provides built-in normalizers for common use-cases along with the capability to customize as required.

 [Expand table](#)

Category	Description
Predefined normalizers	Provided out-of-the-box and can be used without any configuration.
Custom normalizers ¹	For advanced scenarios. Requires user-defined configuration of a combination of existing elements, consisting of char and token filters.

⁽¹⁾ Custom normalizers don't specify tokenizers since normalizers always produce a single token.

Normalizers reference

Predefined normalizers

 [Expand table](#)

Name	Description and Options
standard	Lowercases the text followed by asciifolding.
lowercase	Transforms characters to lowercase.

Name	Description and Options
uppercase	Transforms characters to uppercase.
asciifolding	Transforms characters that aren't in the Basic Latin Unicode block to their ASCII equivalent, if one exists. For example, changing à to a.
elision	Removes elision from beginning of the tokens.

Supported char filters

Normalizers support two character filters that are identical to their counterparts in [custom analyzer character filters](#):

- [mapping ↗](#)
- [pattern_replace ↗](#)

Supported token filters

The list below shows the token filters supported for normalizers and is a subset of the overall [token filters used in custom analyzers](#).

- [arabic_normalization ↗](#)
- [asciifolding ↗](#)
- [cjk_width ↗](#)
- [elision ↗](#)
- [german_normalization ↗](#)
- [hindi_normalization ↗](#)
- [indic_normalization ↗](#)
- [persian_normalization ↗](#)
- [scandinavian_normalization ↗](#)
- [scandinavian_folding ↗](#)
- [sorani_normalization ↗](#)
- [lowercase ↗](#)
- [uppercase ↗](#)

Add custom normalizers

Custom normalizers are [defined within the index schema](#). The definition includes a name, a type, one or more character filters and token filters. The character filters and token filters are the building blocks for a custom normalizer and responsible for the processing of the text. These filters are applied from left to right.

The `token_filter_name_1` is the name of token filter, and `char_filter_name_1` and `char_filter_name_2` are the names of char filters (see [supported token filters](#) and [supported char filters](#) tables below for valid values).

JSON

```
"normalizers":(optional)[
  {
    "name": "name of normalizer",
    "@odata.type": "#Microsoft.Azure.Search.CustomNormalizer",
    "charFilters": [
      "char_filter_name_1",
      "char_filter_name_2"
    ],
    "tokenFilters": [
      "token_filter_name_1"
    ]
  }
],
"charFilters":(optional)[
  {
    "name": "char_filter_name_1",
    "@odata.type": "#char_filter_type",
    "option1": "value1",
    "option2": "value2",
    ...
  }
],
"tokenFilters":(optional)[
  {
    "name": "token_filter_name_1",
    "@odata.type": "#token_filter_type",
    "option1": "value1",
    "option2": "value2",
    ...
  }
]
```

Custom normalizers can be added during index creation or later by updating an existing one. Adding a custom normalizer to an existing index requires the "allowIndexDowntime" flag to be specified in [Update Index](#) and will cause the index to be unavailable for a few seconds.

Custom normalizer example

The example below illustrates a custom normalizer definition with corresponding character filters and token filters. Custom options for character filters and token filters are specified separately as named constructs, and then referenced in the normalizer definition as illustrated below.

- A custom normalizer named "my_custom_normalizer" is defined in the "normalizers" section of the index definition.
- The normalizer is composed of two character filters and three token filters: elision, lowercase, and customized asciifolding filter "my_asciifolding".
- The first character filter "map_dash" replaces all dashes with underscores while the second one "remove_whitespace" removes all spaces.

JSON

```
{
  "name": "myindex",
  "fields": [
    {
      "name": "id",
      "type": "Edm.String",
      "key": true,
      "searchable": false,
    },
    {
      "name": "city",
      "type": "Edm.String",
      "filterable": true,
      "facetable": true,
      "normalizer": "my_custom_normalizer"
    }
  ],
  "normalizers": [
    {
      "name": "my_custom_normalizer",
      "@odata.type": "#Microsoft.Azure.Search.CustomNormalizer",
      "charFilters": [
        "map_dash",
        "remove_whitespace"
      ],
      "tokenFilters": [
        "my_asciifolding",
        "elision",
        "lowercase",
      ]
    }
  ],
  "charFilters": [
    {
      "name": "map_dash",
      "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",
      "mappings": [ "-=>_"]
    },
    {
      "name": "remove_whitespace",
      "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",
      "mappings": [ "\u0020=>" ]
    }
  ]
}
```

```
        }
    ],
    "tokenFilters":[
        {
            "name":"my_asciifolding",
            "@odata.type": "#Microsoft.Azure.Search.AsciiFoldingTokenFilter",
            "preserveOriginal":true
        }
    ]
}
```

Add faceted navigation to search results

Faceted navigation is used for self-directed filtering on query results in a search app, where your application offers form controls for scoping search to groups of documents (for example, categories or brands), and Azure AI Search provides the data structures and filters to back the experience.

In this article, learn the steps for returning a faceted navigation structure in Azure AI Search. Once you're familiar with basic concepts and clients, continue to [Facet examples](#) for syntax about various use cases, including basic facetting and distinct counts.

More facet capabilities are available through preview APIs:

- hierarchical facet structures
- facet filtering
- facet aggregations

[Facet navigation examples](#) provide the syntax and usage for the preview features.

Faceted navigation in a search page

Facets are dynamic because they're based on each specific query result set. A search response brings with it all of the facet buckets used to navigate the documents in the result. The query executes first, and then facets are pulled from the current results and assembled into a faceted navigation structure.

In Azure AI Search, facets are one layer deep and can't be hierarchical unless you use the preview API. If you aren't familiar with faceted navigation structures, the following example shows one on the left. Counts indicate the number of matches for each facet. The same document can be represented in multiple facets.

The hotel rooms and suites offer the perfect blend of beauty and elegance. Our rooms will elevate your stay, whether you're traveling for business, celebrating a honeymoon, or just looking for a remarkable getaway. With views of the valley or the iconic fountains right from your suite, your stay will be nothing short of unforgettable.

|< < 1 2 3 4 5 > >|

Facets can help you find what you're looking for, while ensuring that you don't get zero results. As a developer, facets let you expose the most useful search criteria for navigating your search index.

Faceted navigation in code

Facets are enabled on supported fields in an index, and then specified on a query. The faceted navigation structure is returned at the beginning of the response, followed by the results.

The following REST example is an empty query (`"search": "*"`) that is scoped to the entire index (see the [built-in hotels sample](#)). The `facets` parameter specifies the "Category" field.

HTTP

```
POST https://{{service_name}}.search.windows.net/indexes/hotels/docs/search?api-version={{api_version}}
{
  "search": "*",
  "queryType": "simple",
  "select": "",
  "searchFields": "",
  "filter": "",
```

```
        "facets": [ "Category"],
        "orderby": "",
        "count": true
    }
```

The response for the example starts with the faceted navigation structure. The structure consists of "Category" values and a count of the hotels for each one. It's followed by the rest of the search results, trimmed here to just one document for brevity. This example works well for several reasons. The number of facets for this field fall under the limit (default is 10) so all of them appear, and every hotel in the index of 50 hotels is represented in exactly one of these categories.

Enable facets on fields

You can add facets to new fields that contain plain text or numeric content. Supported data types include strings, dates, boolean fields, and numeric fields (but not vectors).

You can use the Azure portal, REST APIs, Azure SDKs or any method that supports the creation or update of index schemas in Azure AI Search. As a first step, identify which fields to use for faceting.

Choose which fields to attribute

Facets can be calculated over single-value fields and collections. Fields that work best in faceted navigation have these characteristics:

- Human readable (nonvector) content.
- Low cardinality (a few distinct values that repeat throughout documents in your search corpus).
- Short descriptive values (one or two words) that render nicely in a navigation tree.

The values within a field, and not the field name itself, produce the facets in a faceted navigation structure. If the facet is a string field named *Color*, facets are blue, green, and any other value for that field. Review field values to ensure there are no typos, nulls, or casing differences. Consider [assigning a normalizer](#) to a filterable and facetable field to smooth out minor variations in the text. For example, "Canada", "CANADA", and "canada" would all be normalized to one bucket.

Avoid unsupported fields

You can't set facets on existing fields, on vector fields, or fields of type `Edm.GeographyPoint` or `Collection(Edm.GeographyPoint)`.

On complex field collections, "facetable" must be null.

Start with new field definitions

Attributes that affect how a field is indexed can only be set when fields are created. This restriction applies to facets and filters.

If your index already exists, you can add a new field definition that provides facets. Existing documents in the index get a null value for the new field. This null value is replaced the next time you [refresh the index](#).

Azure portal

1. In the search services page of the [Azure portal](#), go to the **Fields** tab of the index and select **Add field**.
2. Provide a name, data type, and attributes. We recommend adding filterable because it's common to set filters based on a facet bucket in the response. We recommend sortable because filters produce unordered results, and you might want to sort them in your application.

You can also set searchable if you also want to support full text search on the field, and retrievable if you want to include the field in the search response.

The screenshot shows the Microsoft Azure portal interface for managing an index named 'hotels'. At the top, there are navigation links for 'Home', 'Copilot', and a user profile. Below the header, the index details are shown: 'Documents: 12', 'Total storage: 61.15 KB', 'Vector index quota usage: 0 Bytes', and 'Max storage: 15 GB'. The 'Fields' tab is currently selected. In the 'Fields' section, there is a table listing fields like 'Id', 'Modified', 'IsDeleted', 'HotelName', 'Category', 'City', 'State', and 'Description', each with its type (String, DateTimeOffset, Int32) and various searchable attributes (Retrievable, Filterable, Sortable, Facetable). The 'Category' field is highlighted with a red box around its row, and its 'Facetable' checkbox is also checked. To the right of the table, there is a panel titled 'Index Field' with fields for 'Field name' (set to 'CategoryFacets') and 'Type' (set to 'Edm.String'). Below this is a 'Configure attributes' section with checkboxes for 'Retrievable', 'Filterable' (which is checked), 'Sortable' (which is checked), and 'Facetable' (which is checked). There are also 'Searchable' and 'Autocomplete settings' checkboxes. At the bottom right of the main area are 'Save' and 'Cancel' buttons.

3. Save the field definition.

Return facets in a query

Recall that facets are dynamically calculated from results in a query response. You only get facets for documents found by the current query.

Azure portal

Use JSON view in Search Explorer to set facet parameters in the [Azure portal ↗](#).

1. Select an index and open Search Explorer in JSON View.
2. Provide a query in JSON. You can type it out, copy the JSON from a REST example, or use intellisense to help with syntax. Refer to the REST example in the next tab for reference on facet expressions.
3. Select **Search** to return faceted results, articulated in JSON.

Here's a screenshot of the [basic facet query example](#) on the [hotels sample index](#). You can paste in other examples in this article to return the results in Search Explorer.

Best practices for working with facets

This section is a collection of tips and workarounds that are helpful for application development.

We recommend the [C#: Add search to web apps](#) for an example of faceted navigation that includes code for the presentation layer. The sample also includes filters, suggestions, and autocomplete. It uses JavaScript and React for the presentation layer.

Initialize a faceted navigation structure with an unqualified or empty search string

It's useful to initialize a search page with an open query (`"search": "*"`) to completely fill in the faceted navigation structure. As soon as you pass query terms in the request, the faceted navigation structure is scoped to just the matches in the results, rather than the entire index. This practice is helpful for verifying facet and filter behaviors during testing. If you include match criteria in the query, the response excludes documents that don't match, which has the potential downstream effect of excluding facets.

Clear facets

When you design the user experience, remember to add a mechanism for clearing facets. A common approach for clearing facets is issuing an open query to reset the page.

Disable facetting to save on storage and improve performance

For performance and storage optimization, set `"facetable": false` for fields that should never be used as a facet. Examples include string fields for unique values, such as an ID or product name, to prevent their accidental (and ineffective) use in faceted navigation. This best practice is especially important for the REST API, which enables filters and facets on string fields by default.

Remember that you can't use `Edm.GeographyPoint` or `Collection(Edm.GeographyPoint)` fields in faceted navigation. Recall that facets work best on fields with low cardinality. Due to how geo-coordinates resolve, it's rare that any two sets of coordinates are equal in a given dataset. As such, facets aren't supported for geo-coordinates. You should use a city or region field to facet by location.

Check for bad data

As you prepare data for indexing, check fields for null values, misspellings or case discrepancies, and single and plural versions of the same word. By default, filters and facets don't undergo lexical analysis or [spell check](#), which means that all values of a "facetable" field are potential facets, even if the words differ by one character.

[Normalizers](#) can mitigate data discrepancies, correcting for casing and character differences. Otherwise, to inspect your data, you can check fields at their source, or run queries that return values from the index.

An index isn't the best place to fix nulls or invalid values. You should fix data problems in your source, assuming it's a database or persistent storage, or in a data cleansing step that you perform prior to indexing.

Ordering facet buckets

Although you can sort within a bucket, there's no parameters for controlling the order of facet buckets in the navigation structure as a whole. If you want facet buckets in a specific order, you must provide it in application code.

Discrepancies in facet counts

Under certain circumstances, you might find that facet counts aren't fully accurate due to the [sharding architecture](#). Every search index is spread across multiple shards, and each shard reports the top N facets by document count, which are then combined into a single result. Because it's just the top N facets for each shard, it's possible to miss or under-count matching documents in the facet response.

To guarantee accuracy, you can artificially inflate the count:<number> to a large number to force full reporting from each shard. You can specify `"count": "0"` for unlimited facets. Or, you can set "count" to a value that's greater than or equal to the number of unique values of the faceted field. For example, if you're faceting by a "size" field that has five unique values, you could set `"count:5"` to ensure all matches are represented in the facet response.

The tradeoff with this workaround is increased query latency, so use it only when necessary.

Preserve a facet navigation structure asynchronously of filtered results

In Azure AI Search, facets exist for current results only. However, it's a common application requirement to retain a static set of facets so that the user can navigate in reverse, retracing steps to explore alternative paths through search content.

If you want a static set of facets alongside a dynamic drilldown experience, you can implement it by using two filtered queries: one scoped to the results, the other used to create a static list of facets for navigation purposes.

Offset large facet counts through filters

Search results and facet results that are too large can be trimmed by [adding filters](#). In the following example, in the query for *cloud computing*, 254 items have *internal specification* as a content type. If results are too large, adding filters can help your users refine the query by adding more criteria.

Items aren't mutually exclusive. If an item meets the criteria of both filters, it's counted in each one. This duplication is possible when faceting on `Collection(Edm.String)` fields, which are often used to implement document tagging.

Output

Search term: "cloud computing"

Content type

Internal specification (254)

Video (10)

[Facet navigation examples](#)

Last updated on 11/05/2025

Faceted navigation examples

This section extends [faceted navigation configuration](#) with examples that demonstrate basic usage and other scenarios.

Facetable fields are defined in an index, but facet parameters and expressions are defined in query requests. If you have an index with facetable fields, you can try new preview features like [facet hierarchies](#), [facet aggregations](#), and [facet filters](#) on existing indexes.

Facet parameters and syntax

Depending on the API, a facet query is usually an array of facet expressions that are applied to search results. Each facet expression contains a facetable field name, optionally followed by a comma-separated list of name-value pairs.

- *facet query* is a query request that includes a facet property.
- *facetable field* is a field definition in the search index attributed with the `facetable` property.
- *count* is the number of matches for each facet found in the search results.

The following table describes facet parameters used in the examples.

 [Expand table](#)

Facet parameter	Description	Usage	Example
<code>count</code>	Maximum number of facet terms per structure.	Integer. Default is 10. There's no upper limit, but higher values degrade performance, especially if the faceted field contains a large number of unique terms. This is due to the way facet queries are distributed across shards. You can set <code>count</code> to zero or to a value that's greater than or equal to the number of unique values in the	<code>Tags,count:5</code> limits the faceted navigation response to 5 facet buckets that containing the most facet counts, but they can be in any order.

Facet	Description	Usage	Example
parameter		facetable field to get an accurate count across all shards. The tradeoff is increased latency.	
sort	Determines order of facet buckets.	Valid values are <code>count</code> , <code>-count</code> , <code>value</code> , <code>-value</code> . Use <code>count</code> to list facets from greatest to smallest. Use <code>-count</code> to sort in ascending order (smallest to greatest). Use <code>value</code> to sort alphanumerically by facet value in ascending order. Use <code>-value</code> to sort descending by value.	"facet=Category, count:3, sort:count" gets the top three facet buckets in search results, listed in descending order by the number of matches in each Category. If the top three categories are Budget, Extended-Stay, and Luxury, and Budget has 5 hits, Extended-Stay has 6, and Luxury has 4, then the facet buckets are ordered as Extended-Stay, Budget, Luxury. Another example is "facet=Rating, sort:-value". It produces facets for all possible ratings, in descending order by value. If ratings are from 1 to 5, the facets are ordered 5, 4, 3, 2, 1, irrespective of how many documents match each rating.
values	Provides values for facet labels.	Set to pipe-delimited numeric or <code>Edm.DateTimeOffset</code> values specifying a dynamic set of facet entry values. The values must be listed in sequential, ascending order to get the expected results.	"facet=baseRate, values:10 20" produces three facet buckets: one for base rate 0 up to but not including 10, one for 10 up to but not including 20, and one for 20 and higher. A string "facet=lastRenovationDate, values:2024-02-01T00:00:00Z" produces two facet buckets: one for hotels renovated before February 2024, and one for hotels renovated February 1, 2024 or later.
interval	Provides an interval sequence for facets that can be grouped into intervals.	An integer interval greater than zero for numbers, or minute, hour, day, week, month, quarter, year for date time values.	"facet=baseRate, interval:100" produces facet buckets based on base rate ranges of size 100. If base rates are all between \$60 and \$600, there are facet buckets for 0-100, 100-200, 200-300, 300-400, 400-500, and 500-600. The string "facet=lastRenovationDate, interval:year" produces one facet bucket for each year a hotel was renovated.
timeoffset	Specifies the UTC	Set to <code>([+-]hh:mm, [+-]hhmm,</code> or	"facet=lastRenovationDate, interval:day, timeoffset:-01:00" uses the day boundary that starts at 01:00:00 UTC (midnight

Facet	Description	Usage	Example
parameter	time offset to account for in setting time boundaries.	[+-]hh). If used, the parameter must be combined with the interval option, and only when applied to a field of type Edm.DateTimeOffset.	in the target time zone).

`count` and `sort` can be combined in the same facet specification, but they can't be combined with `interval` or `values`.

`interval` and `values` can't be combined together.

Interval facets on date time are computed based on the UTC time if `timeoffset` isn't specified. For example, for `"facet=lastRenovationDate,interval:day"`, the day boundary starts at 00:00:00 UTC.

Basic facet example

The following facet queries work against the [hotels sample index](#). You can use [JSON view](#) in Search Explorer to paste in the JSON query. For help with getting started, see [Add faceted navigation to search results](#).

This first query retrieves facets for Categories, Ratings, Tags, and rooms with baseRate values in specific ranges. Notice the last facet is on a subfield of the Rooms collection. Facets count the parent document (Hotels) and not intermediate subdocuments (Rooms), so the response determines the number of *hotels* that have any rooms in each pricing category.

rest

```
POST /indexes/hotels-sample-index/docs/search?api-version={{api_version}}
{
  "search": "ocean view",
  "facets": [ "Category", "Rating", "Tags", "Rooms/BaseRate,values:80|150|220" ],
  "count": true
}
```

This second example uses a filter to narrow down the previous faceted query result after the user selects Rating 3 and category "Motel".

rest

```
POST /indexes/hotels-sample-index/docs/search?api-version={{api_version}}
{
```

```
"search": "water view",
"facets": [ "Tags", "Rooms/BaseRate,values:80|150|220" ],
"filter": "Rating eq 3 and Category eq 'Motel'",
"count": true
}
```

The third example sets an upper limit on unique terms returned in a query. The default is 10, but you can increase or decrease this value using the count parameter on the facet attribute. This example returns facets for city, limited to 5.

rest

```
POST /indexes/hotels-sample-index/docs/search?api-version={{api_version}}
{
  "search": "view",
  "facets": [ "Address/City,count:5" ],
  "count": true
}
```

This example shows three facets for "Category", "Tags", and "Rating", with a count override on "Tags" and a range override for "Rating", which is otherwise stored as a double in the index.

HTTP

```
POST https://{{service_name}}.search.windows.net/indexes/hotels/docs/search?api-
version={{api_version}}
{
  "search": "*",
  "facets": [
    "Category",
    "Tags,count:5",
    "Rating,values:1|2|3|4|5"
  ],
  "count": true
}
```

For each faceted navigation tree, there's a default limit of the top 10 facet instances found by the query. This default makes sense for navigation structures because it keeps the values list to a manageable size. You can override the default by assigning a value to "count". For example, "Tags,count:5" reduces the number of tags under the Tags section to the top five.

For Numeric and DateTime values only, you can explicitly set values on the facet field (for example, `facet=Rating,values:1|2|3|4|5`) to separate results into contiguous ranges (either ranges based on numeric values or time periods). Alternatively, you can add "interval", as in `facet=Rating,interval:1`.

Each range is built using 0 as a starting point, a value from the list as an endpoint, and then trimmed of the previous range to create discrete intervals.

Distinct values example

You can formulate a query that returns a distinct value count for each facetable field. This example formulates an empty or unqualified query ("search": "*") that matches on all documents, but by setting `top` to zero, you get just the counts, with no results.

For brevity, this query includes just two fields marked as `facetable` in the hotels sample index.

HTTP

```
POST https://{{service_name}}.search.windows.net/indexes/hotels/docs/search?api-version={{api_version}}
{
  "search": "*",
  "count": true,
  "top": 0,
  "facets": [
    "Category", "Address/StateProvince"
  ]
}
```

Results from this query are as follows:

JSON

```
{
  "@odata.count": 50,
  "@search.facets": {
    "Address/StateProvince": [
      {
        "count": 9,
        "value": "WA"
      },
      {
        "count": 6,
        "value": "CA"
      },
      {
        "count": 4,
        "value": "FL"
      },
      {
        "count": 3,
        "value": "NY"
      },
      {
        "count": 3,
        "value": "OR"
      },
      {
        "count": 3,
        "value": "TX"
      }
    ]
  }
}
```

```

},
{
  "count": 2,
  "value": "GA"
},
{
  "count": 2,
  "value": "MA"
},
{
  "count": 2,
  "value": "TN"
},
{
  "count": 1,
  "value": "AZ"
}
],
"Category": [
  {
    "count": 13,
    "value": "Budget"
  },
  {
    "count": 12,
    "value": "Suite"
  },
  {
    "count": 7,
    "value": "Boutique"
  },
  {
    "count": 7,
    "value": "Resort and Spa"
  },
  {
    "count": 6,
    "value": "Extended-Stay"
  },
  {
    "count": 5,
    "value": "Luxury"
  }
]
},
"value": []
}

```

Facet hierarchy example

① Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Using the [latest preview REST API](#) or the Azure portal, you can configure a facet hierarchy using the `>` and `;` operators.

[+] Expand table

Operator	Description
<code>></code>	Nesting (hierarchical) operator denotes a parent–child relationship.
<code>;</code>	Semicolon operator denotes multiple fields at the same nesting level, which are all children of the same parent. The parent must contain only one field. Both the parent and child fields must be <code>facetable</code> .

The order of operations in a facet expression that includes facet hierarchies are:

- The options operator (comma `,`) that separates facet parameters for the facet field, such as the comma in `Rooms/BaseRate,values`
- The parentheses, such as the ones enclosing `(Rooms/BaseRate,values:50 ; Rooms/Type)`.
- The nesting operator (angled bracket `>`)
- The append operator (semicolon `;`), demonstrated in a second example `"Tags>(Rooms/BaseRate,values:50 ; Rooms/Type)"` in this section, where two child facets are peers under the Tags parent.

Notice that parentheses are processed before nesting and append operations: `A > B ; C` would be different than `A > (B ; C)`.

There are several examples for facet hierarchies. The first example is a query that returns just a few documents, which is helpful for viewing a full response. Facets count the parent document (Hotels) and not intermediate subdocuments (Rooms), so the response determines the number of *hotels* that have any rooms in each facet bucket.

rest

```
POST /indexes/hotels-sample-index/docs/search?api-version=2025-11-01-Preview
{
  "search": "ocean",
  "facets": ["Address/StateProvince>Address/City", "Tags>Rooms/BaseRate,values:50"],
  "select": "HotelName, Description, Tags, Address/StateProvince, Address/City",
  "count": true
}
```

Results from this query are as follows. Both hotels have pools. For other tags, only one hotel provides the amenity.

JSON

```
{  
    "@odata.count": 2,  
    "@search.facets": {  
        "Tags": [  
            {  
                "value": "pool",  
                "count": 2,  
                "@search.facets": {  
                    "Rooms/BaseRate": [  
                        {  
                            "to": 50,  
                            "count": 0  
                        },  
                        {  
                            "from": 50,  
                            "count": 2  
                        }  
                    ]  
                }  
            },  
            {  
                "value": "air conditioning",  
                "count": 1,  
                "@search.facets": {  
                    "Rooms/BaseRate": [  
                        {  
                            "to": 50,  
                            "count": 0  
                        },  
                        {  
                            "from": 50,  
                            "count": 1  
                        }  
                    ]  
                }  
            },  
            {  
                "value": "bar",  
                "count": 1,  
                "@search.facets": {  
                    "Rooms/BaseRate": [  
                        {  
                            "to": 50,  
                            "count": 0  
                        },  
                        {  
                            "from": 50,  
                            "count": 1  
                        }  
                    ]  
                }  
            }  
        ]  
    }  
}
```

```
        }
    },
{
    "value": "restaurant",

{
    "value": "FL",
    "count": 1,
    "@search.facets": {
        "Address/City": [
            {
                "value": "Tampa",
                "count": 1
            }
        ]
    }
},
{
    "value": "HI",
    "count": 1,
    "@search.facets": {
        "Address/City": [
            {
                "value": "Honolulu",
                "count": 1
            }
        ]
    }
}
```

```

        }
    ]
}
],
},
"value": [
{
    "@search.score": 1.6076145,
    "HotelName": "Ocean Water Resort & Spa",
    "Description": "New Luxury Hotel for the vacation of a lifetime. Bay views from every room, location near the pier, rooftop pool, waterfront dining & more.",
    "Tags": [
        "view",
        "pool",
        "restaurant"
    ],
    "Address": {
        "City": "Tampa",
        "StateProvince": "FL"
    }
},
{
    "@search.score": 1.0594962,
    "HotelName": "Windy Ocean Motel",
    "Description": "Oceanfront hotel overlooking the beach features rooms with a private balcony and 2 indoor and outdoor pools. Inspired by the natural beauty of the island, each room includes an original painting of local scenes by the owner. Rooms include a mini fridge, Keurig coffee maker, and flatscreen TV. Various shops and art entertainment are on the boardwalk, just steps away.",
    "Tags": [
        "pool",
        "air conditioning",
        "bar"
    ],
    "Address": {
        "City": "Honolulu",
        "StateProvince": "HI"
    }
}
]
}

```

This second example extends the previous one, demonstrating multiple top-level facets with multiple children. Notice the semicolon (;) operator separates each child.

rest

```

POST /indexes/hotels-sample-index/docs/search?api-version=2025-11-01-Preview
{
    "search": "+ocean",
    "facets": ["Address/StateProvince > Address/City", "Tags > (Rooms/BaseRate,values:50
; Rooms/Type)"],
    "select": "HotelName, Description, Tags, Address/StateProvince, Address/City",

```

```
"count": true  
}
```

A partial response, trimmed for brevity, shows Tags with child facets for the rooms base rate and type. In the hotels sample index, both hotels that match to `+ocean` have rooms in each type and a pool.

JSON

```
{  
  "@odata.count": 2,  
  "@search.facets": {  
    "Tags": [  
      {  
        "value": "pool",  
        "count": 2,  
        "@search.facets": {  
          "Rooms/BaseRate": [  
            {  
              "to": 50,  
              "count": 0  
            },  
            {  
              "from": 50,  
              "count": 2  
            }  
          ],  
          "Rooms/Type": [  
            {  
              "value": "Budget Room",  
              "count": 2  
            },  
            {  
              "value": "Deluxe Room",  
              "count": 2  
            },  
            {  
              "value": "Standard Room",  
              "count": 2  
            },  
            {  
              "value": "Suite",  
              "count": 2  
            }  
          ]  
        }  
      }  
    ]  
  }  
}  
...  
}
```

This last example shows precedence rules for parentheses that affects nesting levels. Suppose you want to return a facet hierarchy in this order.

```
Address/StateProvince
```

```
  Address/City
```

```
    Category
```

```
    Rating
```

To return this hierarchy, create a query where Category and Rating are siblings under Address/City.

JSON

```
{  
  "search": "beach",  
  "facets": [  
    "Address/StateProvince > (Address/City > (Category ; Rating))"  
  ],  
  "select": "HotelName, Description, Tags, Address/StateProvince, Address/City",  
  "count": true  
}
```

If you remove the innermost parentheses, Category and Rating are no longer siblings because the precedence rules mean that the `>` operator is evaluated before `;`.

JSON

```
{  
  "search": "beach",  
  "facets": [  
    "Address/StateProvince > (Address/City > Category ; Rating)"  
  ],  
  "select": "HotelName, Description, Tags, Address/StateProvince, Address/City",  
  "count": true  
}
```

The top-level parent is still Address/StateProvince, but now Address/City and Rating are on same level.

```
Address/StateProvince
```

```
  Rating
```

```
  Address/City
```

```
    Category
```

Facet filtering example

 Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Using the [latest preview REST API](#) or the Azure portal, you can configure facet filters.

Facet filtering enables you to constrain the facet values returned to those matching a specified regular expression. Two new parameters accept a regular expression that is applied to the facet field:

- `includeTermFilter` filters the facet values to those that match the regular expression
- `excludeTermFilter` filters the facet values to those that don't match the regular expression

If a facet string satisfies both conditions, the `excludeTermFilter` takes precedence because the set of bucket strings is first evaluated with `includeTermFilter` and then excluded with `excludeTermFilter`.

Only those facet values that match the regular expression are returned. You can combine these parameters with other facet options (for example, `count`, `sort`, and [hierarchical faceting](#)) on string fields.

Because the regular expression is nested within a JSON string value, you must escape both the double quote (`"`) and the backslash (`\`) characters. The regular expression itself is delimited by the forward slash (`/`). For more information about escape patterns, see [Regular expression search](#).

The following example shows how to escape special characters in your regular expression such as backslash, double quotes, or regular expression syntax characters.

JSON

```
{  
  "search": "*",
  "facets": [
    "name,includeTermFilter:/EscapeBackslash\\\\OrDoubleQuote\\\"OrRegexCharacter\\/(/)"
  ]
}
```

Here's an example of a facet filter that matches on Budget and Extended-Stay hotels, with Rating as a child of each hotel category.

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2025-11-01-Preview
{
  "search": "*",
  "facets": [ "(Category,includeTermFilter:/(Budget|Extended-"
```

```

Stay())>Rating,values:1|2|3|4|5"],
  "select": "HotelName, Category, Rating",
  "count": true
}

```

The following example is an abbreviated response (hotel documents are omitted for brevity).

JSON

```
{
  "@odata.count": 50,
  "@search.facets": {
    "Category": [
      {
        "value": "Budget",
        "count": 13,
        "@search.facets": {
          "Rating": [
            {
              "to": 1,
              "count": 0
            },
            {
              "from": 1,
              "to": 2,
              "count": 0
            },
            {
              "from": 2,
              "to": 3,
              "count": 4
            },
            {
              "from": 3,
              "to": 4,
              "count": 5
            },
            {
              "from": 4,
              "to": 5,
              "count": 4
            },
            {
              "from": 5,
              "count": 0
            }
          ]
        }
      },
      {
        "value": "Extended-Stay",
        "count": 6,
        "@search.facets": {
          "Rating": [
            {

```

```
        "to": 1,
        "count": 0
    },
{
    "from": 1,
    "to": 2,
    "count": 0
},
{
    "from": 2,
    "to": 3,
    "count": 4
},
{
    "from": 3,
    "to": 4,
    "count": 1
},
{
    "from": 4,
    "to": 5,
    "count": 1
},
{
    "from": 5,
    "count": 0
}
]
}
],
{
    "value": [ ALL 50 HOTELS APPEAR HERE ]
}
```

Facet aggregation example

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Using the [latest preview REST API](#) or the Azure portal, you can aggregate facets.

Facet aggregations allow you to compute metrics from facet values. The aggregation capability works alongside the existing faceting options.

Aggregator	Description
Sum	Returns the total accumulated value from the field across all documents. Applies to numeric types only. Supported in earlier preview releases.
Min	Returns the minimum value from the field across all documents. Applies to numeric types only.
Max	Returns the maximum value from the field across all documents. Applies to numeric types only.
Avg	Returns the average value from the field across all documents. Applies to numeric types only.
Cardinality	Returns the approximate count of distinct values from the field across all documents using the HyperLogLog algorithm . You can request <code>cardinality</code> on facetable fields, including string and datetime fields (along with their corresponding collection forms).

Setting precision thresholds for cardinality aggregation

On a cardinality aggregation, you can set a `precisionThreshold` option as a demarcation between counts that are expected to be close to accurate, and counts that can be less accurate. The maximum value is 40,000. The default value is 3,000.

Faceting is performed in memory. Increasing `precisionThreshold` results in more memory consumption (the `precisionThreshold` value multiplied by 8 bytes).

Example: Sum facet aggregation

You can sum any facetable field of a numeric data type (except vectors and geographic coordinates).

Here's an example using the hotels-sample-index. The Rooms/SleepsCount field is facetable and numeric, so we choose this field to demonstrate sum. If we sum that field, we get the sleep count for the entire hotel. Recall that facets count the parent document (Hotels) and not intermediate subdocuments (Rooms), so the response sums the SleepsCount of all rooms for the entire hotel. In this query, we add a filter to sum the SleepsCount for just one hotel.

rest

```
POST /indexes/hotels-sample-index/docs/search?api-version=2025-11-01-Preview

{
  "search": "*",
  "filter": "HotelId eq '41'",
  "facets": [ "Rooms/SleepsCount", metric: sum"],
  "select": "HotelId, HotelName, Rooms/Type, Rooms/SleepsCount",
```

```
        "count": true
    }
```

A response for the query might look like the following example. Windy Ocean Model can accommodate a total of 40 guests.

JSON

```
{
    "@odata.count": 1,
    "@search.facets": {
        "Rooms/SleepsCount": [
            {
                "sum": 40.0
            }
        ]
    },
    "value": [
        {
            "@search.score": 1.0,
            "HotelId": "41",
            "HotelName": "Windy Ocean Motel",
            "Rooms": [
                {
                    "Type": "Suite",
                    "SleepsCount": 4
                },
                {
                    "Type": "Deluxe Room",
                    "SleepsCount": 2
                },
                {
                    "Type": "Budget Room",
                    "SleepsCount": 2
                },
                {
                    "Type": "Budget Room",
                    "SleepsCount": 2
                },
                {
                    "Type": "Suite",
                    "SleepsCount": 2
                },
                {
                    "Type": "Standard Room",
                    "SleepsCount": 2
                },
                {
                    "Type": "Deluxe Room",
                    "SleepsCount": 2
                },
                {
                    "Type": "Suite",
                    "SleepsCount": 2
                }
            ],
            "TotalSleeps": 40
        }
    ]
}
```

```
{
  "Type": "Suite",
  "SleepsCount": 4
},
{
  "Type": "Standard Room",
  "SleepsCount": 4
},
{
  "Type": "Standard Room",
  "SleepsCount": 2
},
{
  "Type": "Deluxe Room",
  "SleepsCount": 2
},
{
  "Type": "Suite",
  "SleepsCount": 2
},
{
  "Type": "Standard Room",
  "SleepsCount": 2
},
{
  "Type": "Deluxe Room",
  "SleepsCount": 2
},
{
  "Type": "Deluxe Room",
  "SleepsCount": 2
},
{
  "Type": "Standard Room",
  "SleepsCount": 2
}
]
}
]
```

Example: A composite of all aggregations

Here's an example using a hypothetical 'facets' index that shows the syntax for each aggregation. Notice that cardinality has an extra `precisionThreshold` option (default is 3,000) set to 40,000 in this example.

HTTP

```
POST https://search-service.search.windows.net/indexes/facets/docs/search?api-version=2025-11-01-Preview
Authorization: Bearer {{token}}
Content-Type: application/json
```

```
{
  "search": "*",
  "facets": [ // field names are named <something>Value in this example
    "cardinalityValue, metric: cardinality,precisionThreshold: 40000",
    "sumValue,metric: sum",
    "avgValue,metric: avg",
    "minValue,metric: min",
    "maxValue,metric: max"
  ]
}
```

A response for the query might look like the following example.

JSON

```
{
  "@search.facets": {
    "cardinalityValue": [
      {
        "cardinality": 24000 // Number of distinct values in "cardinalityValue" field
      }
    ],
    "sumValue": [
      {
        "sum": 1200000 // Sum of all values in "sumValue" field
      }
    ],
    "avgValue": [
      {
        "avg": 50 // Average of all values in "avgValue" field
      }
    ],
    "minValue": [
      {
        "min": 1 // Minimum value in "minValue" field
      }
    ],
    "maxValue": [
      {
        "max": 100 // Maximum value in "maxValue" field
      }
    ]
  }
}
```

Example: Specify a default to substitute for missing values

All metrics support specifying a default value when a document doesn't contain a value.

- For nonstring types (numeric, datetime, boolean), set the `default` parameter to a specific value: `"default: 42"`.
- For string types, set the `default` parameter to a string, delimited using the single apostrophe delimiter: `"default: 'mystringhere'"`.

You can add a default value to use if a document contains a null for that field: `"facets": [{"Rooms/SleepsCount, metric: sum, default:2"}]`. If a room has a null value for the Rooms/SleepsCount field, the default substitutes for the missing value.

Here's a request that illustrates the default specification for each field type.

HTTP

```
POST https://search-service.search.windows.net/indexes/facets/docs/search?api-version=2025-11-01-Preview
Authorization: Bearer {{token}}
Content-Type: application/json

{
  "search": "*",
  "facets": [ // field names are named <datatype>Value in this example
    "stringField, metric: cardinality, default: 'my string goes here'",
    "doubleField,metric: sum, default: 5.0",
    "intField,metric: sum, default: 5",
    "longField,metric: sum, default: 5"
  ]
}
```

For string fields, a default value is delimited using the single quote character. To escape the character, prefix it with the backslash `\"`. All characters are valid within the string delimiters. The terminating character can't be a backslash.

Example: Multiple metrics on the same field

If the underlying data supports the use case, you can specify multiple metrics on the same field.

HTTP

```
POST https://search-service.search.windows.net/indexes/facets/docs/search?api-version=2025-11-01-Preview
Authorization: Bearer {{token}}
Content-Type: application/json

{
  "search": "*",
  "facets": [
    "fieldA, metric: cardinality, precisionThreshold: 40000",
    "fieldA, metric: sum",
    "fieldA, metric: count"
  ]
}
```

```
        "fieldA, metric: avg",
        "fieldA, metric: min",
        "fieldA, metric: max"
    ]
}
```

A response for the query might look like the following example.

JSON

```
{
  "@search.facets": {
    "fieldA": [
      {
        "cardinality": 24000 // Number of distinct values in "fieldA" field
      },
      {
        "sum": 1200000 // Sum of all values in " fieldA " field
      },
      {
        "avg": 5 // Avg of all values in " fieldA " field
      },
      {
        "min": 0 // Min of all values in " fieldA " field
      },
      {
        "max": 1200 // Max of all values in " fieldA " field
      }
    ]
  }
}
```

Next steps

Revisit [facet navigation configuration](#) for tools and APIs, and review [best practices](#) for working with facets in code.

We recommend the [C#: Add search to web apps](#) for an example of faceted navigation that includes code for the presentation layer. The sample also includes filters, suggestions, and autocomplete. It uses JavaScript and React for the presentation layer.

Shape search results or modify search results composition in Azure AI Search

05/29/2025

This article explains search results composition and how to shape full text search results to fit your scenarios. Search results are returned in a query response. The shape of a response is determined by parameters in the query itself. These parameters include:

- Number of matches found in the index (`count`)
- Number of matches returned in the response (50 by default, configurable through `top`) or per page (`skip` and `top`)
- A search score for each result, used for ranking (`@search.score`)
- Fields included in search results (`select`)
- Sort logic (`orderby`)
- Highlighting of terms within a result, matching on either the whole or partial term in the body
- Optional elements from the semantic ranker (`answers` at the top, `captions` for each match)

Search results can include top-level fields, but most of the response consists of matching documents in an array.

Clients and APIs for defining the query response

You can use the following clients to configure a query response:

- [Search Explorer](#) in the Azure portal, using JSON view so that you can specify any supported parameter
- [Documents - POST \(REST APIs\)](#)
- [SearchClient.Search Method \(Azure SDK for .NET\)](#)
- [SearchClient.Search Method \(Azure SDK for Python\)](#)
- [SearchClient.Search Method \(Azure for JavaScript\)](#)
- [SearchClient.Search Method \(Azure for Java\)](#)

Result composition

Results are mostly tabular, composed of fields of either all `retrievable` fields, or limited to just those fields specified in the `select` parameter. Rows are the matching documents, typically ranked in order of relevance unless your query logic precludes relevance ranking.

You can choose which fields are in search results. While a search document might have a large number of fields, typically only a few are needed to represent each document in results. On a query request, append `select=<field list>` to specify which `retrievable` fields should appear in the response.

Pick fields that offer contrast and differentiation among documents, providing sufficient information to invite a clickthrough response on the part of the user. On an e-commerce site, it might be a product name, description, brand, color, size, price, and rating. For the built-in hotels-sample index, it might be the "select" fields in the following example:

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
  "search": "sandy beaches",
  "select": "HotelId, HotelName, Description, Rating, Address/City",
  "count": true
}
```

Tips for unexpected results

Occasionally, query output isn't what you're expecting to see. For example, you might find that some results appear to be duplicates, or a result that *should* appear near the top is positioned lower in the results. When query outcomes are unexpected, you can try these query modifications to see if results improve:

- Change `searchMode=any` (default) to `searchMode=all` to require matches on all criteria instead of any of the criteria. This is especially true when boolean operators are included in the query.
- Experiment with different lexical analyzers or custom analyzers to see if it changes the query outcome. The default analyzer breaks up hyphenated words and reduces words to root forms, which usually improves the robustness of a query response. However, if you need to preserve hyphens, or if strings include special characters, you might need to configure custom analyzers to ensure the index contains tokens in the right format. For more information, see [Partial term search and patterns with special characters \(hyphens, wildcard, regex, patterns\)](#).

Counting matches

The `count` parameter returns the number of documents in the index that are considered a match for the query. To return the count, add `count=true` to the query request. There's no

maximum value imposed by the search service. Depending on your query and the content of your documents, the count could be as high as every document in the index.

Count is accurate when the index is stable. If the system is actively adding, updating, or deleting documents, the count is approximate, excluding any documents that aren't fully indexed.

Count won't be affected by routine maintenance or other workloads on the search service. However if you have multiple partitions and a single replica, you could experience short-term fluctuations in document count (several minutes) as the partitions are restarted.

Tip

To check indexing operations, you can confirm whether the index contains the expected number of documents by adding `count=true` on an empty search `search=*` query. The result is the full count of documents in your index.

When testing query syntax, `count=true` can quickly tell you whether your modifications are returning greater or fewer results, which can be useful feedback.

Number of results in the response

Azure AI Search uses server-side paging to prevent queries from retrieving too many documents at once. Query parameters that determine the number of results in a response are `top` and `skip`. `top` refers to the number of search results in a page. `skip` is an interval of `top`, and it tells the search engine how many results to skip before getting the next set.

The default page size is 50, while the maximum page size is 1,000. If you specify a value greater than 1,000 and there are more than 1,000 results found in your index, only the first 1,000 results are returned. If the number of matches exceed the page size, the response includes information to retrieve the next page of results. For example:

JSON

```
"@odata.nextLink": "https://contoso-search-eastus.search.windows.net/indexes/realestate-us-sample-index/docs/search?api-version=2024-07-01"
```

The top matches are determined by search score, assuming the query is full text search or semantic. Otherwise, the top matches are an arbitrary order for exact match queries (where uniform `@search.score=1.0` indicates arbitrary ranking).

Set `top` to override the default of 50. In newer preview APIs, if you're using a hybrid query, you can specify `maxTextRecallSize` to return up to 10,000 documents.

To control the paging of all documents returned in a result set, use `top` and `skip` together. This query returns the first set of 15 matching documents plus a count of total matches.

HTTP

```
POST https://contoso-search-eastus.search.windows.net/indexes/realestate-us-sample-index/docs/search?api-version=2024-07-01

{
  "search": "condos with a view",
  "count": true,
  "top": 15,
  "skip": 0
}
```

This query returns the second set, skipping the first 15 to get the next 15 (16 through 30):

HTTP

```
POST https://contoso-search-eastus.search.windows.net/indexes/realestate-us-sample-index/docs/search?api-version=2024-07-01

{
  "search": "condos with a view",
  "count": true,
  "top": 15,
  "skip": 15
}
```

The results of paginated queries aren't guaranteed to be stable if the underlying index is changing. Paging changes the value of `skip` for each page, but each query is independent and operates on the current view of the data as it exists in the index at query time (in other words, there's no caching or snapshot of results, such as those found in a general purpose database).

Following is an example of how you might get duplicates. Assume an index with four documents:

JSON

```
{ "id": "1", "rating": 5 }
{ "id": "2", "rating": 3 }
{ "id": "3", "rating": 2 }
{ "id": "4", "rating": 1 }
```

Now assume you want results returned two at a time, ordered by rating. You would execute this query to get the first page of results: `$top=2&$skip=0&$orderby=rating desc`, producing the following results:

JSON

```
{ "id": "1", "rating": 5 }
{ "id": "2", "rating": 3 }
```

On the service, assume a fifth document is added to the index in between query calls: `{ "id": "5", "rating": 4 }`. Shortly thereafter, you execute a query to fetch the second page: `$top=2&$skip=2&$orderby=rating desc`, and get these results:

JSON

```
{ "id": "2", "rating": 3 }
{ "id": "3", "rating": 2 }
```

Notice that document 2 is fetched twice. This is because the new document 5 has a greater value for rating, so it sorts before document 2 and lands on the first page. While this behavior might be unexpected, it's typical of how a search engine behaves.

Paging through a large number of results

An alternative technique for paging is to use a [sort order](#) and [range filter](#) as a workaround for `skip`.

In this workaround, sort and filter are applied to a document ID field or another field that is unique for each document. The unique field must have `filterable` and `sortable` attribution in the search index.

1. Issue a query to return a full page of sorted results.

HTTP

```
POST /indexes/good-books/docs/search?api-version=2024-07-01
{
  "search": "divine secrets",
  "top": 50,
  "orderby": "id asc"
}
```

2. Choose the last result returned by the search query. An example result with only an ID value is shown here.

JSON

```
{  
  "id": "50"  
}
```

3. Use that ID value in a range query to fetch the next page of results. This ID field should have unique values, otherwise pagination might include duplicate results.

HTTP

```
POST /indexes/good-books/docs/search?api-version=2024-07-01  
{  
  "search": "divine secrets",  
  "top": 50,  
  "orderby": "id asc",  
  "filter": "id ge 50"  
}
```

4. Pagination ends when the query returns zero results.

ⓘ Note

The `filterable` and `sortable` attributes can only be enabled when a field is first added to an index, they cannot be enabled on an existing field.

Ordering results

In a full text search query, results can be ranked by:

- a search score
- a semantic reranker score
- a sort order on a `sortable` field

You can also boost any matches found in specific fields by adding a scoring profile.

Order by search score

For full text search queries, results are automatically [ranked by a search score](#) using a BM25 algorithm, calculated based on term frequency, document length, and average document length.

The `@search.score` range is either unbounded, or 0 up to (but not including) 1.00 on older services.

For either algorithm, a `@search.score` equal to 1.00 indicates an unscored or unranked result set, where the 1.0 score is uniform across all results. Unscored results occur when the query form is fuzzy search, wildcard or regex queries, or an empty search (`search=*`). If you need to impose a ranking structure over unscored results, consider an `orderby` expression to achieve that objective.

Order by the semantic reranker

If you're using [semantic ranker](#), the `@search.rerankerScore` determines the sort order of your results.

The `@search.rerankerScore` range is 1 to 4.00, where a higher score indicates a stronger semantic match.

Order with orderby

If consistent ordering is an application requirement, you can define an [orderby expression](#) on a field. Only fields that are indexed as "sortable" can be used to order results.

Fields commonly used in an `orderby` include rating, date, and location. Filtering by location requires that the filter expression calls the [geo.distance\(\)](#) function, in addition to the field name.

Numeric fields (`Edm.Double`, `Edm.Int32`, `Edm.Int64`) are sorted in numeric order (for example, 1, 2, 10, 11, 20).

String fields (`Edm.String`, `Edm.ComplexType` subfields) are sorted in either [ASCII sort order](#) or [Unicode sort order](#), depending on the language.

- Numeric content in string fields is sorted alphabetically (1, 10, 11, 2, 20).
- Upper case strings are sorted ahead of lower case (APPLE, Apple, BANANA, Banana, apple, banana). You can assign a [text normalizer](#) to preprocess the text before sorting to change this behavior. Using the lowercase tokenizer on a field has no effect on sorting behavior because Azure AI Search sorts on a nonanalyzed copy of the field.
- Strings that lead with diacritics appear last (Äpfel, Öffnen, Üben)

Boost relevance using a scoring profile

Another approach that promotes order consistency is using a [custom scoring profile](#). Scoring profiles give you more control over the ranking of items in search results, with the ability to boost matches found in specific fields. The extra scoring logic can help override minor differences among replicas because the search scores for each document are farther apart. We recommend the [ranking algorithm](#) for this approach.

Hit highlighting

Hit highlighting refers to text formatting (such as bold or yellow highlights) applied to matching terms in a result, making it easy to spot the match. Highlighting is useful for longer content fields, such as a description field, where the match isn't immediately obvious.

Notice that highlighting is applied to individual terms. There's no highlight capability for the contents of an entire field. If you want to highlight over a phrase, you have to provide the matching terms (or phrase) in a quote-enclosed query string. This technique is described further on in this section.

Hit highlighting instructions are provided on the [query request](#). Queries that trigger query expansion in the engine, such as fuzzy and wildcard search, have limited support for hit highlighting.

Requirements for hit highlighting

- Fields must be `Edm.String` or `Collection(Edm.String)`
- Fields must be attributed at `searchable`

Specify highlighting in the request

To return highlighted terms, include the `highlight` parameter in the query request. The parameter is set to a comma-delimited list of fields.

By default, the format mark up is ``, but you can override the tag using `highlightPreTag` and `highlightPostTag` parameters. Your client code handles the response (for example, applying a bold font or a yellow background).

HTTP

```
POST /indexes/good-books/docs/search?api-version=2024-07-01
{
    "search": "divine secrets",
    "highlight": "title, original_title",
    "highlightPreTag": "<b>",
```

```
        "highlightPostTag": "</b>"  
    }  
}
```

By default, Azure AI Search returns up to five highlights per field. You can adjust this number by appending a dash followed by an integer. For example, `"highlight": "description-10"` returns up to 10 highlighted terms on matching content in the description field.

Highlighted results

When highlighting is added to the query, the response includes an `@search.highlights` for each result so that your application code can target that structure. The list of fields specified for "highlight" are included in the response.

In a keyword search, each term is scanned for independently. A query for "divine secrets" returns matches on any document containing either term.

The screenshot shows the Azure AI Search UI for the "good-books" index. The search bar contains the query `search=divine secrets&$select=original_title&highlight=original_title`. The results table displays three documents with their scores and original titles. The first document is "Divine Secrets of the Ya-Ya Sisterhood" with a score of 19.593246. The second is "Divine Madness" with a score of 12.779835. The third is "Grave Secrets" with a score of 12.62534. In the JSON results, the `@search.highlights` field is shown for each document, where the matched terms ("Divine", "Secrets", "Ya-Ya Sisterhood", "Madness", "Grave") are wrapped in `` tags. The screenshot also shows the API version as 2020-06-30-Preview and the Request URL as `https://westus2.search.windows.net/indexes/good-books/docs?api-version=2020-06-30-Preview&search=divine%20secrets&%24select=original_title&highlight=original_title`.

Rank	Title	Score
1	Divine Secrets of the Ya-Ya Sisterhood	19.593246
2	Divine Madness	12.779835
3	Grave Secrets	12.62534

```
4  {  
5      "@search.score": 19.593246,  
6      "@search.highlights": {  
7          "original_title": [  
8              "<em>Divine</em> <em>Secrets</em> of the Ya-Ya Sisterhood"  
9          ]  
10     },  
11     "original_title": "Divine Secrets of the Ya-Ya Sisterhood"  
12   },  
13   {  
14       "@search.score": 12.779835,  
15       "@search.highlights": {  
16           "original_title": [  
17               "<em>Divine</em> Madness"  
18           ]  
19       },  
20       "original_title": "Divine Madness"  
21     },  
22     {  
23         "@search.score": 12.62534,  
24         "@search.highlights": {  
25             "original_title": [  
26                 "Grave <em>Secrets</em>"  
27             ]  
28         },
```

Keyword search highlighting

Within a highlighted field, formatting is applied to whole terms. For example, on a match against "The Divine Secrets of the Ya-Ya Sisterhood", formatting is applied to each term

separately, even though they're consecutive.

JSON

```
"@odata.count": 39,
"value": [
  {
    "@search.score": 19.593246,
    "@search.highlights": {
      "original_title": [
        "<em>Divine</em> <em>Secrets</em> of the Ya-Ya Sisterhood"
      ],
      "title": [
        "<em>Divine</em> <em>Secrets</em> of the Ya-Ya Sisterhood"
      ]
    },
    "original_title": "Divine Secrets of the Ya-Ya Sisterhood",
    "title": "Divine Secrets of the Ya-Ya Sisterhood"
  },
  {
    "@search.score": 12.779835,
    "@search.highlights": {
      "original_title": [
        "<em>Divine</em> Madness"
      ],
      "title": [
        "<em>Divine</em> Madness (Cherub, #5)"
      ]
    },
    "original_title": "Divine Madness",
    "title": "Divine Madness (Cherub, #5)"
  },
  {
    "@search.score": 12.62534,
    "@search.highlights": {
      "original_title": [
        "Grave <em>Secrets</em>"
      ],
      "title": [
        "Grave <em>Secrets</em> (Temperance Brennan, #5)"
      ]
    },
    "original_title": "Grave Secrets",
    "title": "Grave Secrets (Temperance Brennan, #5)"
  }
]
```

Phrase search highlighting

Whole-term formatting applies even on a phrase search, where multiple terms are enclosed in double quotation marks. The following example is the same query, except that "divine secrets"

is submitted as a quotation-enclosed phrase (some REST clients require that you escape the interior quotation marks with a backslash \"):

HTTP

```
POST /indexes/good-books/docs/search?api-version=2024-07-01
{
    "search": "\"divine secrets\"",
    "select": "title,original_title",
    "highlight": "title",
    "highlightPreTag": "<b>",
    "highlightPostTag": "</b>",
    "count": true
}
```

Because the criteria now have both terms, only one match is found in the search index. The response to the previous query looks like this:

JSON

```
{
    "@odata.count": 1,
    "value": [
        {
            "@search.score": 19.593246,
            "@search.highlights": {
                "title": [
                    "<b>Divine</b> <b>Secrets</b> of the Ya-Ya Sisterhood"
                ],
                "original_title": "Divine Secrets of the Ya-Ya Sisterhood",
                "title": "Divine Secrets of the Ya-Ya Sisterhood"
            }
        }
    ]
}
```

Phrase highlighting on older services

Search services that were created before July 15, 2020 implement a different highlighting experience for phrase queries.

For the following examples, assume a query string that includes the quote-enclosed phrase "super bowl". Before July 2020, any term in the phrase is highlighted:

JSON

```
"@search.highlights": {
    "sentence": [
```

```
"The <em>super</em> <em>bowl</em> is <em>super</em> awesome with a  
<em>bowl</em> of chips"
```

```
]
```

For search services created after July 2020, only phrases that match the full phrase query are returned in `@search.highlights`:

JSON

```
"@search.highlights": {  
    "sentence": [  
        "The <em>super</em> <em>bowl</em> is super awesome with a bowl of chips"  
    ]
```

Next steps

To quickly generate a search page for your client, consider these options:

- [Create demo app](#), in the Azure portal, creates an HTML page with a search bar, faceted navigation, and a thumbnail area if you have images.
- [Add search to an ASP.NET Core \(MVC\) app](#) is a tutorial and code sample that builds a functional client.
- [Add search to web apps](#) is a C# tutorial and code sample that uses the React JavaScript libraries for the user experience. The app is deployed using Azure Static Web Apps and it implements pagination.

Return a semantic answer in Azure AI Search

When invoking [semantic ranking and captions](#), you can optionally extract content from the top-matching documents that "answers" the query directly. One or more answers can be included in the response, which you can then render on a search page to improve the user experience of your app.

A semantic answer is verbatim content in your search index that a reading comprehension model has recognized as an answer to the query posed in the request. It's not a generated answer. For guidance on a chat-style user interaction model that uses generative AI to compose answers from your content, see [Retrieval Augmented Generation \(RAG\)](#).

In this article, learn how to request a semantic answer, unpack the response, and find out what content characteristics are most conducive to producing high-quality answers.

Prerequisites

All prerequisites that apply to [semantic queries](#) also apply to answers, including [service tier and region](#).

- Query logic must include the semantic query parameters "queryType=semantic", plus the "answers" parameter. Required parameters are discussed in this article.
- Query strings entered by the user must be recognizable as a question (what, where, when, how).
- Search documents in the index must contain text having the characteristics of an answer, and that text must exist in one of the fields listed in the [semantic configuration](#). For example, given a query "what is a hash table", if none of the fields in the semantic configuration contain passages that include "A hash table is ...", then it's unlikely an answer is returned.

What is a semantic answer?

A semantic answer is a substructure of a [semantic query response](#). It consists of one or more verbatim passages from a search document, formulated as an answer to a query that looks like a question. To return an answer, phrases or sentences must exist in a search document that have the language characteristics of an answer, and the query itself must be posed as a question.

Azure AI Search uses a machine reading comprehension model to recognize and pick the best answer. The model produces a set of potential answers from the available content, and when it reaches a high enough confidence level, it proposes one as an answer.

Answers are returned as an independent, top-level object in the query response payload that you can choose to render on search pages, along side search results. Structurally, it's an array element within the response consisting of text, a document key, and a confidence score.

Formulate a REST query for "answers"

To return a semantic answer, the query must have the semantic `"queryType"`, `"queryLanguage"`, `"semanticConfiguration"`, and the `"answers"` parameters. Specifying these parameters doesn't guarantee an answer, but the request must include them for answer processing to occur.

JSON

```
{  
  "search": "how do clouds form",  
  "queryType": "semantic",  
  "queryLanguage": "en-us",  
  "semanticConfiguration": "my-semantic-config",  
  "answers": "extractive|count-3",  
  "captions": "extractive|highlight-true",  
  "count": "true"  
}
```

- A query string must not be null and should be formulated as question.
- `"queryType"` must be set to "semantic".
- `"queryLanguage"` must be one of the values from the [supported languages list \(REST API\)](#).
- A `"semanticConfiguration"` determines which string fields provide tokens to the extraction model. The same fields that produce captions also produce answers. See [Create a semantic configuration](#) for details.
- For `"answers"`, parameter construction is `"answers": "extractive"`, where the default number of answers returned is one. You can increase the number of answers by adding a `count` as shown in the above example, up to a maximum of 10. Whether you need more than one answer depends on the user experience of your app, and how you want to render results.

Unpack an "answer" from the response

Answers are provided in the `"@search.answers"` array, which appears first in the query response. Each answer in the array includes:

- Document key
- Text or content of the answer, in plain text or with formatting
- Confidence score

If an answer is indeterminate, the response shows up as `"@search.answers": []`. The answers array is followed by the value array, which is the standard response in a semantic query.

Given the query "how do clouds form" which can be directed at an index built on [content from the NASA Earth Book](#), the following example illustrates a verbatim answer (found on page 38):

JSON

```
{  
  "@search.answers": [  
    {  
      "key": "4123",  
      "text": "Sunlight heats the land all day, warming that moist air and causing it to rise high into the atmosphere until it cools and condenses into water droplets. Clouds generally form where air is ascending (over land in this case), but not where it is descending (over the river).",  
      "highlights": "Sunlight heats the land all day, warming that moist air and causing it to rise high into the atmosphere until it cools and condenses into water droplets. Clouds generally form<em> where air is ascending</em> (over land in this case), but not where it is<em> descending</em> (over the river).",  
      "score": 0.94639826  
    },  
    ],  
    "value": [  
      {  
        "@search.score": 0.5479723,  
        "@search.rerankerScore": 1.0321671911515296,  
        "@search.captions": [  
          {  
            "text": "Like all clouds, it forms when the air reaches its dew point—the temperature at which an air mass is cool enough for its water vapor to condense into liquid droplets. This false-color image shows valley fog, which is common in the Pacific Northwest of North America.",  
            "highlights": "Like all<em> clouds</em>, it<em> forms</em> when the air reaches its dew point—the temperature at which an air mass is cool enough for its water vapor to condense into liquid droplets. This false-color image shows valley<em> fog</em>, which is common in the Pacific Northwest of North America."  
          }  
        ],  
        "title": "Earth Atmosphere",  
        "content": "Fog is essentially a cloud lying on the ground. Like all clouds, it forms when the air reaches its dew point—the temperature at \\n\\nwhich an air mass is cool enough for its water vapor to condense into liquid
```

```
droplets.\n\nThis false-color image shows valley fog, which is common in the Pacific Northwest of North America. On clear winter nights, the \n\nground and overlying air cool off rapidly, especially at high elevations. Cold air is denser than warm air, and it sinks down into the \n\nvalleys. The moist air in the valleys gets chilled to its dew point, and fog forms. If undisturbed by winds, such fog may persist for \n\ndays. The Terra satellite captured this image of foggy valleys northeast of Vancouver in February 2010.\n\n",
```

```
    "locations": [
        "Pacific Northwest",
        "North America",
        "Vancouver"
    ]
}
]
```

When designing a search results page that includes answers, be sure to handle cases where answers aren't found.

Within @search.answers:

- "key" is the document key or ID of the match. Given a document key, you can use [Lookup Document API](#) to retrieve any or all parts of the search document to include on the search page or a detail page.
- "text" and "highlights" provide identical content, in both plain text and with highlights.

By default, highlights are styled as ``, which you can override using the existing `highlightPreTag` and `highlightPostTag` parameters. As noted elsewhere, the substance of an answer is verbatim content from a search document. The extraction model looks for characteristics of an answer to find the appropriate content, but doesn't compose new language in the response.

- "score" is a confidence score that reflects the strength of the answer. If there are multiple answers in the response, this score is used to determine the order. Top answers and top captions can be derived from different search documents, where the top answer originates from one document, and the top caption from another, but in general the same documents appear in the top positions within each array.

Answers are followed by the "value" array, which always includes scores, captions, and any fields that are retrievable by default. If you specified the select parameter, the "value" array is limited to the fields that you specified. See [Configure semantic ranker](#) for details.

Tips for producing high-quality answers

For best results, return semantic answers on a document corpus having the following characteristics:

- The "semanticConfiguration" must include fields that offer sufficient text in which an answer is likely to be found. Fields more likely to contain answers should be listed first in "prioritizedContentFields". Only verbatim text from a document can appear as an answer.
- Query strings must not be null (search=*) and the string should have the characteristics of a question, such as "what is" or "how to", as opposed to a keyword search consisting of terms or phrases in arbitrary order. If the query string doesn't appear to be a question, answer processing is skipped, even if the request specifies "answers" as a query parameter.
- Semantic extraction and summarization have limits over how many tokens per document can be analyzed in a timely fashion. In practical terms, if you have large documents that run into hundreds of pages, try to break up the content into smaller documents first.

Examples of *full* Lucene search syntax (advanced queries)

Article • 04/14/2025

When constructing queries for Azure AI Search, you can replace the default [simple query parser](#) with the more powerful [Lucene query parser](#) to formulate specialized and advanced query expressions.

The Lucene parser supports complex query formats, such as field-scoped queries, fuzzy search, infix and suffix wildcard search, proximity search, term boosting, and regular expression search. The extra power comes with more processing requirements so you should expect a slightly longer execution time. In this article, you can step through examples that demonstrate query operations based on full syntax.

! Note

Many of the specialized query constructions enabled through the full Lucene query syntax are not [text-analyzed](#), which can be surprising if you expect stemming or lemmatization. Lexical analysis is only performed on complete terms (a term query or phrase query). Query types with incomplete terms (prefix query, wildcard query, regex query, fuzzy query) are added directly to the query tree, bypassing the analysis stage. The only transformation performed on partial query terms is lowercasing.

Hotels sample index

The following queries are based on the hotels-sample-index, which you can create by following the instructions in this [quickstart](#).

Example queries are articulated using the REST API and POST requests. You can paste and run them in a [REST client](#). Or, use the JSON view of [Search Explorer](#) in the Azure portal. In JSON view, you can paste in the query examples shown here in this article.

Request headers must have the following values:

[] [Expand table](#)

Key	Value
Content-Type	application/json
api-key	<your-search-service-api-key>, either query or admin key

URI parameters must include your search service endpoint with the index name, docs collections, search command, and API version, similar to the following example:

HTTP

```
https://{{service-name}}.search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2024-07-01
```

The request body should be formed as valid JSON:

JSON

```
{  
    "search": "*",  
    "queryType": "full",  
    "select": "HotelId, HotelName, Category, Tags, Description",  
    "count": true  
}
```

- `search` set to `*` is an unspecified query, equivalent to null or empty search. It's not especially useful, but it's the simplest search you can do, and it shows all retrievable fields in the index, with all values.
- `queryType` set to `full` invokes the full Lucene query parser and it's required for this syntax.
- `select` set to a comma-delimited list of fields is used for search result composition, including only those fields that are useful in the context of search results.
- `count` returns the number of documents matching the search criteria. On an empty search string, the count is all documents in the index (50 in the `hotels-sample-index`).

Example 1: Fielded search

Fielded search scopes individual, embedded search expressions to a specific field. This example searches for hotel names with the term `hotel` in them, but not `motel`. You can specify multiple fields using `AND`.

When you use this query syntax, you can omit the `searchFields` parameter when the fields you want to query are in the search expression itself. If you include `searchFields` with fielded search, the `fieldName:searchExpression` always takes precedence over `searchFields`.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
    "search": "HotelName:(hotel NOT motel) AND Category:'Boutique'", 
    "queryType": "full",
    "select": "HotelName, Category",
    "count": true
}
```

The response for this query should look similar to the following example, filtered on *Boutique*, returning hotels that include *hotel* in the name, while excluding results that include *motel* in the name.

JSON

```
{
    "@odata.count": 5,
    "value": [
        {
            "@search.score": 2.2289815,
            "HotelName": "Stay-Kay City Hotel",
            "Category": "Boutique"
        },
        {
            "@search.score": 1.3862944,
            "HotelName": "City Skyline Antiquity Hotel",
            "Category": "Boutique"
        },
        {
            "@search.score": 1.355046,
            "HotelName": "Old Century Hotel",
            "Category": "Boutique"
        },
        {
            "@search.score": 1.355046,
            "HotelName": "Sublime Palace Hotel",
            "Category": "Boutique"
        },
        {
            "@search.score": 1.355046,
            "HotelName": "Red Tide Hotel",
            "Category": "Boutique"
        }
    ]
}
```

The search expression can be a single term or a phrase, or a more complex expression in parentheses, optionally with Boolean operators. Some examples include the following:

- `HotelName:(hotel NOT motel)`

- Address/StateProvince:("WA" OR "CA")
- Tags:("free wifi" NOT "free parking") AND "coffee in lobby"

Be sure to put a phrase within quotation marks if you want both strings to be evaluated as a single entity, as in this case searching for two distinct locations in the Address/StateProvince field. Depending on the client, you might need to escape (\) the quotation marks.

The field specified in `fieldName:searchExpression` must be a searchable field. To learn how field definitions are attributed, see [Create Index \(REST API\)](#).

Example 2: Fuzzy search

Fuzzy search matches on terms that are similar, including misspelled words. To do a fuzzy search, append the tilde ~ symbol at the end of a single word with an optional parameter, a value between 0 and 2, that specifies the edit distance. For example, `blue~` or `blue~1` would return blue, blues, and glue.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
  "search": "Tags:conserge~",
  "queryType": "full",
  "select": "HotelName, Category, Tags",
  "searchFields": "HotelName, Category, Tags",
  "count": true
}
```

The response for this query resolves to `concierge` in the matching documents, trimmed for brevity:

JSON

```
{
  "@odata.count": 9,
  "value": [
    {
      "@search.score": 1.4947624,
      "HotelName": "Twin Vortex Hotel",
      "Category": "Luxury",
      "Tags": [
        "bar",
        "restaurant",
        "concierge"
      ]
    },
    {
```

```
    "@search.score": 1.1685618,  
    "HotelName": "Stay-Kay City Hotel",  
    "Category": "Boutique",  
    "Tags": [  
        "view",  
        "air conditioning",  
        "concierge"  
    ]  
,  
{  
    "@search.score": 1.1465473,  
    "HotelName": "Old Century Hotel",  
    "Category": "Boutique",  
    "Tags": [  
        "pool",  
        "free wifi",  
        "concierge"  
    ]  
,  
...  
}
```

Phrases aren't supported directly but you can specify a fuzzy match on each term of a multi-part phrase, such as `search=Tags:landy~ AND sevic~`. This query expression finds 15 matches on *laundry service*.

ⓘ Note

Fuzzy queries are not analyzed. Query types with incomplete terms (prefix query, wildcard query, regex query, fuzzy query) are added directly to the query tree, bypassing the analysis stage. The only transformation performed on partial query terms is lower casing.

Example 3: Proximity search

Proximity search finds terms that are near each other in a document. Insert a tilde `~` symbol at the end of a phrase followed by the number of words that create the proximity boundary.

This query searches for the terms *hotel* and *airport* within five words of each other in a document. The quotation marks are escaped (`\\"`) to preserve the phrase:

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01  
{  
    "search": "Description: \"hotel airport\"~5",  
    "queryType": "full",
```

```
    "select": "HotelName, Description",
    "searchFields": "HotelName, Description",
    "count": true
}
```

The response for this query should look similar to the following example:

JSON

```
{
  "@odata.count": 1,
  "value": [
    {
      "@search.score": 0.69167054,
      "HotelName": "Trails End Motel",
      "Description": "Only 8 miles from Downtown. On-site bar/restaurant, Free hot breakfast buffet, Free wireless internet, All non-smoking hotel. Only 15 miles from airport."
    }
  ]
}
```

Example 4: Term boosting

Term boosting refers to ranking a document higher if it contains the boosted term, relative to documents that don't contain the term. To boost a term, use the caret, `^`, symbol with a boost factor (a number) at the end of the term you're searching. The boost factor default is 1, and although it must be positive, it can be less than 1 (for example, 0.2). Term boosting differs from scoring profiles in that scoring profiles boost certain fields, rather than specific terms.

In this *before* query, search for *beach access* and notice that there are six documents that match on one or both terms.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
  "search": "beach access",
  "queryType": "full",
  "select": "HotelName, Description, Tags",
  "searchFields": "HotelName, Description, Tags",
  "count": true
}
```

In fact, only two documents match on *access*. The first instance is in second position, even though the document is missing the term *beach*.

JSON

```
{
  "@odata.count": 6,
  "value": [
    {
      "@search.score": 1.068669,
      "HotelName": "Johnson's Family Resort",
      "Description": "Family oriented resort located in the heart of the northland. Operated since 1962 by the Smith family, we have grown into one of the largest family resorts in the state. room entertainment includes complimentary W-Fi and flat-screen TVs. ",
    "Tags": [
        "air conditioning",
        "laundry service",
        "24-hour front desk service"
    ],
}
]
}

```

In the *after* query, repeat the search, this time boosting results with the term *beach* over the term *access*. A human readable version of the query is `search=Description:beach^2 access`. Depending on your client, you might need to express `^2` as `%5E2`.

HTTP

```

POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
    "search": "Description:beach^2 access",
    "queryType": "full",
    "select": "HotelName, Description, Tags",

```

```
    "searchFields": "HotelName, Description, Tags",
    "count": true
}
```

After you boost the term *beach*, the match on Campus Commander Hotel moves down to fifth place.

JSON

```
{
  "@odata.count": 6,
  "value": [
    {
      "@search.score": 2.137338,

      "air conditioning",
      "laundry service",
      "24-hour front desk service"
    ],
  }
]
}

```

Example 5: Regex

A regular expression search finds a match based on the contents between forward slashes / and lower-case strings, as documented in the [RegExp class](#).

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
  "search": "HotelName:/(Mo|Ho)tel/",
  "queryType": "full",
  "select": "HotelName",
  "count": true
}
```

The response for this query should look similar to the following example (trimmed for brevity):

JSON

```
{
  "@odata.count": 25,
  "value": [
    {
      "@search.score": 1,
      "HotelName": "Country Residence Hotel"
    },
    {
      "@search.score": 1,
      "HotelName": "Downtown Mix Hotel"
    },
    {
      "@search.score": 1,
      "HotelName": "Gastronomic Landscape Hotel"
    },
    . . .
    {
      "@search.score": 1,
      "HotelName": "Trails End Motel"
    },
    {
      "@search.score": 1,
      "HotelName": "Nordick's Valley Motel"
    },
    {
      "@search.score": 1,
      "HotelName": "King's Cellar Hotel"
    }
  ]
}
```

! Note

Regex queries are not analyzed. The only transformation performed on partial query terms is lower casing.

Example 6: Wildcard search

You can use generally recognized syntax for multiple (*) or single (?) character wildcard searches. The Lucene query parser supports the use of these symbols with a single term, and not a phrase.

In this query, search for hotel names that contain the prefix *sc*. You can't use a * or ? symbol as the first character of a search.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2024-07-01
{
  "search": "HotelName:sc*",
  "queryType": "full",
  "select": "HotelName",
  "count": true
}
```

The response for this query should look similar to the following example:

JSON

```
{
  "@odata.count": 1,
  "value": [
    {
      "@search.score": 1,
      "HotelName": "Waterfront Scottish Inn"
    }
  ]
}
```

(!) Note

Wildcard queries are not analyzed. The only transformation performed on partial query terms is lower casing.

Partial term search and patterns with special characters (hyphens, wildcard, regex, patterns)

Article • 04/14/2025

A *partial term search* refers to queries consisting of term fragments, where instead of a whole term, you might have just the beginning, middle, or end of term (sometimes referred to as prefix, infix, or suffix queries). A partial term search might include a combination of fragments, often with special characters such as hyphens, dashes, or slashes that are part of the query string. Common use-cases include parts of a phone number, URL, codes, or hyphenated compound words.

Partial terms and special characters can be problematic if the index doesn't have a token representing the text fragment you want to search for. During the [lexical analysis phase](#) of keyword indexing (assuming the default standard analyzer), special characters are discarded, compound words are split up, and whitespace is deleted. If you're searching for a text fragment that was modified during lexical analysis, the query fails because no match is found. Consider this example: a phone number like `+1 (425) 703-6214` (tokenized as `"1"`, `"425"`, `"703"`, `"6214"`) won't show up in a `"3-62"` query because that content doesn't actually exist in the index.

The solution is to invoke an analyzer during indexing that preserves a complete string, including spaces and special characters if necessary, so that you can include the spaces and characters in your query string. Having a whole, untokenized string enables pattern matching for "starts with" or "ends with" queries, where the pattern you provide can be evaluated against a term that isn't transformed by lexical analysis.

If you need to support search scenarios that call for analyzed and non-analyzed content, consider creating two fields in your index, one for each scenario. One field undergoes lexical analysis. The second field stores an intact string, using a content-preserving analyzer that emits whole-string tokens for pattern matching.

About partial term search

Azure AI Search scans for whole tokenized terms in the index and won't find a match on a partial term unless you include wildcard placeholder operators (`*` and `?`), or format the query as a regular expression.

Partial terms are specified using these techniques:

- [Regular expression queries](#) can be any regular expression that is valid under Apache Lucene.
- [Wildcard operators with prefix matching](#) refers to a generally recognized pattern that includes the beginning of a term, followed by `*` or `?` suffix operators, such as `search=cap*` matching on "Cap'n Jack's Waterfront Inn" or "Highline Capital". Prefixing matching is supported in both simple and full Lucene query syntax.
- [Wildcard with infix and suffix matching](#) places the `*` and `?` operators inside or at the beginning of a term, and requires regular expression syntax (where the expression is enclosed with forward slashes). For example, the query string (`search=/.*numeric.*/`) returns results on "alphanumeric" and "alphanumeric" as suffix and infix matches.

For regular expression, wildcard, and fuzzy search, analyzers aren't used at query time. For these query forms, which the parser detects by the presence of operators and delimiters, the query string is passed to the engine without lexical analysis. For these query forms, the analyzer specified on the field is ignored.

Note

When a partial query string includes characters, such as slashes in a URL fragment, you might need to add escape characters. In JSON, a forward slash `/` is escaped with a backward slash `\`. As such, `search=/.*microsoft.com\ azure\ ./` is the syntax for the URL fragment "microsoft.com/azure/".

Solving partial/pattern search problems

When you need to search on fragments or patterns or special characters, you can override the default analyzer with a custom analyzer that operates under simpler tokenization rules, retaining the entire string in the index.

The approach looks like this:

1. Define a second field to store an intact version of the string (assuming you want analyzed and non-analyzed text at query time)
2. Evaluate and choose among the various analyzers that emit tokens at the right level of granularity
3. Assign the analyzer to the field
4. Build and test the index

1 - Create a dedicated field

Analyzers determine how terms are tokenized in an index. Since analyzers are assigned on a per-field basis, you can create fields in your index to optimize for different scenarios. For example, you might define "featureCode" and "featureCodeRegex" to support regular full text search on the first, and advanced pattern matching on the second. The analyzers assigned to each field determine how the contents of each field are tokenized in the index.

JSON

```
{  
  "name": "featureCode",  
  "type": "Edm.String",  
  "retrievable": true,  
  "searchable": true,  
  "analyzer": null  
},  
{  
  "name": "featureCodeRegex",  
  "type": "Edm.String",  
  "retrievable": true,  
  "searchable": true,  
  "analyzer": "my_custom_analyzer"  
},
```

2 - Set an analyzer

When choosing an analyzer that produces whole-term tokens, the following analyzers are common choices:

 Expand table

Analyzer	Behaviors
language analyzers	Preserves hyphens in compound words or strings, vowel mutations, and verb forms. If query patterns include dashes, using a language analyzer might be sufficient.
keyword ↗	Content of the entire field is tokenized as a single term.
whitespace ↗	Separates on white spaces only. Terms that include dashes or other characters are treated as a single token.
custom analyzer	(recommended) Creating a custom analyzer lets you specify both the tokenizer and token filter. The previous analyzers must be used as-is. A custom analyzer lets you pick which tokenizers and token filters to use.

A recommended combination is the [keyword tokenizer ↗](#) with a [lower-case token](#)

Analyzer	Behaviors
	filter ↗ . By itself, the built-in keyword analyzer ↗ doesn't lower-case any upper-case text, which can cause queries to fail. A custom analyzer gives you a mechanism for adding the lower-case token filter.

Using a REST client, you can add the [Test Analyzer REST call](#) to inspect tokenized output.

The index must exist on the search service, but it can be empty. Given an existing index and a field containing dashes or partial terms, you can try various analyzers over specific terms to see what tokens are emitted.

1. First, check the Standard analyzer to see how terms are tokenized by default.

JSON

```
{
  "text": "SVP10-NOR-00",
  "analyzer": "standard"
}
```

2. Evaluate the response to see how the text is tokenized within the index. Notice how each term is lower-cased, hyphens removed, and substrings broken up into individual tokens. Only those queries that match on these tokens will return this document in the results. A query that includes "10-NOR" will fail.

JSON

```
{
  "tokens": [
    {
      "token": "svp10",
      "startOffset": 0,
      "endOffset": 5,
      "position": 0
    },
    {
      "token": "nor",
      "startOffset": 6,
      "endOffset": 9,
      "position": 1
    },
    {
      "token": "00",
      "startOffset": 10,
      "endOffset": 12,
      "position": 2
    }
  ]
}
```

```
    ]  
}
```

3. Now modify the request to use the `whitespace` or `keyword` analyzer:

JSON

```
{  
  "text": "SVP10-NOR-00",  
  "analyzer": "keyword"  
}
```

4. This time, the response consists of a single token, upper-cased, with dashes preserved as a part of the string. If you need to search on a pattern or a partial term such as "10-NOR", the query engine now has the basis for finding a match.

JSON

```
{  
  
  "tokens": [  
    {  
      "token": "SVP10-NOR-00",  
      "startOffset": 0,  
      "endOffset": 12,  
      "position": 0  
    }  
  ]  
}
```

ⓘ Important

Be aware that query parsers often lower-case terms in a search expression when building the query tree. If you are using an analyzer that does not lower-case text inputs during indexing, and you are not getting expected results, this could be the reason. The solution is to add a lower-case token filter, as described in the "Use custom analyzers" section below.

3 - Configure an analyzer

Whether you're evaluating analyzers or moving forward with a specific configuration, you'll need to specify the analyzer on the field definition, and possibly configure the analyzer itself if

you aren't using a built-in analyzer. When swapping analyzers, you typically need to rebuild the index (drop, recreate, and reload).

Use built-in analyzers

Built-in analyzers can be specified by name on an `analyzer` property of a field definition, with no extra configuration required in the index. The following example demonstrates how you would set the `whitespace` analyzer on a field.

For other scenarios and to learn more about other built-in analyzers, see [Built-in analyzers](#).

JSON

```
{  
  "name": "phoneNumber",  
  "type": "Edm.String",  
  "key": false,  
  "retrievable": true,  
  "searchable": true,  
  "analyzer": "whitespace"  
}
```

Use custom analyzers

If you're using a [custom analyzer](#), define it in the index with a user-defined combination of tokenizer, token filter, with possible configuration settings. Next, reference it on a field definition, just as you would a built-in analyzer.

When the objective is whole-term tokenization, a custom analyzer that consists of a **keyword tokenizer** and **lower-case token filter** is recommended.

- The keyword tokenizer creates a single token for the entire contents of a field.
- The lowercase token filter transforms upper-case letters into lower-case text. Query parsers typically lowercase any uppercase text inputs. Lower-casing homogenizes the inputs with the tokenized terms.

The following example illustrates a custom analyzer that provides the keyword tokenizer and a lowercase token filter.

JSON

```
{  
  "fields": [  
    {  
      "name": "accountNumber",  
      "analyzer": "lowercase_keyword",  
      "tokenizer": "keyword",  
      "filter": "lowercase"  
    }  
  ]  
}
```

```

    "analyzer": "myCustomAnalyzer",
    "type": "Edm.String",
    "searchable": true,
    "filterable": true,
    "retrievable": true,
    "sortable": false,
    "facetable": false
  }
],
"analyzers": [
{
  "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
  "name": "myCustomAnalyzer",
  "charFilters": [],
  "tokenizer": "keyword_v2",
  "tokenFilters": ["lowercase"]
}
],
"tokenizers": [],
"charFilters": [],
"tokenFilters": []
}

```

➊ Note

The `keyword_v2` tokenizer and `lowercase` token filter are known to the system and using their default configurations, which is why you can reference them by name without having to define them first.

4 - Build and test

Once you've defined an index with analyzers and field definitions that support your scenario, load documents that have representative strings so that you can test partial string queries.

Use a REST client to query partial terms and special characters described in this article.

The previous sections explained the logic. This section steps through each API you should call when testing your solution.

- [Delete Index](#) removes an existing index of the same name so that you can recreate it.
- [Create Index](#) creates the index structure on your search service, including analyzer definitions and fields with an analyzer specification.
- [Load Documents](#) imports documents having the same structure as your index, as well as searchable content. After this step, your index is ready to query or test.

- [Test Analyzer](#) was introduced in [Set an analyzer](#). Test some of the strings in your index using various analyzers to understand how terms are tokenized.
- [Search Documents](#) explains how to construct a query request, using either [simple syntax](#) or [full Lucene syntax](#) for wildcard and regular expressions.

For partial term queries, such as querying "3-6214" to find a match on "+1 (425) 703-6214", you can use the simple syntax: `search=3-6214&queryType=simple`.

For infix and suffix queries, such as querying "num" or "numeric" to find a match on "alphanumeric", use the full Lucene syntax and a regular expression:

`search=/.*num.*/&queryType=full`

Optimizing prefix and suffix queries

Matching prefixes and suffixes using the default analyzer requires additional query features. Prefixes require [wildcard search](#) and suffixes require [regular expression search](#). Both of these features can reduce query performance.

The following example adds an [EdgeNGramTokenFilter](#) to make prefix or suffix matches faster. Tokens are generated in 2-25 character combinations that include characters. Here's an example progression from two to seven tokens: MS, MSF, MSFT, MSFT/, MSFT/S, MSFT/SQ, MSFT/SQ. `EdgeNGramTokenFilter` requires a `side` parameter which determines which side of the string character combinations are generated from. Use `front` for prefix queries and `back` for suffix queries.

Extra tokenization results in a larger index. If you have sufficient capacity to accommodate the larger index, this approach with its faster response time might be the best solution.

JSON

```
{
  "fields": [
    {
      "name": "accountNumber_prefix",
      "indexAnalyzer": "ngram_front_analyzer",
      "searchAnalyzer": "keyword",
      "type": "Edm.String",
      "searchable": true,
      "filterable": false,
      "retrievable": true,
      "sortable": false,
      "facetable": false
    },
    {
      "name": "accountNumber_suffix",
      "indexAnalyzer": "ngram_back_analyzer",
      "searchAnalyzer": "keyword",
      "type": "Edm.String",
      "searchable": true,
      "filterable": false,
      "retrievable": true,
      "sortable": false,
      "facetable": false
    }
  ]
}
```

```

    "indexAnalyzer": "ngram_back_analyzer",
    "searchAnalyzer": "keyword",
    "type": "Edm.String",
    "searchable": true,
    "filterable": false,
    "retrievable": true,
    "sortable": false,
    "facetable": false
  }
],
"analyzers": [
  {
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "name": "ngram_front_analyzer",
    "charFilters": [],
    "tokenizer": "keyword_v2",
    "tokenFilters": ["lowercase", "front_edgeNGram"]
  },
  {
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "name": "ngram_back_analyzer",
    "charFilters": [],
    "tokenizer": "keyword_v2",
    "tokenFilters": ["lowercase", "back_edgeNGram"]
  }
],
"tokenizers": [],
"charFilters": [],
"tokenFilters": [
  {
    "@odata.type": "#Microsoft.Azure.Search.EdgeNGramTokenFilterV2",
    "name": "front_edgeNGram",
    "minGram": 2,
    "maxGram": 25,
    "side": "front"
  },
  {
    "@odata.type": "#Microsoft.Azure.Search.EdgeNGramTokenFilterV2",
    "name": "back_edgeNGram",
    "minGram": 2,
    "maxGram": 25,
    "side": "back"
  }
]
}

```

To search for account numbers that start with 123, we can use the following query:

```
{
  "search": "123",
```

```
"searchFields": "accountNumber_prefix"  
}
```

To search for account numbers that end with 456, we can use the following query:

```
{  
  "search": "456",  
  "searchFields": "accountNumber_suffix"  
}
```

Next steps

This article explains how analyzers both contribute to query problems and solve query problems. As a next step, take a closer look at analyzers affect indexing and query processing.

Fuzzy search to correct misspellings and typos

Article • 04/14/2025

Azure AI Search supports fuzzy search, a type of query that compensates for typos and misspelled terms in the input string. Fuzzy search scans for terms having a similar composition. Expanding search to cover near-matches has the effect of autocorrecting a typo when the discrepancy is just a few misplaced characters.

What is fuzzy search?

It's a query expansion exercise that produces a match on terms having a similar composition. When a fuzzy search is specified, the search engine builds a graph (based on [deterministic finite automaton theory](#)) of similarly composed terms, for all whole terms in the query. For example, if your query includes three terms "university of washington", a graph is created for every term in the query `search=university~ of~ washington~` (there's no stop-word removal in fuzzy search, so "of" gets a graph).

The graph consists of up to 50 expansions, or permutations, of each term, capturing both correct and incorrect variants in the process. The engine then returns the topmost relevant matches in the response.

For a term like "university", the graph might have "unversty, universty, university, universe, inverse". Any documents that match on those in the graph are included in results. In contrast with other queries that analyze the text to handle different forms of the same word ("mice" and "mouse"), the comparisons in a fuzzy query are taken at face value without any linguistic analysis on the text. "Universe" and "inverse", which are semantically different, will match because the syntactic discrepancies are small.

A match succeeds if the discrepancies are limited to two or fewer edits, where an edit is an inserted, deleted, substituted, or transposed character. The string correction algorithm that specifies the differential is the [Damerau-Levenshtein distance](#) metric. It's described as the "minimum number of operations (insertions, deletions, substitutions, or transpositions of two adjacent characters) required to change one word into the other".

In Azure AI Search:

- Fuzzy query applies to whole terms. Phrases aren't supported directly but you can specify a fuzzy match on each term of a multi-part phrase through AND constructions. For example, `search=dr~ AND cleanin~`. This query expression finds matches on "dry cleaning".

- The default distance of an edit is 2. A value of `~0` signifies no expansion (only the exact term is considered a match), but you could specify `~1` for one degree of difference, or one edit.
- A fuzzy query can expand a term up to 50 permutations. This limit isn't configurable, but you can effectively reduce the number of expansions by decreasing the edit distance to 1.
- Responses consist of documents containing a relevant match (up to 50).

During query processing, fuzzy queries don't undergo [lexical analysis](#). The query input is added directly to the query tree and expanded to create a graph of terms. The only transformation performed is lower casing.

Collectively, the graphs are submitted as match criteria against tokens in the index. As you can imagine, fuzzy search is inherently slower than other query forms. The size and complexity of your index can determine whether the benefits are enough to offset the latency of the response.

Note

Because fuzzy search tends to be slow, it might be worthwhile to investigate alternatives such as n-gram indexing, with its progression of short character sequences (two and three character sequences for bigram and trigram tokens). Depending on your language and query surface, n-gram might give you better performance. The trade off is that n-gram indexing is very storage intensive and generates much bigger indexes.

Another alternative, which you could consider if you want to handle just the most egregious cases, would be a [synonym map](#). For example, mapping "search" to "serach, serch, sarch", or "retrieve" to "retreive".

Indexing for fuzzy search

String fields that are attributed as "searchable" are candidates for fuzzy search.

Analyzers aren't used to create an expansion graph, but that doesn't mean analyzers should be ignored in fuzzy search scenarios. Analyzers are important for tokenization during indexing, where tokens in the inverted indexes are used for matching against the graph.

As always, if test queries aren't producing the matches you expect, experiment with different indexing analyzers. For example, try a [language analyzer](#) to see if you get better results. Some languages, particularly those with vowel mutations, can benefit from the inflection and irregular word forms generated by the Microsoft natural language processors. In some cases,

using the right language analyzer can make a difference in whether a term is tokenized in a way that is compatible with the value provided by the user.

How to invoke fuzzy search

Fuzzy queries are constructed using the full Lucene query syntax, invoking the [full Lucene query parser](#), and appending a tilde character ~ after each whole term entered by the user.

Here's an example of a query request that invokes fuzzy search. It includes four terms, two of which are misspelled:

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
    "search": "seattle~ waterfront~ view~ hotle~",
    "queryType": "full",
    "searchMode": "any",
    "searchFields": "HotelName, Description",
    "select": "HotelName, Description, Address/City",
    "count": "true"
}
```

1. Set the query type to the full Lucene syntax (`queryType=full`).
2. Provide the query string where each term is followed by a tilde (~) operator at the end of each whole term (`search=<string>~`). An expansion graph is created for every term in the query input.

Include an optional parameter, a number between 0 and 2 (default), if you want to specify the edit distance (~1). For example, "blue~" or "blue~1" would return "blue", "blues", and "glue".

Optionally, you can improve query performance by scoping the request to specific fields. Use the `searchFields` parameter to specify which fields to search. You can also use the `select` property to specify which fields are returned in the query response.

Testing fuzzy search

For simple testing, we recommend [Search explorer](#) or a [REST client](#) for iterating over a query expression. Both tools are interactive, which means you can quickly step through multiple variants of a term and evaluate the responses that come back.

When results are ambiguous, [hit highlighting](#) can help you identify the match in the response.

(!) Note

The use of hit highlighting to identify fuzzy matches has limitations and only works for basic fuzzy search. If your index has scoring profiles, or if you layer the query with more syntax, hit highlighting might fail to identify the match.

Example 1: fuzzy search with the exact term

Assume the following string exists in a "Description" field in a search document: "Test queries with special characters, plus strings for MSFT, SQL and Java."

Start with a fuzzy search on "special" and add hit highlighting to the Description field:

Console

```
search=special~&highlight=Description
```

In the response, because you added hit highlighting, formatting is applied to "special" as the matching term.

Output

```
"@search.highlights": {  
  "Description": [  
    "Test queries with <em>special</em> characters, plus strings for MSFT, SQL  
    and Java."  
  ]  
}
```

Try the request again, misspelling "special" by taking out several letters ("pe"):

Console

```
search=scial~&highlight=Description
```

So far, no change to the response. Given the default of 2 degrees distance, removing two characters "pe" from "special" still allows for a successful match on that term.

Output

```
"@search.highlights": {
    "Description": [
        "Test queries with <em>special</em> characters, plus strings for MSFT, SQL
        and Java."
    ]
}
```

Trying one more request, further modify the search term by taking out one last character for a total of three deletions (from "special" to "scal"):

Console

```
search=scal~&highlight=Description
```

Notice that the same response is returned, but now instead of matching on "special", the fuzzy match is on "SQL".

Output

```
"@search.score": 0.4232868,
"@search.highlights": {
    "Description": [
        "Mix of special characters, plus strings for MSFT, <em>SQL</em>, 2019,
        Linux, Java."
    ]
}
```

The point of this expanded example is to illustrate the clarity that hit highlighting can bring to ambiguous results. In all cases, the same document is returned. Had you relied on document IDs to verify a match, you might have missed the shift from "special" to "SQL".

Create a hybrid query in Azure AI Search

08/28/2025

Hybrid search combines text (keyword) and vector queries in a single search request. Both queries execute in parallel. The results are merged and reordered by new search scores, using Reciprocal Rank Fusion (RRF) to return a unified result set. In many cases, [per benchmark tests](#), hybrid queries with semantic ranking return the most relevant results.

In this article, learn how to:

- Set up a basic hybrid request
- Add parameters and filters
- Improve relevance using semantic ranking or vector weights
- Optimize query behaviors by controlling inputs (`maxTextRecallSize`)

Prerequisites

- A search index containing `searchable` vector and nonvector fields. We recommend the [Import data \(new\)](#) wizard to create an index quickly. Otherwise, see [Create an index](#) and [Add vector fields to a search index](#).
- (Optional) If you want the [semantic ranker](#), your search service must be Basic tier or higher, with [semantic ranker enabled](#).
- (Optional) If you want built-in text-to-vector conversion of a query string, [create and assign a vectorizer](#) to vector fields in the search index.

Choose an API or tool

- Search Explorer in the Azure portal (supports both stable and preview API search syntax) has a JSON view that lets you paste in a hybrid request.
- Newer stable or preview packages of the Azure SDKs (see change logs for SDK feature support).
- [Stable REST APIs](#) or a recent preview API version if you're using preview features like `maxTextRecallSize` and `countAndFacetMode(preview)`.

For readability, we use REST examples to explain how the APIs work. You can use a REST client like Visual Studio Code with the REST extension to build hybrid queries. You can also use the Azure SDKs. For more information, see [Quickstart: Vector search](#).

Set up a hybrid query

This section explains the basic structure of a hybrid query and how to set one up in either Search Explorer or for execution in a REST client.

Results are returned in plain text, including vectors in fields marked as `retrievable`. Because numeric vectors aren't useful in search results, choose other fields in the index as a proxy for the vector match. For example, if an index has "descriptionVector" and "descriptionText" fields, the query can match on "descriptionVector" but the search result can show "descriptionText". Use the `select` parameter to specify only human-readable fields in the results.

Azure portal

1. Sign in to the [Azure portal](#) and find your search service.
2. Under **Search management > Indexes**, select an index that has vectors and non-vector content. [Search Explorer](#) is the first tab.
3. Under **View**, switch to **JSON view** so that you can paste in a vector query.
4. Replace the default query template with a hybrid query. A basic hybrid query has a text query specified in `search`, and a vector query specified under `vectorQueries.vector`. The text query and vector query can be equivalent or divergent, but it's common for them to share the same intent.

This example is from the [vector quickstart](#) that has vector and nonvector content, and several query examples. For brevity, the vector is truncated in this article.

JSON

```
{  
  "search": "historic hotel walk to restaurants and shopping",  
  "vectorQueries": [  
    {  
      "vector": [0.01944167, 0.0040178085, -0.007816401 ...  
      <remaining values omitted> ],  
      "k": 7,  
      "fields": "DescriptionVector",  
      "kind": "vector",  
      "exhaustive": true  
    }  
  ]  
}
```

5. Select **Search**.

💡 Tip

Search results are easier to read if you hide the vectors. In **Query Options**, turn on **Hide vector values in search results**.

6. Here's another version of the query. This one adds a `count` for the number of matches found, a `select` parameter for choosing specific fields, and a `top` parameter to return the top seven results.

JSON

```
{  
    "count": true,  
    "search": "historic hotel walk to restaurants and shopping",  
    "select": "HotelId, HotelName, Category, Tags, Description",  
    "top": 7,  
    "vectorQueries": [  
        {  
            "vector": [0.01944167, 0.0040178085, -0.007816401 ...  
<remaining values omitted> ],  
            "k": 7,  
            "fields": "DescriptionVector",  
            "kind": "vector",  
            "exhaustive": true  
        }  
    ]  
}
```

Set `maxTextRecallSize` and `countAndFacetMode`

⚠ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

A hybrid query can be tuned to control how much of each subquery contributes to the combined results. Setting `maxTextRecallSize` specifies how many BM25-ranked results are passed to the hybrid ranking model.

If you use `maxTextRecallSize`, you might also want to set `CountAndFacetMode`. This parameter determines whether the `count` and `facets` should include all documents that matched the search query, or only those documents retrieved within the `maxTextRecallSize` window. The default value is "countAllResults".

We recommend the [latest preview REST API](#) for setting these options.

💡 Tip

Another approach for hybrid query tuning is [vector weighting](#), used to increase the importance of vector queries in the request.

1. Use [Search - POST \(preview\)](#) or [Search - GET \(preview\)](#) to specify preview parameters.
2. Add a `hybridSearch` query parameter object to set the maximum number of documents recalled through the BM25-ranked results of a hybrid query. It has two properties:
 - `maxTextRecallSize` specifies the number of BM25-ranked results to provide to the Reciprocal Rank Fusion (RRF) ranker used in hybrid queries. The default is 1,000. The maximum is 10,000.
 - `countAndFacetMode` reports the counts for the BM25-ranked results (and for facets if you're using them). The default is all documents that match the query. Optionally, you can scope "count" to the `maxTextRecallSize`.
3. Set `maxTextRecallSize`:
 - Decrease `maxTextRecallSize` if vector similarity search is generally outperforming the text-side of the hybrid query.
 - Increase `maxTextRecallSize` if you have a large index, and the default isn't capturing a sufficient number of results. With a larger BM25-ranked result set, you can also set `top`, `skip`, and `next` to retrieve portions of those results.

The following REST examples show two use-cases for setting `maxTextRecallSize`.

The first example reduces `maxTextRecallSize` to 100, limiting the text side of the hybrid query to just 100 document. It also sets `countAndFacetMode` to include only those results from `maxTextRecallSize`.

HTTP

```
POST https://[service-name].search.windows.net/indexes/[index-name]/docs/search?  
api-version=2024-05-01-Preview
```

```
{  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [1.0, 2.0, 3.0],  
            "fields": "my_vector_field",  
            "k": 10  
        }  
    ],  
    "search": "hello world",  
    "hybridSearch": {  
        "maxTextRecallSize": 100,  
        "countAndFacetMode": "countRetrievableResults"  
    }  
}
```

The second example raises `maxTextRecallSize` to 5,000. It also uses top, skip, and next to pull results from large result sets. In this case, the request pulls in BM25-ranked results starting at position 1,500 through 2,000 as the text query contribution to the RRF composite result set.

HTTP

```
POST https://[service-name].search.windows.net/indexes/[index-name]/docs/search?  
api-version=2024-05-01-Preview
```

```
{  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [1.0, 2.0, 3.0],  
            "fields": "my_vector_field",  
            "k": 10  
        }  
    ],  
    "search": "hello world",  
    "top": 500,  
    "skip": 1500,  
    "next": 500,  
    "hybridSearch": {  
        "maxTextRecallSize": 5000,  
        "countAndFacetMode": "countRetrievableResults"  
    }  
}
```

Examples of hybrid queries

This section has multiple query examples that illustrate hybrid query patterns.

Example: Hybrid search with filter

This example adds a filter, which is applied to the `filterable` nonvector fields of the search index.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
Content-Type: application/json
api-key: {{admin-api-key}}
{
    "vectorQueries": [
        {
            "vector": [
                -0.009154141,
                0.018708462,
                ...
                -0.02178128,
                -0.00086512347
            ],
            "fields": "DescriptionVector",
            "kind": "vector",
            "k": 10
        }
    ],
    "search": "historic hotel walk to restaurants and shopping",
    "vectorFilterMode": "preFilter",
    "filter": "ParkingIncluded",
    "top": "10"
}
```

Key points:

- Filters are applied to the content of filterable fields. In this example, the `ParkingIncluded` field is a boolean and it's marked as `filterable` in the index schema.
- In hybrid queries, filters can be applied before query execution to reduce the query surface or after query execution to trim results. `"preFilter"` is the default. To use `postFilter` or `strictPostFilter` (preview), set the `filter processing mode` as shown in this example.
- When you postfilter query results, the number of results might be less than top-n.

Example: Hybrid search with filters targeting vector subqueries (preview)

Using the [latest preview REST API](#), you can override a global filter on the search request by applying a secondary filter that targets just the vector subqueries in a hybrid request.

This feature provides fine-grained control by ensuring that filters only influence the vector search results, leaving keyword-based search results unaffected.

The targeted filter fully overrides the global filter, including any filters used for [security trimming](#) or geospatial search. In cases where global filters are required, such as security trimming, you must explicitly include these filters in both the top-level filter and in each vector-level filter to ensure security and other constraints are consistently enforced.

To apply targeted vector filters:

- Use the [latest preview Search Documents REST API](#) or an Azure SDK beta package that provides the feature.
- Modify a query request, adding a new `vectorQueries.filterOverride` parameter set to an [OData filter expression](#).

Here's an example of hybrid query that adds a filter override. The global filter "Rating gt 3" is replaced at run time by the `filterOverride`.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-08-01-preview
```

```
{
  "vectorQueries": [
    {
      "vector": [
        -0.009154141,
        0.018708462,
        ...
        -0.02178128,
        -0.00086512347
      ],
      "fields": "DescriptionVector",
      "kind": "vector",
      "exhaustive": true,
      "filterOverride": "Address/City eq 'Seattle'",
      "k": 10
    }
  ],
  "search": "historic hotel walk to restaurants and shopping",
  "select": "HotelName, Description, Address/City, Rating",
  "filter": "Rating gt 3"
  "debug": "vector",
```

```
    "top": 10
}
```

Example: Semantic hybrid search

Assuming that you [have semantic ranker](#) and your index definition includes a [semantic configuration](#), you can formulate a query that includes vector search and keyword search, with semantic ranking over the merged result set. Optionally, you can add captions and answers.

Whenever you use semantic ranking with vectors, make sure `k` is set to 50. Semantic ranker uses up to 50 matches as input. Specifying less than 50 deprives the semantic ranking models of necessary inputs.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
Content-Type: application/json
api-key: {{admin-api-key}}
{
  "vectorQueries": [
    {
      "vector": [
        -0.009154141,
        0.018708462,
        ...
        -0.02178128,
        -0.00086512347
      ],
      "fields": "DescriptionVector",
      "kind": "vector",
      "k": 50
    }
  ],
  "search": "historic hotel walk to restaurants and shopping",
  "select": "HotelName, Description, Tags",
  "queryType": "semantic",
  "semanticConfiguration": "my-semantic-config",
  "captions": "extractive",
  "answers": "extractive",
  "top": "50"
}
```

Key points:

- Semantic ranker accepts up to 50 results from the merged response.
- "queryType" and "semanticConfiguration" are required.

- "captions" and "answers" are optional. Values are extracted from verbatim text in the results. An answer is only returned if the results include content having the characteristics of an answer to the query.

Example: Semantic hybrid search with filter

Here's the last query in the collection. It's the same semantic hybrid query as the previous example, but with a filter.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
Content-Type: application/json
api-key: {{admin-api-key}}
{
  "vectorQueries": [
    {
      "vector": [
        -0.009154141,
        0.018708462,
        . . .
        -0.02178128,
        -0.00086512347
      ],
      "fields": "DescriptionVector",
      "kind": "vector",
      "k": 50
    }
  ],
  "search": "historic hotel walk to restaurants and shopping",
  "select": "HotelName, Description, Tags",
  "queryType": "semantic",
  "semanticConfiguration": "my-semantic-config",
  "captions": "extractive",
  "answers": "extractive",
  "filter": "ParkingIncluded",
  "vectorFilterMode": "preFilter",
  "top": "50"
}
```

Key points:

- The filter mode can affect the number of results available to the semantic reranker. As a best practice, it's smart to give the semantic ranker the maximum number of documents (50). If prefilters or postfilters are too selective, you might be underserving the semantic ranker by giving it fewer than 50 documents to work with.

- `preFilter` is applied before query execution. If prefilter reduces the search area to 100 documents, the vector query executes over the `DescriptionVector` field for those 100 documents, returning the k=50 best matches. Those 50 matching documents then pass to RRF for merged results, and then to semantic ranker.
- `postFilter` is applied after query execution. If k=50 returns 50 matches on the vector query side, followed by a post-filter applied to the 50 matches, your results are reduced by the number of documents that meet filter criteria. This leaves you with fewer than 50 documents to pass to semantic ranker. Keep this in mind if you're using semantic ranking. The semantic ranker works best if it has 50 documents as input.
- `strictPostFilter` (preview) is applied on the unfiltered top-`k` results after query execution. It always returns less than or equal to `k` documents. If the unfiltered k=50 returns 50 unfiltered results, and the filter matches 30 documents, only 30 documents are returned in the result set, even if the index has more than 30 documents that match the filter. Since this mode has the greatest reduction in recall, we don't recommend that you use it with semantic ranker.

Configure a query response

When you're setting up the hybrid query, think about the response structure. The search engine ranks the matching documents and returns the most relevant results. The response is a flattened rowset. Parameters on the query determine which fields are in each row and how many rows are in the response.

Fields in a response

Search results are composed of `retrievable` fields from your search index. A result is either:

- All `retrievable` fields (a REST API default).
- Fields explicitly listed in a `select` parameter on the query.

The examples in this article used a `select` statement to specify text (nonvector) fields in the response.

Note

Vectors aren't reverse engineered into human readable text, so avoid returning them in the response. Instead, choose nonvector fields that are representative of the search

document. For example, if the query targets a "DescriptionVector" field, return an equivalent text field if you have one ("Description") in the response.

Number of results

A query might match to any number of documents, as many as all of them if the search criteria are weak (for example "search=*" for a null query). Because it's seldom practical to return unbounded results, you should specify a maximum for the *overall response*:

- `"top": n` results for keyword-only queries (no vector)
- `"k": n` results for vector-only queries
- `"top": n` results for hybrid queries (with or without semantic) that include a "search" parameter

Both `k` and `top` are optional. Unspecified, the default number of results in a response is 50.

You can set `top` and `skip` to [page through more results](#) or change the default.

(!) Note

If you're using hybrid search in 2024-05-01-preview API, you can control the number of results from the keyword query using [`maxTextRecallSize`](#). Combine this with a setting for `k` to control the representation from each search subsystem (keyword and vector).

Semantic ranker results

(!) Note

The semantic ranker can take up to 50 results.

If you're using semantic ranker in 2024-05-01-preview or later, it's a best practice to set `k` and `maxTextRecallSize` to sum to at least 50 total. You can then restrict the results returned to the user with the `top` parameter.

If you're using semantic ranker in previous APIs do the following:

- For keyword-only search (no vectors) set `top` to 50
- For hybrid search set `k` to 50, to ensure that the semantic ranker gets at least 50 results.

Ranking

Multiple sets are created for hybrid queries, with or without the optional [semantic reranking](#). Ranking of results is computed by Reciprocal Rank Fusion (RRF).

In this section, compare the responses between single vector search and simple hybrid search for the top result. The different ranking algorithms, HNSW's similarity metric and RRF is this case, produce scores that have different magnitudes. This behavior is by design. RRF scores can appear quite low, even with a high similarity match. Lower scores are a characteristic of the RRF algorithm. In a hybrid query with RRF, more of the reciprocal of the ranked documents are included in the results, given the relatively smaller score of the RRF ranked documents, as opposed to pure vector search.

Single Vector Search: @search.score for results ordered by cosine similarity (default vector similarity distance function).

JSON

```
{  
  "@search.score": 0.8399121,  
  "HotelId": "49",  
  "HotelName": "Swirling Currents Hotel",  
  "Description": "Spacious rooms, glamorous suites and residences, rooftop pool,  
 walking access to shopping, dining, entertainment and the city center.",  
  "Category": "Luxury",  
  "Address": {  
    "City": "Arlington"  
  }  
}
```

Hybrid Search: @search.score for hybrid results ranked using Reciprocal Rank Fusion.

JSON

```
{  
  "@search.score": 0.032786883413791656,  
  "HotelId": "49",  
  "HotelName": "Swirling Currents Hotel",  
  "Description": "Spacious rooms, glamorous suites and residences, rooftop pool,  
 walking access to shopping, dining, entertainment and the city center.",  
  "Category": "Luxury",  
  "Address": {  
    "City": "Arlington"  
  }  
}
```

Relevance in keyword search (BM25 scoring)

08/27/2025

This article explains the BM25 relevance scoring algorithm used to compute search scores for [full text search](#). BM25 relevance applies to full text search only. Filter queries, autocomplete and suggested queries, wildcard search, and fuzzy search queries aren't scored or ranked for relevance.

Scoring algorithms used in full text search

Azure AI Search provides the following scoring algorithms for full text search:

 [Expand table](#)

Algorithm	Usage	Range
BM25Similarity	Fixed algorithm on all search services created after July 2020. You can configure this algorithm, but you can't switch to an older one (classic).	Unbounded.
ClassicSimilarity	Default on older search services that predate July 2020. On older services, you can opt-in for BM25 and choose a the BM25 algorithm on a per-index basis.	0 < 1.00

Both BM25 and Classic are TF-IDF-like retrieval functions that use the term frequency (TF) and the inverse document frequency (IDF) as variables to calculate relevance scores for each document-query pair, which is then used for ranking results. While conceptually similar to classic, BM25 is rooted in probabilistic information retrieval that produces more intuitive matches, as measured by user research.

BM25 offers [advanced customization options](#), such as allowing the user to decide how the relevance score scales with the term frequency of matched terms.

How BM25 ranking works

Relevance scoring refers to the computation of a search score (`@search.score`) that serves as an indicator of an item's relevance in the context of the current query. The range is unbounded. However, the higher the score, the more relevant the item.

The search score is computed based on statistical properties of the string input and the query itself. Azure AI Search finds documents that match on search terms (some or all, depending on `searchMode`), favoring documents that contain many instances of the search term. The search score goes up even higher if the term is rare across the data index, but common within the document. The basis for this approach to computing relevance is known as *TF-IDF* or term frequency-inverse document frequency.

Search scores can be repeated throughout a result set. When multiple hits have the same search score, the ordering of the same scored items is undefined and not stable. Run the query again, and you might see items shift position, especially if you're using the free service or a billable service with multiple replicas. Given two items with an identical score, there's no guarantee that one appears first.

To break the tie among repeating scores, you can add an `$orderby clause` to first order by score, then order by another sortable field (for example, `$orderby=search.score() desc, Rating desc`).

Only fields marked as `searchable` in the index, or `searchFields` in the query, are used for scoring. Only fields marked as `retrievable`, or fields specified in `select` in the query, are returned in search results, along with their search score.

! Note

A `@search.score = 1` indicates an un-scored or un-ranked result set. The score is uniform across all results. Un-scored results occur when the query form is fuzzy search, wildcard or regex queries, or an empty search (`search=*`, sometimes paired with filters, where the filter is the primary means for returning a match).

The following video segment fast-forwards to an explanation of the generally available ranking algorithms used in Azure AI Search. You can watch the full video for more background.

https://www.youtube-nocookie.com/embed/Y_X6USgvB1g?

[version=3&start=322&end=643 ↗](#)

Scores in a text results

Whenever results are ranked, `@search.score` property contains the value used to order the results.

The following table identifies the scoring property, algorithm, and range.

Search method	Parameter	Scoring algorithm	Range
full text search	@search.score	BM25 algorithm, using the parameters specified in the index .	Unbounded.

Score variation

Search scores convey general sense of relevance, reflecting the strength of match relative to other documents in the same result set. But scores aren't always consistent from one query to the next, so as you work with queries, you might notice small discrepancies in how search documents are ordered. There are several explanations for why this might occur.

Cause	Description
Identical scores	If multiple documents have the same score, any one of them might appear first.
Data volatility	Index content varies as you add, modify, or delete documents. Term frequencies will change as index updates are processed over time, affecting the search scores of matching documents.
Multiple replicas	For services using multiple replicas, queries are issued against each replica in parallel. The index statistics used to calculate a search score are calculated on a per-replica basis, with results merged and ordered in the query response. Replicas are mostly mirrors of each other, but statistics can differ due to small differences in state. For example, one replica might have deleted documents contributing to their statistics, which were merged out of other replicas. Typically, differences in per-replica statistics are more noticeable in smaller indexes. The following section provides more information about this condition.

Sharding effects on query results

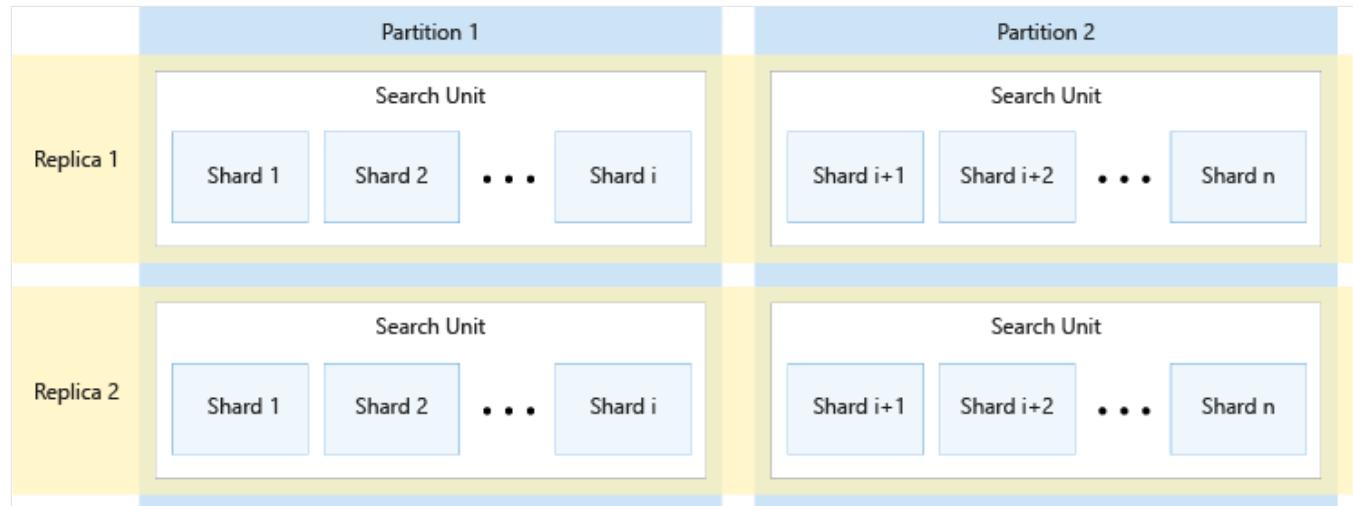

A *shard* is a chunk of an index. Azure AI Search subdivides an index into *shards* to make the process of adding partitions faster (by moving shards to new search units). On a search service, shard management is an implementation detail and nonconfigurable, but knowing that an index is sharded helps to understand the occasional anomalies in ranking and autocomplete behaviors:

- **Ranking anomalies:** Search scores are computed at the shard level first, and then aggregated up into a single result set. Depending on the characteristics of shard content,

matches from one shard might be ranked higher than matches in another one. If you notice counter intuitive rankings in search results, it's most likely due to the effects of sharding, especially if indexes are small. You can avoid these ranking anomalies by choosing to [compute scores globally across the entire index](#), but doing so will incur a performance penalty.

- Autocomplete anomalies: Autocomplete queries, where matches are made on the first several characters of a partially entered term, accept a fuzzy parameter that forgives small deviations in spelling. For autocomplete, fuzzy matching is constrained to terms within the current shard. For example, if a shard contains "Microsoft" and a partial term of "micro" is entered, the search engine will match on "Microsoft" in that shard, but not in other shards that hold the remaining parts of the index.

The following diagram shows the relationship between replicas, partitions, shards, and search units. It shows an example of how a single index is spanned across four search units in a service with two replicas and two partitions. Each of the four search units stores only half of the shards of the index. The search units in the left column store the first half of the shards, comprising the first partition, while those in the right column store the second half of the shards, comprising the second partition. Since there are two replicas, there are two copies of each index shard. The search units in the top row store one copy, comprising the first replica, while those in the bottom row store another copy, comprising the second replica.

The diagram above is only one example. Many combinations of partitions and replicas are possible, up to a maximum of 36 total search units.

! Note

The number of replicas and partitions divides evenly into 12 (specifically, 1, 2, 3, 4, 6, 12). Azure AI Search pre-divides each index into 12 shards so that it can be spread in equal portions across all partitions. For example, if your service has three partitions and you create an index, each partition will contain four shards of the index. How Azure AI Search

shards an index is an implementation detail, subject to change in future releases. Although the number is 12 today, you shouldn't expect that number to always be 12 in the future.

Scoring statistics and sticky sessions

For scalability, Azure AI Search distributes each index horizontally through a sharding process, which means that [portions of an index are physically separate](#).

By default, the score of a document is calculated based on statistical properties of the data *within a shard*. This approach is generally not a problem for a large corpus of data, and it provides better performance than having to calculate the score based on information across all shards. That said, using this performance optimization could cause two very similar documents (or even identical documents) to end up with different relevance scores if they end up in different shards.

If you prefer to compute the score based on the statistical properties across all shards, you can do so by adding `scoringStatistics=global` as a [query parameter](#) (or add `"scoringStatistics": "global"` as a body parameter of the [query request](#)).

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels/docs/search?api-version=2025-09-01
{
    "search": "<query string>",
    "scoringStatistics": "global"
}
```

Using `scoringStatistics` will ensure that all shards in the same replica provide the same results. That said, different replicas can be slightly different from one another as they're always getting updated with the latest changes to your index. In some scenarios, you might want your users to get more consistent results during a "query session". In such scenarios, you can provide a `sessionId` as part of your queries. The `sessionId` is a unique string that you create to refer to a unique user session.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels/docs/search?api-version=2025-09-01
{
    "search": "<query string>",
    "sessionId": "<string>"
}
```

As long as the same `sessionId` is used, a best-effort attempt is made to target the same replica, increasing the consistency of results your users will see.

 Note

Reusing the same `sessionId` values repeatedly can interfere with the load balancing of the requests across replicas and adversely affect the performance of the search service. The value used as sessionId can't start with a '_' character.

Relevance tuning

In Azure AI Search, for keyword search and the text portion of a hybrid query, you can configure BM25 algorithm parameters plus tune search relevance and boost search scores through the following mechanisms.

 Expand table

Approach	Implementation	Description
BM25 algorithm configuration	Search index	Configure how document length and term frequency affect the relevance score.
Scoring profiles	Search index	Provide criteria for boosting the search score of a match based on content characteristics. For example, you can boost matches based on their revenue potential, promote newer items, or perhaps boost items that have been in inventory too long. A scoring profile is part of the index definition, composed of weighted fields, functions, and parameters. You can update an existing index with scoring profile changes, without incurring an index rebuild.
Semantic ranking	Query request	Applies machine reading comprehension to search results, promoting more semantically relevant results to the top.
featuresMode parameter	Query request	This parameter is mostly used for unpacking a BM25-ranked score, but it can be used for in code that provides a custom scoring solution .

featuresMode parameter (preview)

 Note

The `featuresMode` parameter isn't documented in the REST APIs, but you can use it on a preview REST API call to Search Documents for text (Keyword) search that's BM25-ranked.

Search Documents (preview) requests support a `featuresMode` parameter that provides more detail about a BM25 relevance score at the field level. Whereas the `@searchScore` is calculated for the document all-up (how relevant is this document in the context of this query), `featuresMode` reveals information about individual fields, as expressed in a `@search.features` structure. The structure contains all fields used in the query (either specific fields through `searchFields` in a query, or all fields attributed as `searchable` in an index).

Valid values for `featuresMode`:

- "none" (default). No feature-level scoring details are returned.
- "enabled". Returns detailed scoring breakdowns per field

For each field, `@search.features` give you the following values:

- Number of unique tokens found in the field
- Similarity score, or a measure of how similar the content of the field is, relative to the query term
- Term frequency, or the number of times the query term was found in the field

This parameter is especially useful when you're trying to understand why certain documents rank higher or lower in search results. It helps explain how different fields contribute to the overall score.

For a query that targets a "description" field, a request might look like this:

HTTP

```
POST {{baseUrl}}/indexes/hotels-sample-index/docs/search?api-version=2025-08-01-  
preview HTTP/1.1  
Content-Type: application/json  
Authorization: Bearer {{accessToken}}  
  
{  
    "search": "lake view",  
    "select": "HotelId, HotelName, Tags, Description",  
    "featuresMode": "enabled",  
    "searchFields": "Description, Tags",  
    "count": true  
}
```

A response that includes `@search.features` might look like the following example.

JSON

```
"value": [
  {
    "@search.score": 3.0860271,
    "@search.features": {
      "Description": {
        "uniqueTokenMatches": 2.0,
        "similarityScore": 3.0860272,
        "termFrequency": 2.0
      }
    },
    "HotelName": "Downtown Mix Hotel",
    "Description": "Mix and mingle in the heart of the city. Shop and dine, mix and mingle in the heart of downtown, where fab lake views unite with a cheeky design.",
    "Tags": [
      "air conditioning",
      "laundry service",
      "free wifi"
    ]
  },
  {
    "@search.score": 2.7294855,
    "@search.features": {
      "Description": {
        "uniqueTokenMatches": 1.0,
        "similarityScore": 1.6023184,
        "termFrequency": 1.0
      },
      "Tags": {
        "uniqueTokenMatches": 1.0,
        "similarityScore": 1.1271671,
        "termFrequency": 1.0
      }
    },
    "HotelName": "Ocean Water Resort & Spa",
    "Description": "New Luxury Hotel for the vacation of a lifetime. Bay views from every room, location near the pier, rooftop pool, waterfront dining & more.",
    "Tags": [
      "view",
      "pool",
      "restaurant"
    ]
  }
]
```

You can consume these data points in [custom scoring solutions](#) or use the information to debug search relevance problems.

Number of ranked results in a full text query response

By default, if you aren't using pagination, the search engine returns the top 50 highest ranking matches for full text search. You can use the `top` parameter to return a smaller or larger number of items (up to 1,000 in a single response). You can use `skip` and `next` to page results. Paging determines the number of results on each logical page and supports content navigation. For more information, see [Shape search results](#).

If your full text query is part of a [hybrid query](#), you can [set maxTextRecallSize](#) to increase or decrease the number of results from the text side of the query.

Full text search is subject to a maximum limit of 1,000 matches (see [API response limits](#)). Once 1,000 matches are found, the search engine no longer looks for more.

Configure BM25 relevance scoring

Article • 02/24/2025

In this article, learn how to configure the [BM25 relevance scoring algorithm](#) used by Azure AI Search for full text search queries. It also explains how to enable BM25 on older search services.

BM25 applies to:

- Queries that use the `search` parameter for full text search, on text fields having a `searchable` attribution.
- Scoring is scoped to `searchFields`, or to all `searchable` fields if `searchFields` is null.

The search engine uses BM25 to calculate a `@searchScore` for each match in a given query. Matching documents are ranked by their search score, with the top results returned in the query response. It's possible to get some [score variation](#) in results, even from the same query executing over the same search index, but usually these variations are small and don't change the overall ranking of results.

BM25 has defaults for weighting term frequency and document length. You can customize these properties if the defaults aren't suited to your content. Configuration changes are scoped to individual indexes, which means you can adjust relevance scoring based on the characteristics of each index.

Default scoring algorithm

Depending on the age of your search service, Azure AI Search supports two [scoring algorithms](#) for a full text search query:

- Okapi BM25 algorithm (after July 15, 2020)
- Classic similarity algorithm (before July 15, 2020)

BM25 ranking is the default because it tends to produce search rankings that align better with user expectations. It includes [parameters](#) for tuning results based on factors such as document size. For search services created after July 2020, BM25 is the only scoring algorithm. If you try to set "similarity" to `ClassicSimilarity` on a new service, an HTTP 400 error is returned because that algorithm isn't supported by the service.

For older services, classic similarity remains the default algorithm. Older services can [upgrade to BM25](#) on a per-index basis. When switching from classic to BM25, you can expect to see some differences how search results are ordered.

Set BM25 parameters

BM25 ranking provides two parameters for tuning the relevance score calculation.

1. Use a [Create or Update Index](#) request to set BM25 parameters:

HTTP

```
PUT [service-name].search.windows.net/indexes/[index-name]?api-version=2024-07-01&allowIndexDowntime=true
{
    "similarity": {
        "@odata.type": "#Microsoft.Azure.Search.BM25Similarity",
        "b" : 0.75,
        "k1" : 1.2
    }
}
```

2. If the index is live, append the `allowIndexDowntime=true` URI parameter on the request, shown on the previous example.

Because Azure AI Search doesn't allow updates to a live index, you need to take the index offline so that the parameters can be added. Indexing and query requests fail while the index is offline. The duration of the outage is the amount of time it takes to update the index, usually no more than several seconds. When the update is complete, the index comes back automatically.

3. Set `"b"` and `"k1"` to custom values, and then send the request.

[+] [Expand table](#)

Property	Type	Description
k1	number	<p>Controls the scaling function between the term frequency of each matching terms to the final relevance score of a document-query pair. Values are usually 0.0 to 3.0, with 1.2 as the default.</p> <p>A value of 0.0 represents a "binary model", where the contribution of a single matching term is the same for all matching documents, regardless of how many times that term appears in the text. Larger k1 values allow the score to continue to increase as more instances of the same term is found in the document.</p> <p>Using a larger k1 value is important in cases where multiple terms are included in a search query. In those cases, you might want to favor documents matching more query terms, over documents that only match a single term, multiple times. For example, when querying for</p>

Property	Type	Description
		<p>the terms "Apollo Spaceflight", you might want to lower the score of an article about Greek Mythology that contains the term "Apollo" a few dozen times, without mentions of "Spaceflight", relative to another article that explicitly mentions both "Apollo" and "Spaceflight" a handful of times only.</p>
b	number	<p>Controls how the length of a document affects the relevance score. Values are between 0 and 1, with 0.75 as the default.</p> <p>A value of 0.0 means the length of the document doesn't influence the score. A value of 1.0 means the effect of term frequency on relevance score is normalized by the document's length.</p> <p>Normalizing the term frequency by the document's length is useful in cases where you want to penalize longer documents. In some cases, longer documents (such as a complete novel), are more likely to contain many irrelevant terms, compared to shorter documents.</p>

Enable BM25 scoring on older services

If you're running a search service that was created from March 2014 through July 15, 2020, you can enable BM25 by setting a "similarity" property on new indexes. The property is only exposed on new indexes, so if you want BM25 on an existing index, you must drop and [rebuild the index](#) with a "similarity" property set to

`Microsoft.Azure.Search.BM25Similarity`.

Once an index exists with a "similarity" property, you can switch between `BM25Similarity` or `ClassicSimilarity`.

The following links describe the Similarity property in the Azure SDKs.

[\[+\] Expand table](#)

Client library	Similarity property
.NET	SearchIndex.Similarity
Java	SearchIndex.setSimilarity
JavaScript	SearchIndex.Similarity
Python	similarity property on SearchIndex

REST example

You can also use the [REST API](#). The following example creates a new index with the "similarity" property set to BM25:

```
HTTP  
  
PUT [service-name].search.windows.net/indexes/[index name]?api-version=2024-07-01  
{  
    "name": "indexName",  
    "fields": [  
        {  
            "name": "id",  
            "type": "Edm.String",  
            "key": true  
        },  
        {  
            "name": "name",  
            "type": "Edm.String",  
            "searchable": true,  
            "analyzer": "en.lucene"  
        },  
        ...  
    ],  
    "similarity": {  
        "@odata.type": "#Microsoft.Azure.Search.BM25Similarity"  
    }  
}
```

Relevance in vector search

07/09/2025

During vector query execution, the search engine looks for similar vectors to find the best candidates to return in search results. Depending on how you indexed the vector content, the search for relevant matches is either exhaustive, or constrained to nearest neighbors for faster processing. Once candidates are found, similarity metrics are used to score each result based on the strength of the match.

This article explains the algorithms used to find relevant matches and the similarity metrics used for scoring. It also offers tips for improving relevance if search results don't meet expectations.

Algorithms used in vector search

Vector search algorithms include:

- [Exhaustive K-Nearest Neighbors \(KNN\)](#), which performs a brute-force scan of the entire vector space.
- [Hierarchical Navigable Small World \(HNSW\)](#), which performs an [Approximate Nearest Neighbor \(ANN\)](#) search.

Only vector fields marked as `searchable` in the index or `searchFields` in the query are used for searching and scoring.

About exhaustive KNN

Exhaustive KNN calculates the distances between all pairs of data points and finds the exact `k` nearest neighbors for a query point. Because the algorithm doesn't require fast random access of data points, KNN doesn't consume [vector index size](#) quota. However, it provides the global set of nearest neighbors.

Exhaustive KNN is computationally intensive, so use it for small to medium datasets or when the need for precision outweighs the need for query performance. Another use case is building a dataset to evaluate the recall of an [ANN algorithm](#), as exhaustive KNN can be used to build the ground truth set of nearest neighbors.

About HNSW

HNSW is an ANN algorithm optimized for high-recall, low-latency applications with unknown or volatile data distribution. During indexing, HNSW creates extra data structures that organize data points into a hierarchical graph. During query execution, HNSW navigates through this graph to find the most relevant matches, enabling efficient nearest neighbor searches.

HNSW requires all data points to reside in memory for fast random access, which consumes [vector index size](#) quota. This design balances search accuracy with computational efficiency and makes HNSW suitable for most scenarios, especially when searching over larger datasets.

HNSW offers several tunable configuration parameters to optimize throughput, latency, and recall for your search application. For example, fields that specify HNSW also support exhaustive KNN using the [query request](#) parameter `"exhaustive": true`. However, fields indexed for `exhaustiveKnn` don't support HNSW queries because the extra data structures that enable efficient search don't exist.

About ANN

ANN is a class of algorithms for finding matches in vector space. This class of algorithms uses different data structures or data partitioning methods to significantly reduce the search space and accelerate query processing.

ANN algorithms sacrifice some accuracy but offer scalable and faster retrieval of approximate nearest neighbors, which makes them ideal for balancing accuracy and efficiency in modern information retrieval applications. You can adjust the parameters of your algorithm to fine-tune the recall, latency, memory, and disk footprint requirements of your search application.

Azure AI Search uses HNSW for its ANN algorithm.

How nearest neighbor search works

Vector queries execute against an embedding space consisting of vectors generated from the same embedding model. Generally, the input value within a query request is fed into the same machine learning model that generated embeddings in the vector index. The output is a vector in the same embedding space. Since similar vectors are clustered close together, finding matches is equivalent to finding the vectors that are closest to the query vector, and returning the associated documents as the search result.

For example, if a query request is about hotels, the model maps the query into a vector that exists somewhere in the cluster of vectors representing documents about hotels. Identifying which vectors are the most similar to the query, based on a similarity metric, determines which documents are the most relevant.

When vector fields are indexed for exhaustive KNN, the query executes against "all neighbors". For fields indexed for HNSW, the search engine uses an HNSW graph to search over a subset of nodes within the vector index.

Creating the HNSW graph

During indexing, the search service constructs the HNSW graph. The goal of indexing a new vector into an HNSW graph is to add it to the graph structure in a manner that allows for efficient nearest neighbor search. The following steps summarize the process:

1. Initialization: Start with an empty HNSW graph, or the existing HNSW graph if it's not a new index.
2. Entry point: This is the top-level of the hierarchical graph and serves as the starting point for indexing.
3. Adding to the graph: Different hierarchical levels represent different granularities of the graph, with higher levels being more global, and lower levels being more granular. Each node in the graph represents a vector point.
 - Each node is connected to up to `m` neighbors that are nearby. This is the `m` parameter.
 - The number of data points considered as candidate connections is governed by the `efConstruction` parameter. This dynamic list forms the set of closest points in the existing graph for the algorithm to consider. Higher `efConstruction` values result in more nodes being considered, which often leads to denser local neighborhoods for each vector.
 - These connections use the configured similarity `metric` to determine distance. Some connections are "long-distance" connections that connect across different hierarchical levels, creating shortcuts in the graph that enhance search efficiency.
4. Graph pruning and optimization: This can happen after indexing all vectors, and it improves navigability and efficiency of the HNSW graph.

Navigating the HNSW graph at query time

A vector query navigates the hierarchical graph structure to scan for matches. The following steps summarize the steps in the process:

1. Initialization: The algorithm initiates the search at the top-level of the hierarchical graph. This entry point contains the set of vectors that serve as starting points for search.

2. Traversal: Next, it traverses the graph level by level, navigating from the top-level to lower levels, selecting candidate nodes that are closer to the query vector based on the configured distance metric, such as cosine similarity.
3. Pruning: To improve efficiency, the algorithm prunes the search space by only considering nodes that are likely to contain nearest neighbors. This is achieved by maintaining a priority queue of potential candidates and updating it as the search progresses. The length of this queue is configured by the parameter `efSearch`.
4. Refinement: As the algorithm moves to lower, more granular levels, HNSW considers more neighbors near the query, which allows the candidate set of vectors to be refined, improving accuracy.
5. Completion: The search completes when the desired number of nearest neighbors have been identified, or when other stopping criteria are met. This desired number of nearest neighbors is governed by the query-time parameter `k`.

Similarity metrics used to measure nearness

The algorithm finds candidate vectors to evaluate similarity. To perform this task, a similarity metric calculation compares the candidate vector to the query vector and measures the similarity. The algorithm keeps track of the ordered set of most similar vectors that its found, which forms the ranked result set when the algorithm has reached completion.

[] Expand table

Metric	Description
<code>cosine</code>	This metric measures the angle between two vectors, and isn't affected by differing vector lengths. Mathematically, it calculates the angle between two vectors. Cosine is the similarity metric used by Azure OpenAI embedding models , so if you're using Azure OpenAI, specify <code>cosine</code> in the vector configuration.
<code>dotProduct</code>	This metric measures both the length of each pair of two vectors, and the angle between them. Mathematically, it calculates the products of vectors' magnitudes and the angle between them. For normalized vectors, this is identical to <code>cosine</code> similarity, but slightly more performant.
<code>euclidean</code>	(also known as <code>l2 norm</code>) This metric measures the length of the vector difference between two vectors. Mathematically, it calculates the Euclidean distance between two vectors, which is the l2-norm of the difference of the two vectors.

! Note

If you run two or more vector queries in parallel, or if you do a hybrid search that combines vector and text queries in the same request, [Reciprocal Rank Fusion \(RRF\)](#) is used for scoring the final search results.

Scores in a vector search results

Scores are calculated and assigned to each match, with the highest matches returned as `k` results. The `@search.score` property contains the score. The following table shows the range within which a score will fall.

 Expand table

Search method	Parameter	Scoring metric	Range
vector search	<code>@search.score</code>	Cosine	0.333 - 1.00

For `cosine` metric, it's important to note that the calculated `@search.score` isn't the cosine value between the query vector and the document vectors. Instead, Azure AI Search applies transformations such that the score function is monotonically decreasing, meaning score values will always decrease in value as the similarity becomes worse. This transformation ensures that search scores are usable for ranking purposes.

There are some nuances with similarity scores:

- Cosine similarity is defined as the cosine of the angle between two vectors.
- Cosine distance is defined as `1 - cosine_similarity`.

To create a monotonically decreasing function, the `@search.score` is defined as `1 / (1 + cosine_distance)`.

Developers who need a cosine value instead of the synthetic value can use a formula to convert the search score back to cosine distance:

C#

```
double ScoreToSimilarity(double score)
{
    double cosineDistance = (1 - score) / score;
    return -cosineDistance + 1;
}
```

Having the original cosine value can be useful in custom solutions that set up thresholds to trim results of low quality results.

Tips for relevance tuning

If you aren't getting relevant results, experiment with changes to [query configuration](#). There are no specific tuning features, such as a scoring profile or field or term boosting, for vector queries:

- Experiment with [chunk size and overlap](#). Try increasing the chunk size and ensuring there's sufficient overlap to preserve context or continuity between chunks.
- For HNSW, try different levels of `efConstruction` to change the internal composition of the proximity graph. The default is 400. The range is 100 to 1,000.
- Increase `k` results to feed more search results into a chat model, if you're using one.
- Try [hybrid queries](#) with semantic ranking. In benchmark testing, this combination consistently produced the most relevant results.

Relevance scoring in hybrid search using Reciprocal Rank Fusion (RRF)

09/28/2025

Reciprocal Rank Fusion (RRF) is an algorithm that evaluates the search scores from multiple, previously ranked results to produce a unified result set. In Azure AI Search, RRF is used when two or more queries execute in parallel. Namely, for [hybrid queries](#) and for [multiple vector queries](#). Each individual query produces a ranked result set, and RRF merges and homogenizes the rankings into a single result set for the query response.

RRF is based on the concept of *reciprocal rank*, which is the inverse of the rank of the first relevant document in a list of search results. The goal of the technique is to take into account the position of the items in the original rankings, and give higher importance to items that are ranked higher in multiple lists. This can help improve the overall quality and reliability of the final ranking, making it more useful for the task of fusing multiple ordered search results.

How RRF ranking works

RRF works by taking the search results from multiple methods, assigning a reciprocal rank score to each document in the results, and then combining the scores to create a new ranking. The concept is that documents appearing in the top positions across multiple search methods are likely to be more relevant and should be ranked higher in the combined result.

Here's a simple explanation of the RRF process:

1. Obtain ranked search results from multiple queries executing in parallel.
2. Assign reciprocal rank scores for result in each of the ranked lists. RRF generates a new `@search.score` for each match in each result set. For each document in the search results, the engine assigns a reciprocal rank score based on its position in the list. The score is calculated as $1/(rank + k)$, where `rank` is the position of the document in the list, and `k` is a constant, which was experimentally observed to perform best if it's set to a small value like 60. **Note that this `k` value is a constant in the RRF algorithm and entirely separate from the `k` that controls the number of nearest neighbors.**
3. Combine scores. For each document, the engine sums the reciprocal rank scores obtained from each search system, producing a combined score for each document.
4. The engine ranks documents based on combined scores and sorts them. The resulting list is the fused ranking.

Only fields marked as `searchable` in the index, or `searchFields` in the query, are used for scoring. Only fields marked as `retrievable`, or fields specified in `select` in the query, are returned in search results, along with their search score.

Parallel query execution

RRF is used anytime there's more than one query execution. The following examples illustrate query patterns where parallel query execution occurs:

- A full text query, plus one vector query (simple hybrid scenario), equals two query executions.
- A full text query, plus one vector query targeting two vector fields, equals three query executions.
- A full text query, plus two vector queries targeting five vector fields, equals 11 query executions

Scores in a hybrid search results

Whenever results are ranked, `@search.score` property contains the value used to order the results. Scores are generated by ranking algorithms that vary for each method. Each algorithm has its own range and magnitude.

The following chart identifies the scoring property returned on each match, algorithm, and range of scores for each relevance ranking algorithm. For more information and a diagram of the scoring workflow, see [Relevance in Azure AI Search](#).

 Expand table

Search method	Parameter	Scoring algorithm	Range
full-text search	<code>@search.score</code>	BM25 algorithm	No upper limit.
vector search	<code>@search.score</code>	HNSW algorithm, using the similarity metric specified in the HNSW configuration.	0.333 - 1.00 (Cosine), 0 to 1 for Euclidean and DotProduct.
hybrid search	<code>@search.score</code>	RRF algorithm	Upper limit is bounded by the number of queries being fused, with each query contributing a maximum of approximately $1/k$ to the RRF score (this is the <code>k</code> parameter).

Search method	Parameter	Scoring algorithm	Range
semantic ranking	<code>@search.rerankerScore</code>	Semantic ranking	0.00 - 4.00

Semantic ranking occurs after RRF merging of results. Its score (`@search.rerankerScore`) is always reported separately in the query response. Semantic ranker can rerank full text and hybrid search results, assuming those results include fields having semantically rich content. It can rerank pure vector queries if the search documents include text fields that contain semantically relevant content.

Unpack a search score into subscores

You can deconstruct a search score to view its subscores. For vector queries, this information can help you determine an appropriate value for [vector weighting](#) or [setting minimum thresholds](#).

To get subscores:

- Use the [Search Documents REST API](#) or an Azure SDK package that provides the feature.
- Modify a query request, adding a new `debug` parameter set to either `vector`, `semantic` if using semantic ranker, or `all`.

Here's an example of hybrid query that returns subscores in debug mode:

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-09-01
```

```
{
  "vectorQueries": [
    {
      "vector": [
        -0.009154141,
        0.018708462,
        ...
        -0.02178128,
        -0.00086512347
      ],
      "fields": "DescriptionVector",
    }
  ]
}
```

```

        "kind": "vector",
        "exhaustive": true,
        "k": 10
    },
    {
        "vector": [
            -0.009154141,
            0.018708462,
            ...
            -0.02178128,
            -0.00086512347
        ],
        "fields": "DescriptionVector",
        "kind": "vector",
        "exhaustive": true,
        "k": 10
    }
],
"search": "historic hotel walk to restaurants and shopping",
"select": "HotelName, Description, Address/City",
"debug": "vector",
"top": 10
}

```

Weighted scores

You can also [weight vector queries](#) to increase or decrease their importance in a hybrid query.

Recall that when computing RRF for a certain document, the search engine looks at the rank of that document for each result set where it shows up. Assume a document shows up in three separate search results, where the results are from two vector queries and one text BM25-ranked query. The position of the document varies in each result.

[] [Expand table](#)

Match found	Position in results	@search.score	weight multiplier	@search.score (weighted)
vector results one	position 1	0.8383955	0.5	0.41919775
vector results two	position 5	0.81514114	2.0	1.63028228
BM25 results	position 10	0.8577363	NA	0.8577363

The document's position in each result set corresponds to an initial score, which is added up to create the final RRF score for that document.

If you add vector weighting, the initial scores are subject to a weighting multiplier that increases or decreases the score. The default is 1.0, which means no weighting and the initial score is used as-is in RRF scoring. However, if you add a weight of 0.5, the score is reduced and that result becomes less important in the combined ranking. Conversely, if you add a weight of 2.0, the score becomes a larger factor in the overall RRF score.

In this example, the `@search.score` (weighted) values are passed to the RRF ranking model.

Number of ranked results in a hybrid query response

By default, if you aren't using pagination, the search engine returns the top 50 highest ranking matches for full text search, and the most similar `k` matches for vector search. In a hybrid query, `top` determines the number of results in the response. Based on defaults, the top 50 highest ranked matches of the unified result set are returned.

Often, the search engine finds more results than `top` and `k`. To return more results, use the paging parameters `top`, `skip`, and `next`. Paging is how you determine the number of results on each logical page and navigate through the full payload. You can [set `maxTextRecallSize`](#) to larger values (the default is 1,000) to return more results from the text side of hybrid query.

By default, full text search is subject to a maximum limit of 1,000 matches (see [API response limits](#)). Once 1,000 matches are found, the search engine no longer looks for more.

For more information, see [How to work with search results](#).

- [Vector search](#)

Add scoring profiles to boost search scores

Scoring profiles are used to boost or suppress the ranking of matching documents based on user-defined criteria. In this article, learn how to specify and assign a scoring profile that boosts a search score based on parameters that you provide. You can create scoring profiles based on:

- Weighted string fields, where boosting is based on a match found in a designated field. For example, matches found in a "Subject" field are considered more relevant than the same match found in a "Description" field.
- Functions for numeric fields, including dates and geographic coordinates. Functions for numeric content support boosting on distance (applies to geographic coordinates), freshness (applies to datetime fields), range, and magnitude.
- Functions for string collections (tags). A tags function boosts a document's search score if any item in the collection is matched by the query.
- (preview) [An aggregation of distinct boosts](#). Within a single scoring profile, you can specify multiple scoring functions, and then set `"functionAggregation": "product"`. Documents that score highly across all functions are prioritized, while those that score weak in one or more fields are suppressed.

You can add a scoring profile to an index by editing its JSON definition in the Azure portal or programmatically through APIs like [Create or Update Index REST](#) or equivalent index update APIs in any Azure SDK. There's no index rebuild requirements so you can add, modify, or delete a scoring profile with no effect on indexed documents.

Prerequisites

- A search index with text or numeric (nonvector) fields.

Rules for scoring profiles

You can use scoring profiles in [keyword search](#), [vector search](#), [hybrid search](#), and with [semantic reranking](#)). However, scoring profiles only apply to nonvector fields, so make sure your index has text or numeric fields that can be boosted or weighted.

You can have up to 100 scoring profiles within an index (see [service Limits](#)), but you can only specify one profile at a time in any given query.

You can use [semantic ranking](#) with scoring profiles and apply a [scoring profile after semantic ranking](#) occurs. Otherwise, when multiple ranking or relevance features are in play, semantic

ranking is the last step. [How search scoring works](#) provides an illustration of the order of operations.

Extra rules apply specifically to functions.

! Note

Unfamiliar with relevance concepts? Visit [Relevance and scoring in Azure AI Search](#) for background. You can also watch this [video segment on YouTube](#) ↗ for scoring profiles over BM25-ranked results.

Scoring profile definition

A scoring profile is defined in an index schema. It consists of weighted fields, functions, and parameters.

The following definition shows a simple profile named "geo". This example boosts results that have the search term in the hotelName field. It also uses the `distance` function to favor results that are within 10 kilometers of the current location. If someone searches on the term 'inn', and 'inn' happens to be part of the hotel name, documents that include hotels with 'inn' within a 10-kilometer radius of the current location appear higher in the search results.

JSON

```
"scoringProfiles": [
  {
    "name": "geo",
    "text": {
      "weights": {
        "hotelName": 5
      }
    },
    "functions": [
      {
        "type": "distance",
        "boost": 5,
        "fieldName": "location",
        "interpolation": "logarithmic",
        "distance": {
          "referencePointParameter": "currentLocation",
          "boostingDistance": 10
        }
      }
    ]
  }
]
```

To use this scoring profile, your query is formulated to specify `scoringProfile` parameter in the request. If you're using the REST API, queries are specified through GET and POST requests. In the following example, "currentLocation" has a delimiter of a single dash (-). It's followed by longitude and latitude coordinates, where longitude is a negative value.

HTTP

```
POST /indexes/hotels/docs&api-version=2025-09-01
{
  "search": "inn",
  "scoringProfile": "geo",
  "scoringParameters": ["currentLocation--122.123,44.77233"]
}
```

Query parameters, including `scoringParameters`, are described in [Search Documents \(REST API\)](#).

For more scenarios, see the examples for [freshness and distance](#) and [weighted text and functions](#) in this article.

Add a scoring profile to a search index

1. Start with an [index definition](#). You can add and update scoring profiles on an existing index without having to rebuild it. Use [Get Index](#) to pull down an existing index, and use [Create or Update Index](#) request to post a revision.
2. Paste in the [template](#) provided in this article.
3. Provide a name that adheres to [naming conventions](#).
4. Specify boosting criteria. A single profile can contain [text weighted fields](#), [functions](#), or both.

You should work iteratively, using a data set that helps you prove or disprove the efficacy of a given profile.

Scoring profiles can be defined in the Azure portal as shown in the following screenshot, or programmatically through [REST APIs](#) or in Azure SDKs, such as the `ScoringProfile` class in [.NET](#) or [Python](#) client libraries.

The screenshot shows the Microsoft Azure portal interface for a search service named 'hotels-sample-index'. At the top, there's a navigation bar with 'Microsoft Azure' and a search bar. Below it, the service name 'hotels-sample-index' is shown with a '... more' button. Underneath, there are tabs for 'Index' (selected), 'Documents' (50 documents, 310.75 kB), 'Storage' (0), and 'Actions' (Save, Discard, Refresh, Create Demo App, Delete). The main content area has tabs for 'Search explorer', 'Fields', 'CORS', 'Scoring profiles' (which is underlined and highlighted with a red box), and 'Index Definition (JSON)'. Below these tabs, there's a section for 'Scoring profiles' with a button '+ Add scoring profile' (also highlighted with a red box) and a checkbox 'Set as default profile'. There are also 'Name' and 'Functions' fields and a search icon. A message at the bottom says 'You haven't created any scoring profiles. Click "Add scoring profile" to create one.'

Template

This section shows the syntax and template for scoring profiles. For a description of properties, see the [REST API reference](#).

JSON

```
"scoringProfiles": [
  {
    "name": "name of scoring profile",
    "text": (optional, only applies to searchable fields) {
      "weights": {
        "searchable_field_name": relative_weight_value (positive #'s),
        ...
      }
    },
    "functions": (optional) [
      {
        "type": "magnitude | freshness | distance | tag",
        "boost": # (positive number used as multiplier for raw score != 1),
        "fieldName": "(...)",
        "interpolation": "constant | linear (default) | quadratic | logarithmic",
        "magnitude": {
          "boostingRangeStart": #,
          "boostingRangeEnd": #,
          "constantBoostBeyondRange": true | false (default)
        }
        // ( - or - )

        "freshness": {
          "boostingDuration": "..." (value representing timespan over which boosting occurs)
        }
        // ( - or - )
      }
    ]
  }
]
```

```

    "distance": {
        "referencePointParameter": "...", (parameter to be passed in queries to
use as reference location)
        "boostingDistance": # (the distance in kilometers from the reference
location where the boosting range ends)
    }

    // ( - or -)

    "tag": {
        "tagsParameter": "..."(parameter to be passed in queries to specify a
list of tags to compare against target field)
    }
},
],
"functionAggregation": (optional, applies only when functions are specified)
"sum (default) | average | minimum | maximum | firstMatching"
}
],
"defaultScoringProfile": (optional) "...",

```

Use text-weighted fields

Use text-weighted fields when field context is important and queries include `searchable` string fields. For example, if a query includes the term "airport", you might favor "airport" in the HotelName field rather than the Description field.

Weighted fields are name-value pairs composed of a `searchable` field and a positive number that is used as a multiplier. If the original field score of HotelName is 3, the boosted score for that field becomes 6, contributing to a higher overall score for the parent document itself.

JSON

```

"scoringProfiles": [
{
    "name": "boostSearchTerms",
    "text": {
        "weights": {
            "HotelName": 2,
            "Description": 5
        }
    }
}
]

```

Use functions

Use functions when simple relative weights are insufficient or don't apply, as is the case of distance and freshness, which are calculations over numeric data. You can specify multiple functions per scoring profile. For more information about the EDM data types used in Azure AI Search, see [Supported data types](#).

[] Expand table

Function	Description	Use cases
distance	Boost by proximity or geographic location. This function can only be used with <code>Edm.GeographyPoint</code> fields.	Use for "find near me" scenarios.
freshness	Boost by values in a datetime field (<code>Edm.DateTimeOffset</code>). Set <code>boostingDuration</code> to specify a value representing a timespan over which boosting occurs.	Use when you want to promote recent (newer) dates. You can also boost items like calendar events with future dates such that are closer to the present, as compared with items that are further into the future. One end of the range is fixed to the current time.
magnitude	Magnitude is the computed distance between the document's value (such as a date or location) and the reference point (such as "now" or a target location). It's the input to the scoring function and determines how much boost is applied. Alter rankings based on the range of values for a numeric field. The value must be an integer or floating-point number. For star ratings of 1 through 4, this would be 1. For margins over 50%, this would be 50. This function can only be used with <code>Edm.Double</code> and <code>Edm.Int</code> fields. For the magnitude function, you can reverse the range, high to low, if you want the inverse pattern (for example, to boost lower-priced items more than higher-priced items). Given a range of prices from \$100 to \$1, you would set <code>boostingRangeStart</code> at 100 and <code>boostingRangeEnd</code> at 1 to boost the lower-priced items.	Use when you want to boost by profit margin, ratings, clickthrough counts, number of downloads, highest price, lowest price, or a count of downloads. When two items are relevant, the item with the higher rating is displayed first.
tag	Boost by tags that are common to both search documents and query strings. Tags are provided in a <code>tagsParameter</code> . This function can only be used with search fields of type <code>Edm.String</code> and <code>Collection(Edm.String)</code> .	Use when you have tag fields. If a given tag within the list is itself a comma-delimited list, you can use a text normalizer on the field to strip out the commas at query time (map the comma character to a space). This approach "flattens" the list

Function	Description	Use cases
		so that all terms are a single, long string of comma-delimited terms.

Freshness and distance scoring are special cases of magnitude-based scoring, where the magnitude is automatically computed from a datetime or geographic field.

Rules for using functions

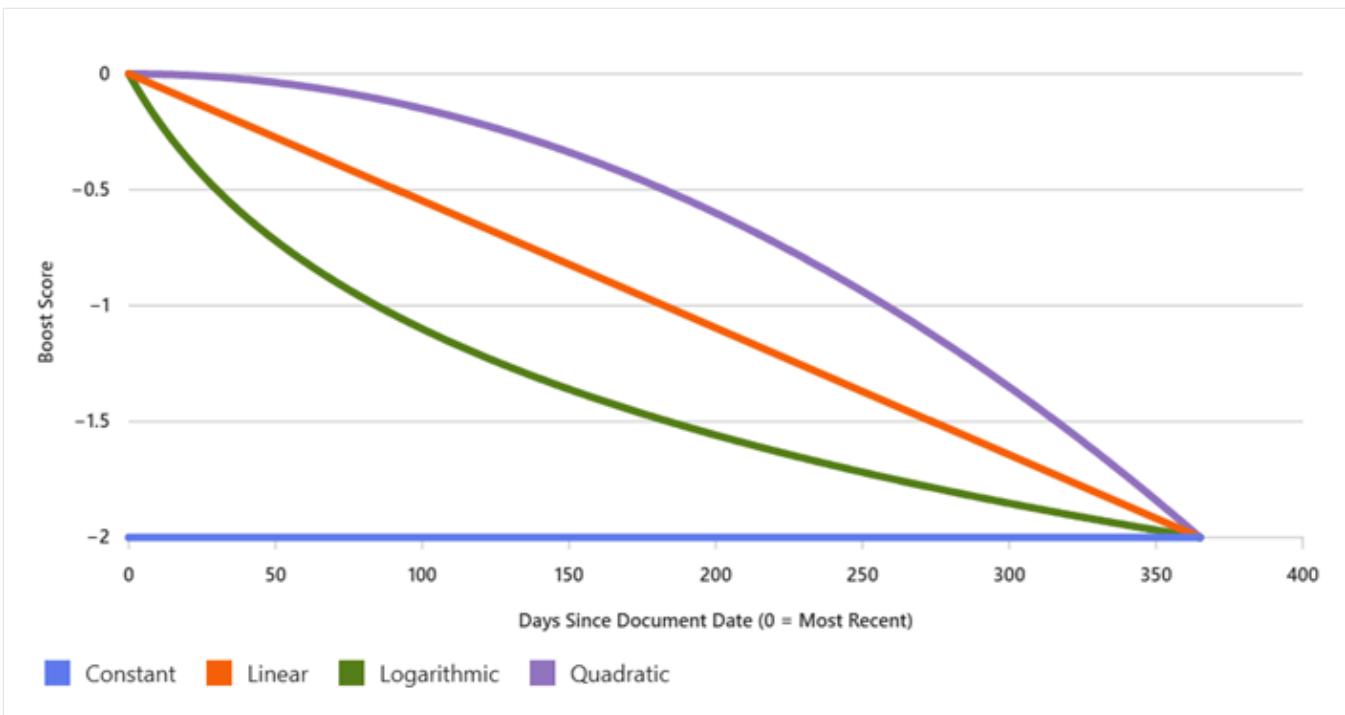

- Functions can only be applied to fields that are attributed as `filterable`.
- Function type ("freshness", "magnitude", "distance", "tag") must be lower case.
- Functions can't include null or empty values.
- Functions can only have a single field per function definition. To use magnitude twice in the same profile, provide two definitions magnitude, one for each field.

Set interpolations

Interpolations set the shape of the slope used for boosting freshness and distance. Because scoring is high to low, the slope is always decreasing, but the interpolation determines the curve of the downward slope and how aggressively the boost score changes as document dates get older.

[] Expand table

Interpolation	Description
<code>linear</code>	For items that are within the max and min range, boosting is applied in a constantly decreasing amount. Recommended when you want a gradual decay in relevance. Linear is the default interpolation for a scoring profile.
<code>constant</code>	For items that are within the start and ending range, a constant boost is applied to the rank results. Use this when you want a flat penalty regardless of age.
<code>quadratic</code>	Quadratic initially decreases at smaller pace and then accelerates as it approaches the end range, it decreases at a much higher interval. Use this interpolation when you want to strongly favor the most recent documents and sharply demote older ones. This interpolation option isn't allowed in the tag scoring function.
<code>logarithmic</code>	Logarithmic initially decreases at higher pace and then as it approaches the end range, it decreases at a much smaller interval. Recommended when you have a strong preference for very recent content but less sensitivity as documents age. This interpolation option isn't allowed in the tag scoring function.

Set boostingDuration for freshness function

`boostingDuration` is an attribute of the `freshness` function. You use it to set an expiration period after which boosting stops for a particular document. For example, to boost a product line or brand for a 10-day promotional period, you would specify the 10-day period as "P10D" for those documents.

`boostingDuration` must be formatted as an XSD "dayTimeDuration" value (a restricted subset of an ISO 8601 duration value). The pattern for this is: "P[nD][T[nH][nM][nS]]".

The following table provides several examples.

[] [Expand table](#)

Duration	boostingDuration
1 day	"P1D"
2 days and 12 hours	"P2DT12H"
15 minutes	"PT15M"
30 days, 5 hours, 10 minutes, and 6.334 seconds	"P30DT5H10M6.334S"
1 year	"365D"

For more examples, see [XML Schema: Datatypes \(W3.org web site\)](#).

Example: boosting by freshness or distance

The shape of the boost curve (constant, linear, logarithmic, quadratic) affects how aggressively scores change across the range.

When using the freshness function, if you want the boost to have a more dramatic effect on more recent dates, choose a quadratic interpolation. Quadratic amplifies the effect of near recent dates and closer locations and tapers off more slowly at the far end of the range. In contrast, a logarithmic curve shifts more sharply at the far end.

Here's an example scoring profile that demonstrates how to boost by freshness.

JSON

```
{  
  "name": "docs-index",  
  "fields": [  
    { "name": "id", "type": "Edm.String", "key": true, "filterable": true },  
    { "name": "title", "type": "Edm.String", "searchable": true },  
    { "name": "content", "type": "Edm.String", "searchable": true },  
    { "name": "lastUpdated", "type": "Edm.DateTimeOffset", "filterable": true,  
     "sortable": true }  
  ],  
  "scoringProfiles": [  
    {  
      "name": "freshnessBoost",  
      "text": {  
        "weights": {  
          "content": 1.0  
        }  
      },  
      "functions": [  
        {  
          "type": "freshness",  
          "fieldName": "lastUpdated",  
          "boost": 2.0,  
          "interpolation": "quadratic",  
          "parameters": {  
            "boostingDuration": "365D"  
          }  
        }  
      ]  
    }  
  ]  
}
```

- The `freshness` function computes a magnitude from "now" to `lastUpdated`.
- A positive boost with quadratic interpolation increases lift for recent dates, tapering quickly for older ones.

- "boostingDuration": "365D" defines the time window over which freshness is evaluated, for example boosting documents dated within the last year.
- "interpolation": "quadratic" means the boost effect is stronger for documents closer to the current date and tapers off more sharply for older ones.

In the next example, a linear interpolation provides a steady preference for most-recent content across the 30-day window. Increase boost if the signal needs to win against other relevance factors.

JSON

```
{
  "name": "freshness30_linear",
  "functions": [
    {
      "type": "freshness",
      "fieldName": "lastUpdated",
      "boost": 3.0,
      "interpolation": "linear",
      "parameters": { "boostingDuration": "P30D" }
    }
  ]
}
```

Example: boosting by weighted text and functions

Tip

See this [blog post](#) and [notebook](#) for a demonstration of using scoring profiles and document boosting in vector and generative AI scenarios.

The following example shows the schema of an index with two scoring profiles (`boostGenre`, `newAndHighlyRated`). Any query against this index that includes either profile as a query parameter uses the profile to score the result set.

The `boostGenre` profile uses weighted text fields, boosting matches found in `albumTitle`, `genre`, and `artistName` fields. The fields are boosted 1.5, 5, and 2 respectively. Why is `genre` boosted so much higher than the others? If search is conducted over data that is somewhat homogeneous (as is the case with '`genre`' in the `musicstoreindex`), you might need a larger variance in the relative weights. For example, in the `musicstoreindex`, '`rock`' appears as both a genre and in identically phrased genre descriptions. If you want `genre` to outweigh `genre` description, the `genre` field needs a much higher relative weight.

JSON

```
{
  "name": "musicstoreindex",
  "fields": [
    { "name": "key", "type": "Edm.String", "key": true },
    { "name": "albumTitle", "type": "Edm.String" },
    { "name": "albumUrl", "type": "Edm.String", "filterable": false },
    { "name": "genre", "type": "Edm.String" },
    { "name": "genreDescription", "type": "Edm.String", "filterable": false },
    { "name": "artistName", "type": "Edm.String" },
    { "name": "orderableOnline", "type": "Edm.Boolean" },
    { "name": "rating", "type": "Edm.Int32" },
    { "name": "tags", "type": "Collection(Edm.String)" },
    { "name": "price", "type": "Edm.Double", "filterable": false },
    { "name": "margin", "type": "Edm.Int32", "retrievable": false },
    { "name": "inventory", "type": "Edm.Int32" },
    { "name": "lastUpdated", "type": "Edm.DateTimeOffset" }
  ],
  "scoringProfiles": [
    {
      "name": "boostGenre",
      "text": {
        "weights": {
          "albumTitle": 1.5,
          "genre": 5,
          "artistName": 2
        }
      }
    },
    {
      "name": "newAndHighlyRated",
      "functions": [
        {
          "type": "freshness",
          "fieldName": "lastUpdated",
          "boost": -10,
          "interpolation": "quadratic",
          "freshness": {
            "boostingDuration": "P365D"
          }
        },
        {
          "type": "magnitude",
          "fieldName": "rating",
          "boost": 10,
          "interpolation": "linear",
          "magnitude": {
            "boostingRangeStart": 1,
            "boostingRangeEnd": 5,
            "constantBoostBeyondRange": false
          }
        }
      ]
    }
  ]
}
```

```
]  
}
```

Example: function aggregation

! Note

This capability is currently in preview, available through the [2025-11-01-preview REST API](#) and in Azure SDK preview packages that provide the feature.

Within a single scoring profile, you can specify multiple scoring functions, and then set `"functionAggregation": "product"`. Documents that score highly across all functions are prioritized, while those that score weak in one or more fields are suppressed.

In this example, create a scoring profile that includes two boosting functions that boost by `rating` and `baseRate`, and then set `functionAggregation` to `product`.

HTTP

        "BaseRate": 275.0  
    }  
}  
}
```

Tuning tips

- Start conservative: boost in the 1.25–2.0 range; increase only if recency is truly decisive.
- Window sizing: Use P30D for hot content, P90D/P180D for moderate recency, P365D for long-tail.
- Interpolation choice:
 - quadratic when you want a strong push to recent.
 - linear when you want a steady gradient.
 - logarithmic when you want a gentle preference.
- Aggregation: If combining multiple functions, sum is easiest; switch to max when you want a single signal to dominate

Semantic ranking in Azure AI Search

In Azure AI Search, *semantic ranker* is a feature that measurably improves search relevance by using Microsoft's language understanding models to rerank search results. Semantic ranker is also built into [agentic retrieval](#). This article is a high-level introduction to help you understand the behaviors and benefits of semantic ranker.

Semantic ranker is a premium feature, billed by usage, but you can use it for free subject to [service limits](#) for the free tier. We recommend this article for background, but if you'd rather get started, [follow these steps](#).

What is semantic ranking?

Semantic ranker is a collection of query-side capabilities that improve the quality of an initial [BM25-ranked](#) or [RRF-ranked](#) search result for text-based queries, the text portion of vector queries, and hybrid queries. Semantic ranking extends the query execution pipeline in three ways:

- First, it always adds secondary ranking over an initial result set that was scored using BM25 or Reciprocal Rank Fusion (RRF). This secondary ranking uses multi-lingual, deep learning models adapted from Microsoft Bing to promote the most semantically relevant results.
- Second, it returns captions and optionally extracts answers in the response, which you can render on a search page to improve the user's search experience.
- Third, if you enable query rewrite, it expands an initial query string into multiple semantically similar query strings.

Secondary ranking and "answers" apply to the query response. Query rewrite is part of the query request.

Here are the capabilities of the semantic reranker.

 Expand table

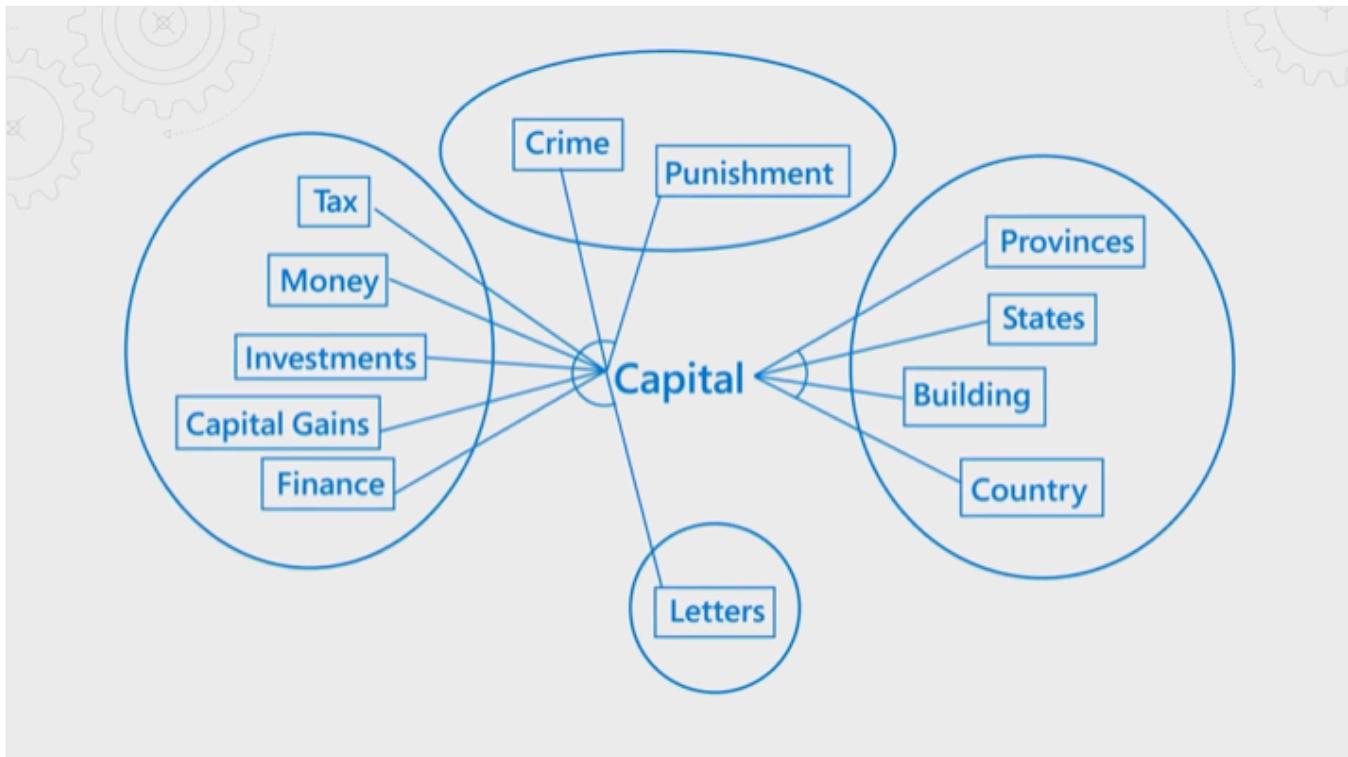

Capability	Description
L2 ranking	Uses the context or semantic meaning of a query to compute a new relevance score over preranked results.
Semantic captions and highlights	Extracts verbatim sentences and phrases from fields that best summarize the content, with highlights over key passages for easy scanning. Captions that summarize a result are useful when individual content fields are too dense for the search results page.

Capability	Description
	Highlighted text elevates the most relevant terms and phrases so that users can quickly determine why a match was considered relevant.
Semantic answers	An optional and extra substructure returned from a semantic query. It provides a direct answer to a query that looks like a question. It requires that a document has text with the characteristics of an answer.
Query rewrite	Using text queries or the text portion of a vector query, semantic ranker creates up to 10 variants of the query, perhaps correcting typos or spelling errors, or rephrasing a query using generated synonyms. The rewritten query runs on the search engine. The results are scored using BM25 or RRF scoring, and then rescored by semantic ranker.

How semantic ranker works

Semantic ranker feeds a query and results to language understanding models hosted by Microsoft and scans for better matches.

The following illustration explains the concept. Consider the term "capital". It has different meanings depending on whether the context is finance, law, geography, or grammar. Through language understanding, the semantic ranker can detect context and promote results that fit query intent.

Semantic ranking is both resource and time intensive. In order to complete processing within the expected latency of a query operation, inputs to the semantic ranker are consolidated and reduced so that the reranking step can be completed as quickly as possible.

There are three steps to semantic ranking:

- Collect and summarize inputs
- Score results using the semantic ranker
- Output rescored results, captions, and answers

How inputs are collected and summarized

In semantic ranking, the query subsystem passes search results as an input to summarization and ranking models. Because the ranking models have input size constraints and are processing intensive, search results must be sized and structured (summarized) for efficient handling.

1. Semantic ranker starts with a [BM25-ranked result](#) from a text query or an [RRF-ranked result](#) from a vector or hybrid query. Only text is used in the reranking exercise, and only the top 50 results progress to semantic ranking, even if results include more than 50. Typically, fields used in semantic ranking are informational and descriptive.
2. For each document in the search result, the summarization model accepts up to 2,000 tokens, where a token is approximately 10 characters. Inputs are assembled from the "title", "keyword", and "content" fields listed in the [semantic configuration](#).
3. Excessively long strings are trimmed to ensure the overall length meets the input requirements of the summarization step. This trimming exercise is why it's important to add fields to your semantic configuration in priority order. If you have very large documents with text-heavy fields, anything after the maximum limit is ignored.

[] [Expand table](#)

Semantic field	Token limit
"title"	128 tokens
"keywords"	128 tokens
"content"	remaining tokens

4. Summarization output is a summary string for each document, composed of the most relevant information from each field. Summary strings are sent to the ranker for scoring, and to machine reading comprehension models for captions and answers.

As of November 2024, the maximum length of each generated summary string passed to the semantic ranker is 2,048 tokens. Previously, it was 256 tokens.

How results are scored

Scoring is done over the caption, and any other content from the summary string that fills out the 2,048 token length.

1. Captions are evaluated for conceptual and semantic relevance, relative to the query provided.
2. A `@search.rerankerScore` is assigned to each document based on the semantic relevance of the document for the given query. Scores range from 4 to 0 (high to low), where a higher score indicates higher relevance.

[] [Expand table](#)

Score	Meaning
4.0	The document is highly relevant and answers the question completely, though the passage might contain extra text unrelated to the question.
3.0	The document is relevant but lacks details that would make it complete.
2.0	The document is somewhat relevant; it answers the question either partially or only addresses some aspects of the question.
1.0	The document is related to the question, and it answers a small part of it.
0.0	The document is irrelevant.

3. Matches are listed in descending order by score and included in the query response payload. The payload includes answers, plain text and highlighted captions, and any fields that you marked as retrievable or specified in a select clause.

! Note

For any given query, the distributions of `@search.rerankerScore` can exhibit slight variations due to conditions at the infrastructure level. Ranking model updates have also been known to affect the distribution. For these reasons, if you're writing custom code for minimum thresholds, or [setting the threshold property](#) for vector and hybrid queries, don't make the limits too granular.

Outputs of semantic ranker

From each summary string, the machine reading comprehension models find passages that are the most representative.

Outputs are:

- A [semantic caption](#) for the document. Each caption is available in a plain text version and a highlight version, and is frequently fewer than 200 words per document.
- An optional [semantic answer](#), assuming you specified the `answers` parameter, the query was posed as a question, and a passage is found in the long string that provides a likely answer to the question.

Captions and answers are always verbatim text from your index. There's no generative AI model in this workflow that creates or composes new content.

Semantic capabilities and limitations

What semantic ranker *can* do:

- Promote matches that are semantically closer to the intent of original query.
- Find strings to use as captions and answers. Captions and answers are returned in the response and can be rendered on a search results page.

What semantic ranker *can't* do is rerun the query over the entire corpus to find semantically relevant results. Semantic ranking reranks the existing result set, consisting of the top 50 results as scored by the default ranking algorithm. Furthermore, semantic ranker can't create new information or strings. Captions and answers are extracted verbatim from your content so if the results don't include answer-like text, the language models won't produce one.

Although semantic ranking isn't beneficial in every scenario, certain content can benefit significantly from its capabilities. The language models in semantic ranker work best on searchable content that is information-rich and structured as prose. A knowledge base, online documentation, or documents that contain descriptive content see the most gains from semantic ranker capabilities.

The underlying technology is from Bing and Microsoft Research, and integrated into the Azure AI Search infrastructure as an add-on feature. For more information about the research and AI investments backing semantic ranker, see [How AI from Bing is powering Azure AI Search \(Microsoft Research Blog\)](#).

The following video provides an overview of the capabilities.

https://www.youtube-nocookie.com/embed/yOf0WfVd_V0

How semantic ranker uses synonym maps

If you have already enabled support for [synonym maps associated to a field](#) in your search index, and that field is included in the [semantic ranker configuration](#), the semantic ranker will automatically apply the configured synonyms during the reranking process.

Availability and pricing

Semantic ranker is available [in selected regions](#). It's used as a standalone feature and as a built-in component of [agentic retrieval](#).

You can disable semantic ranker for your search service, use it on a limited basis for free, or use it more expansively with pay-as-you-go billing:

 [Expand table](#)

Plan	Description
Free	A free tier search service provides 1,000 semantic ranker requests per month and 50 million free agentic reasoning tokens per month. Higher tiers can also use the free plan.
Standard	The standard plan is pay-as-you-go pricing once the monthly free quota is consumed. After the first 1,000 semantic ranker requests, you are charged for each additional 1,000 requests. After the first 50 million agentic reasoning tokens per month, you are charged a nominal fee for each one million agentic reasoning tokens. The transition from Free to Standard is seamless. You aren't notified when the transition occurs. For more information about charges by currency, see the Azure AI Search pricing page .

The [Azure AI Search pricing page](#) shows you the billing rate for different currencies and intervals.

Charges for semantic ranker are levied when query requests include `queryType=semantic` and the search string isn't empty (for example, `search=pet friendly hotels in New York`). If your search string is empty (`search=*`), you aren't charged, even if the `queryType` is set to `semantic`.

How to get started with semantic ranker

1. [Check regional availability](#).
2. [Sign in to Azure portal](#).
3. [Configure semantic ranker for the search service, choosing a pricing plan](#). The free plan is the default.
4. [Configure semantic ranker in a search index](#).

5. Set up queries to return semantic captions and highlights.

6. Optionally, return semantic answers.

Last updated on 11/19/2025

Enable or disable semantic ranker

Semantic ranker is a premium feature billed by usage. By default, semantic ranker is enabled on a new billable search service and it's configured for the free plan, but anyone with *Contributor* permissions can disable it or change the billing plan. If you don't want anyone to use the feature, you can [disable it service-wide using the management REST API](#). If you disable semantic ranking, you also disable [agentic retrieval](#).

Check availability

To check if semantic ranker is available in your region, see the [Azure AI Search regions list](#).

Enable semantic ranker

Semantic ranker might not be enabled on older services. Follow these steps to enable [semantic ranker](#) at the service level. Once enabled, it's available to all indexes. You can't turn it on or off for specific indexes.

Azure portal

1. Open the [Azure portal](#).
2. Navigate to your search service. On the **Overview** page, make sure the pricing tier is set to **Basic** or higher.
3. On the left-navigation pane, select **Settings > Premium features**.
4. Select either the **Free plan** (default) or the **Standard plan**. You can switch between the free plan and the standard plan at any time.

The screenshot shows the 'Premium features' section of the Azure AI Search service. On the left, there's a sidebar with options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Resource visualizer, Search management, Settings, Premium features (which is highlighted with a red box), Knowledge Center, Keys, Scale, and Search traffic analytics. The main area has a heading 'Premium features' with a sub-section 'Availability'. It shows two plans: 'Free' and 'Standard'. The 'Free' plan is highlighted with a red box and includes details: 1,000 semantic ranker requests per month and 50M free agentic retrieval tokens per month. It costs '\$0.00/month' and has a 'Selected Plan' button. The 'Standard' plan includes details: First 1,000 semantic ranker requests per month free, \$1.00 per additional 1,000 requests; First 50M agentic retrieval tokens per month free, \$0.022 per additional 1M agentic retrieval tokens. It has a 'Select Plan' button.

The free plan is capped at 1,000 queries per month. After the first 1,000 queries in the free plan, an error message indicates you exhausted your quota on the next semantic query. When quota is exhausted, you can upgrade to the standard plan to continue using semantic ranking.

Disable semantic ranker using the REST API

To turn off feature enablement, or for full protection against accidental usage and charges, you can disable semantic ranker by using the [Create or Update Service API](#) on your search service. After the feature is disabled, any requests that include the semantic query type are rejected.

Management REST API calls are authenticated through Microsoft Entra ID. For instructions on how to authenticate, see [Manage your Azure AI Search service with REST APIs](#).

HTTP

PATCH

```
https://management.azure.com/subscriptions/{{subscriptionId}}/resourcegroups/{{resource-group}}/providers/Microsoft.Search/searchServices/{{search-service-name}}?api-version=2025-05-01
{
  "properties": {
    "semanticSearch": "disabled"
  }
}
```

To re-enable semantic ranker, run the previous request again and set `semanticSearch` to either **Free** (default) or **Standard**.

Next step

[Configure semantic ranker](#)

Last updated on 11/18/2025

Configure semantic ranker and return captions in search results

Semantic ranking iterates over an initial result set, applying an L2 ranking methodology that promotes the most semantically relevant results to the top of the stack. You can also get semantic captions, with highlights over the most relevant terms and phrases, and [semantic answers](#).

This article explains how to configure a search index for semantic reranking.

(!) Note

If you have existing code that calls preview or previous API versions, see [Migrate semantic ranking code](#) for help with modifying your code.

Prerequisites

- Azure AI Search in any [region that provides semantic ranking](#).
- Semantic ranker [enabled on your search service](#).
- An existing search index with rich text content. Semantic ranking applies to strings (nonvector) fields and works best on content that is informational or descriptive.

Choose a client

You can specify a semantic configuration on new or existing indexes, using any of the following tools and software development kits (SDKs) to add a semantic configuration:

- [Azure portal](#), using the index designer to add a semantic configuration.
- [Visual Studio Code](#) with the [REST client](#) and a [Create or Update Index \(REST\) API](#).
- [Azure SDK for .NET](#)
- [Azure SDK for Python](#)
- [Azure SDK for Java](#)
- [Azure SDK for JavaScript](#)

Add a semantic configuration

Some workloads create a semantic configuration automatically. If you're using [agentic retrieval](#) and a [knowledge source that indexes content](#) on Azure AI Search, your generated index

already has a semantic configuration that works for your content.

For other workloads, you can set up a semantic configuration yourself. A *semantic configuration* is a section in your index that establishes the field inputs used for semantic ranking. You can add or update a semantic configuration at any time, no rebuild necessary. If you create multiple configurations, you can specify a default. At query time, specify a semantic configuration on a [query request](#), or leave it blank to use the default.

You can create up to 100 semantic configurations in a single index.

A semantic configuration has a name and the following properties:

 [Expand table](#)

Property	Characteristics
Title field	A short string, ideally under 25 words. This field could be the title of a document, name of a product, or a unique identifier. If you don't have suitable field, leave it blank.
Content fields	Longer chunks of text in natural language form, subject to maximum token input limits on the machine learning models. Common examples include the body of a document, description of a product, or other free-form text.
Keyword fields	A list of keywords, such as the tags on a document, or a descriptive term, such as the category of an item.

You can only specify one title field, but you can have as many content and keyword fields as you like. For content and keyword fields, list the fields in priority order because lower priority fields might get truncated.

Across all semantic configuration properties, the fields you assign must be:

- Attributed as `searchable` and `retrievable`
- Strings of type `Edm.String`, `Collection(Edm.String)`, string subfields of `Edm.ComplexType`

Azure portal

1. Sign in to the [Azure portal](#)  and navigate to a search service that has [semantic ranking enabled](#).
2. From **Indexes** on the left-navigation pane, select an index.
3. Select **Semantic configurations** and then select **Add semantic configuration**.

Under 'Keyword fields', there is a 'Field name' dropdown with 'Tags'. At the bottom right of the dialog, there is a 'Save' button highlighted with a red box and a 'Cancel' button.

5. Select **Save** to save the configuration settings.
6. Select **Save** again on the index page to save the semantic configuration in the index.

Opt in for prerelease semantic ranking models

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Using [previewREST APIs](#) and preview Azure SDKs that provide the property, you can optionally configure an index to use prerelease semantic ranking models if one is deployed in your region. There's no mechanism for knowing if a prerelease is available, or if it was used on specific query. For this reason, we recommend that you use this property in test environments, and only if you're interested in trying out the very latest semantic ranking models.

The configuration property is `"flightingOptIn": true`, and it's set in the semantic configuration section of an index. The property is null or false by default. You can set it true on a create or update request at any time, and it affects semantic queries moving forward, assuming the query stipulates a semantic configuration that includes the property.

Next steps

Test your semantic configuration by running a semantic query.

[Create a semantic query](#)

Last updated on 11/21/2025

Add semantic ranking to queries in Azure AI Search

You can apply semantic ranking to text queries, hybrid queries, and vector queries if your search documents contain string fields and the [vector query has a text representation](#) in the search document.

This article explains how to invoke the semantic ranker on queries. It assumes you're using the most recent stable or preview APIs. For help with older versions, see [Migrate semantic ranking code](#).

Prerequisites

- Azure AI Search in any [region that provides semantic ranking](#), with [semantic ranker enabled](#).
- An existing search index with a [semantic configuration](#) and rich text content.
- Familiarity with [semantic ranking](#).

Note

Captions and answers are extracted verbatim from text in the search document. The semantic subsystem uses machine reading comprehension to recognize content having the characteristics of a caption or answer, but doesn't compose new sentences or phrases except in the case of [query rewrite](#). For this reason, content that includes explanations or definitions work best for semantic ranking. If you want chat-style interaction with generated responses, see [Agentic retrieval](#) or [Retrieval Augmented Generation \(RAG\)](#).

Choose a client

You can use any of the following tools and SDKs to build a query that uses semantic ranking:

- [Azure portal](#) ↗, using the index designer to add a semantic configuration.
- [Visual Studio Code](#) ↗ with a [REST client](#) ↗
- [Azure SDK for .NET](#) ↗
- [Azure SDK for Python](#) ↗
- [Azure SDK for Java](#) ↗
- [Azure SDK for JavaScript](#) ↗

Avoid features that bypass relevance scoring

A few query capabilities bypass relevance scoring, which makes them incompatible with semantic ranking. If your query logic includes the following features, you can't semantically rank your results:

- A query with `search=*` or an empty search string, such as pure filter-only query, won't work because there's nothing to measure semantic relevance against and so the search scores are zero. The query must provide terms or phrases that can be evaluated during processing, and that produces search documents that are scored for relevance. Scored results are inputs to the semantic ranker.
- Sorting (`orderBy` clauses) on specific fields overrides search scores and a semantic score. Given that the semantic score is supposed to provide the ranking, adding an `orderBy` clause results in an HTTP 400 error if you apply semantic ranking over ordered results.

Set up the query

By default, queries don't use semantic ranking. To use semantic ranking, two different parameters can be used. Each parameter supports a different set of query formats.

All semantic queries, whether specified through `search` plus `queryType`, or through `semanticQuery`, must be plain text and they can't be empty. As you can see from the table below, the `queryType-semantic` parameter supports a subset of query formats.

[+] Expand table

Parameter	Plain text search	Simple text search syntax	Full text search syntax	Vector search	Hybrid Search	Semantic answers and captions
<code>queryType-semantic</code> ¹	✓	✗	✗	✗	✓	✓
<code>semanticQuery="<your plain text query>"</code> ²	✓	✓	✓	✓	✓	✓

¹ `queryType=semantic` can't support explicit `simple` or `full` values because the `queryType` parameter is being used for `semantic`. The effective query behaviors are the defaults of the simple parser.

² The `semanticQuery` parameter can be used for all query types. However, it isn't supported in the Azure portal [Search Explorer](#).

Regardless of the parameter chosen, the index should contain text fields with rich semantic content and a [semantic configuration](#).

Azure portal

Search explorer includes options for semantic ranking. Recall that you can't set the `semanticQuery` parameter in the Azure portal.

1. Sign in to the [Azure portal](#).
2. Open a search index and select **Search explorer**.
3. Select **Query options**. If you already defined a semantic configuration, it's selected by default. If you don't have one, [create a semantic configuration](#) for your index.
4. Enter a query, such as "historic hotel with good food", and select **Search**.
5. Alternatively, select **JSON view** and paste definitions into the query editor. The Azure portal doesn't support using `semanticQuery`, so setting `queryType` to "`semantic`" is required:

The screenshot shows the Azure portal interface for a search index named "hotels-sample-index". The "Search explorer" tab is selected. In the top right, there are dropdown menus for "2023-10-01-Preview" and "View". A red box highlights the "JSON query editor" section, which contains the following JSON code:

```
1 {  
2   "search": "historic hotel with good food",  
3   "select": "HotelName, Description, Category, Tags",  
4   "queryType": "semantic",  
5   "semanticConfiguration": "my-semantic-config",  
6   "captions": "extractive",  
7   "answers": "extractive|count-3",  
8   "queryLanguage": "en-US"  
9 }
```

Next to the JSON editor, a red box highlights the "JSON view" button in the "View" dropdown menu. Below the editor, the "Results" section displays the search results in JSON format. One result is shown in detail:

```
1 {  
2   "@odata.context":  
3   "@search.answers": [],  
4   "value": [  
5     {  
6       "@search.score": 1.4323225,  
7       "@search.rerankerScore": 2.344247817993164,  
8       "@search.captions": [  
9         {  
10           "text": "Nordick's Motel. Only 90 miles (about 2 hours) from the nation's capital and nearby mos",  
11           "highlights": ""  
12         }  
13       ],  
14       "HotelName": "Nordick's Motel",  
15       "Description": "Only 90 miles (about 2 hours) from the nation's capital and nearby most everything t",  
16       "Category": "Resort and Spa",  
17       "Tags": [  
18         "restaurant",  
19         "air conditioning",  
20         "restaurant"  
21       ]  
22     },
```

On the right side of the results panel, there is a vertical scrollable list of other search results.

JSON example for setting query type to semantic that you can paste into the view:

JSON

```
{  
  "search": "funky or interesting hotel with good food on site",  
  "count": true,  
  "queryType": "semantic",  
  "semanticConfiguration": "my-semantic-config",  
  "captions": "extractive|highlight-true",  
  "answers": "extractive|count-3",  
  "highlightPreTag": "<strong>",  
  "highlightPostTag": "</strong>",  
  "select": "HotelId, HotelName, Description, Category"  
}
```

Evaluate the response

Only the top 50 matches from the initial results can be semantically ranked. As with all queries, a response is composed of all fields marked as retrievable, or just those fields listed in the `select` parameter. A response includes the original relevance score, and might also include a count, or batched results, depending on how you formulated the request.

In semantic ranking, the response has more elements: a new [semantically ranked relevance score](#), an optional caption in plain text and with highlights, and an optional [answer](#). If your results don't include these extra elements, then your query might be misconfigured. As a first step towards troubleshooting the problem, check the semantic configuration to ensure it's specified in both the index definition and query.

In a client app, you can structure the search page to include a caption as the description of the match, rather than the entire contents of a specific field. This approach is useful when individual fields are too dense for the search results page.

The response for the above example query ("*interesting hotel with restaurant on site and cozy lobby or shared area*") returns three answers (`"answers": "extractive|count-e"`). Captions are returned because the "captions" property is set, with plain text and highlighted versions. If an answer can't be determined, it's omitted from the response. For brevity, this example shows just the three answers and the three highest scoring results from the query.

JSON

```
{  
  "@odata.count": 29,  
  "@search.answers": [  
    {  
      "HotelId": 1,  
      "HotelName": "The Grand Hotel",  
      "Description": "A large, historic hotel located in the heart of the city.",  
      "Category": "Luxury",  
      "Score": 0.95  
    },  
    {  
      "HotelId": 2,  
      "HotelName": "The Plaza Hotel",  
      "Description": "A modern hotel with a focus on comfort and convenience.",  
      "Category": "Mid-range",  
      "Score": 0.92  
    },  
    {  
      "HotelId": 3,  
      "HotelName": "The Royal Hotel",  
      "Description": "A classic hotel with a traditional atmosphere.",  
      "Category": "Budget",  
      "Score": 0.88  
    }  
  ]  
}
```

}
```

Expected workloads

For semantic ranking, you should expect a search service to support up to 10 concurrent queries per replica.

The service throttles semantic ranking requests if volumes are too high. An error message that includes these phrases indicate the service is at capacity for semantic ranking:

JSON

```
Error in search query: Operation returned an invalid status 'Partial Content'  
@search.semanticPartialResponseReason`  
CapacityOverloaded
```

If you anticipate consistent throughput requirements near, at, or higher than this level, please file a support ticket so that we can provision for your workload.

Next steps

Semantic ranking can be used in hybrid queries that combine keyword search and vector search into a single request and a unified response.

[Hybrid query with semantic ranker](#)

Last updated on 11/06/2025

Rewrite queries with semantic ranker in Azure AI Search (Preview)

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Query rewriting is the process of transforming a user's query into a more effective one, adding more terms and refining search results. The search service sends the search query (or a variation of it) to a generative model that generates alternative queries.

Query rewriting improves results from [semantic ranking](#) by correcting typos or spelling errors in user queries, and expanding queries with synonyms.

Search with query rewriting works like this:

- The user query is sent via the `search` property in the request.
- The search service sends the search query (or a variation of it) to a generative model that generates alternative queries.
- The search service uses the original query and the rewritten queries to retrieve search results.

Query rewriting is an optional feature. Without query rewriting, the search service just uses the original query to retrieve search results.

ⓘ Note

The rewritten queries might not contain all of the exact terms the original query had. This might impact search results if the query was highly specific and required exact matches for unique identifiers or product codes.

Prerequisites

- [Azure AI Search](#) in any [region that provides query rewrite](#), with [semantic ranker enabled](#).
- An existing search index with a [semantic configuration](#) and rich text content. The examples in this guide use the [hotels-sample-index](#) sample data to demonstrate query

rewriting.

- To follow the instructions in this article, you need a web client that supports REST API requests. The examples in this article were tested with [Visual Studio Code](#) and the [REST Client](#) extension.

 Tip

Content that includes explanations or definitions work best for semantic ranking.

Make a search request with query rewrites

In this REST API example, use [Search Documents \(preview\)](#) to formulate the request.

1. Paste the following request into a web client as a template.

HTTP

```
POST https://[search-service-name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2025-11-01-preview
{
    "search": "newer hotel near the water with a great restaurant",
    "semanticConfiguration": "en-semantic-config",
    "queryType": "semantic",
    "queryRewrites": "generative|count-5",
    "queryLanguage": "en-US",
    "debug": "queryRewrites",
    "top": 1
}
```

- Replace `search-service-name` with your search service name.
- Replace `hotels-sample-index` with your index name if it's different.
- Set "search" to a full text search query. The search property is required for query rewriting, unless you specify [vector queries](#). If you specify vector queries, then the "search" text must match the `"text"` property of the `"vectorQueries"` object. Your search string can support either the [simple syntax](#) or [full Lucene syntax](#).
- Set "semanticConfiguration" to a [predefined semantic configuration](#) embedded in your index.
- Set "queryType" to "semantic". You either need to set "queryType" to "semantic" or include a nonempty "semanticQuery" property in the request. [Semantic ranking](#) is required for query rewriting.

- Set "queryRewrites" to "generative|count-5" to get up to five query rewrites. You can set the count to any value between 1 and 10.
- Since you requested query rewrites by setting the "queryRewrites" property, you must set "queryLanguage" to the search text language. The search service uses the same language for the query rewrites. In this example, you use "en-US". The supported locales are: en-AU, en-CA, en-GB, en-IN, en-US, ar-EG, ar-JO, ar-KW, ar-MA, ar-SA, bg-BG, bn-IN, ca-ES, cs-CZ, da-DK, de-DE, el-GR, es-ES, es-MX, et-EE, eu-ES, fa-AE, fi-FI, fr-CA, fr-FR, ga-IE, gl-ES, gu-IN, he-IL, hi-IN, hr-BA, hr-HR, hu-HU, hy-AM, id-ID, is-IS, it-IT, ja-JP, kn-IN, ko-KR, lt-LT, lv-LV, ml-IN, mr-IN, ms-BN, ms-MY, nb-NO, nl-BE, nl-NL, no-NO, pa-IN, pl-PL, pt-BR, pt-PT, ro-RO, ru-RU, sk-SK, sl-SL, sr-BA, sr-ME, sr-RS, sv-SE, ta-IN, te-IN, th-TH, tr-TR, uk-UA, ur-PK, vi-VN, zh-CN, zh-TW.
- Set "debug" to "queryRewrites" to get the query rewrites in the response.

 **Tip**

Only set "debug": "queryRewrites" for testing purposes. For better performance, don't use debug in production.

- Set "top" to 1 to return only the top search result.

2. Send the request to execute the query and return results.

Next, you evaluate the search results with the query rewrites.

Evaluate the response

Here's an example of a response that includes query rewrites:

JSON

```
"@search.debug": {
  "semantic": null,
  "queryRewrites": {
    "text": {
      "inputQuery": "newer hotel near the water with a great restaurant",
      "rewrites": [
        "new waterfront hotels with top-rated eateries",
        "new waterfront hotels with top-rated restaurants",
        "new waterfront hotels with excellent dining",
        "new waterfront hotels with top-rated dining",
        "new water-side hotels with top-rated restaurants"
      ]
    }
  }
}
```

```

        ],
      },
      "vectors": []
    },
  },
  "value": [
    {
      "@search.score": 58.992092,
      "@search.rerankerScore": 2.815633535385132,
      "HotelId": "18",
      "HotelName": "Ocean Water Resort & Spa",
      "Description": "New Luxury Hotel for the vacation of a lifetime. Bay views from every room, location near the pier, rooftop pool, waterfront dining & more.",
      "Description_fr": "Nouvel h\u00f4tel de luxe pour des vacances inoubliables. Vue sur la baie depuis chaque chambre, emplacement pr\u00e8s de la jet\u00e9e, piscine sur le toit, restaurant au bord de l'eau et plus encore.",
      "Category": "Luxury",
      "Tags": [
        "view",
        "pool",
        "restaurant"
      ],
      "ParkingIncluded": true,
      "LastRenovationDate": "2020-11-14T00:00:00Z",
      "Rating": 4.2,
      "Location": {
        "type": "Point",
        "coordinates": [
          -82.537735,
          27.943701
        ],
        "crs": {
          "type": "name",
          "properties": {
            "name": "EPSG:4326"
          }
        }
      },
      //... more properties redacted for brevity
    }
  ]
]

```

Here are some key points to note:

- Because you set the "debug" property to "queryRewrites" for testing, the response includes a `@search.debug` object with the text input query and query rewrites.
- Because you set the "queryRewrites" property to "generative|count-5", the response includes up to five query rewrites.
- The `"inputQuery"` value is the query sent to the generative model for query rewriting. The input query isn't always the same as the user's `"search"` query.

Here's an example of a response without query rewrites.

JSON

```
"@search.debug": {
  "semantic": null,
  "queryRewrites": {
    "text": {
      "inputQuery": "",
      "rewrites": []
    },
    "vectors": []
  }
},
"value": [
  {
    "@search.score": 7.774868,
    "@search.rerankerScore": 2.815633535385132,
    "HotelId": "18",
    "HotelName": "Ocean Water Resort & Spa",
    "Description": "New Luxury Hotel for the vacation of a lifetime. Bay views from every room, location near the pier, rooftop pool, waterfront dining & more.",
    "Description_fr": "Nouvel h\u00f4tel de luxe pour des vacances inoubliables. Vue sur la baie depuis chaque chambre, emplacement pr\u00e8s de la jet\u00e9e, piscine sur le toit, restaurant au bord de l'eau et plus encore.",
    "Category": "Luxury",
    "Tags": [
      "view",
      "pool",
      "restaurant"
    ],
    "ParkingIncluded": true,
    "LastRenovationDate": "2020-11-14T00:00:00Z",
    "Rating": 4.2,
    "Location": {
      "type": "Point",
      "coordinates": [
        -82.537735,
        27.943701
      ],
      "crs": {
        "type": "name",
        "properties": {
          "name": "EPSG:4326"
        }
      }
    },
    //... more properties redacted for brevity
  }
]
```

Vector queries with query rewrite

You can include vector queries in your search request to combine keyword search and vector search into a single request and a unified response.

Here's an example of a query that includes a vector query with query rewrites. Modify a [previous example](#) to include a vector query.

- Add a "vectorQueries" object to the request. This object includes a vector query with the "kind" set to "text".
- The "text" value is the same as the "search" value. These values must be identical for query rewriting to work.

HTTP

```
POST https://[search-service-name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2025-11-01-preview
{
    "search": "newer hotel near the water with a great restaurant",
    "vectorQueries": [
        {
            "kind": "text",
            "text": "newer hotel near the water with a great restaurant",
            "k": 50,
            "fields": "Description",
            "queryRewrites": "generative|count-3"
        }
    ],
    "semanticConfiguration": "en-semantic-config",
    "queryType": "semantic",
    "queryRewrites": "generative|count-5",
    "queryLanguage": "en-US",
    "top": 1
}
```

The response includes query rewrites for both the text query and the vector query.

Test query rewrites with debug

You should test your query rewrites to ensure that they're working as expected. Set the `"debug": "queryRewrites"` property in your query request to get the query rewrites in the response. Setting `"debug"` is optional for testing purposes. For better performance, don't set this property in production.

Partial response reasons

You might observe that the debug (test) response includes an empty array for the `text.rewrites` and `vectors` properties.

JSON

```
{  
    "@odata.context": "https://demo-search-svc.search.windows.net/indexes('hotels-sample-index')/$metadata#docs(*)",  
    "@search.debug": {  
        "semantic": null,  
        "queryRewrites": {  
            "text": {  
                "rewrites": []  
            },  
            "vectors": []  
        }  
    },  
    "@search.semanticPartialResponseReason": "Transient",  
    "@search.semanticQueryRewriteResultType": "OriginalQueryOnly",  
    //... more properties redacted for brevity  
}
```

In the preceding example:

- The response includes a `@search.semanticPartialResponseReason` property with a value of "Transient". This message means that at least one of the queries failed to complete.
- The response also includes a `@search.semanticQueryRewriteResultType` property with a value of "OriginalQueryOnly". This message means that the query rewrites are unavailable. Only the original query is used to retrieve search results.

Next steps

Semantic ranking can be used in hybrid queries that combine keyword search and vector search into a single request and a unified response.

[Hybrid query with semantic ranker](#)

Last updated on 11/21/2025

Migrate semantic ranking code from previous versions

If your semantic ranking code was written against early preview APIs, this article identifies the code changes necessary for migrating to newer API versions. Breaking changes for semantic ranker are limited to query logic in recent APIs, but if your code was written against the initial preview version, you might need to change your semantic configuration as well.

Breaking changes

There are two breaking changes for semantic ranker across REST API versions:

- `searchFields` was replaced by `semanticConfiguration` in 2021-04-30-preview
- `queryLanguage` was ignored starting in 2023-07-01-preview, but reinstated for query rewrite in 2024-11-01-preview

Other version-specific updates pertain to new capabilities, but don't break existing code and are therefore not breaking changes.

If you're using Azure SDKs, multiple APIs have been renamed over time. The SDK change logs provide the details.

API versions providing semantic ranking

Check your code for the REST API version or SDK package version to confirm which one provides semantic ranking. The following API versions have some level of support for semantic ranking.

 Expand table

Release type	REST API version	Semantic ranker updates
initial	2020-06-30-preview	Adds <code>queryType=semantic</code> to Search Documents
preview	2021-04-30-preview	Adds <code>semanticConfiguration</code> to Create or Update Index
preview	2023-07-01-preview	Updates <code>semanticConfiguration</code> . Starting on July 14, 2023 updates to the Microsoft-hosted semantic models made semantic ranker language-agnostic, effectively decommissioning the <code>queryLanguage</code> property for semantic ranking. There's no breaking change in code,

Release type	REST API version	Semantic ranker updates
		but the property is ignored. Customers were advised to remove this property from code.
preview	2023-10-01-preview	Adds <code>semanticQuery</code> to send a query used only for reranking purposes.
stable	2023-11-01	Generally available. Introduced changes to <code>semanticConfiguration</code> that progressed to the stable version. If your code targets this version or later, it's compatible with newer API versions unless you adopt new preview features.
preview	2024-05-01-preview	No change
stable	2024-07-01	No change
preview	2024-09-01-preview	No change
preview	2024-11-01-preview	Adds query rewrite. The <code>queryLanguage</code> property is now required if you use query rewrite (preview) .
preview	2025-03-01-preview	Adds opt-in to prerelease versions of semantic models.
preview	2025-05-01-preview	No API updates in this preview, but semantic ranking now has better integration with scoring profiles .
preview	2025-08-01-preview	No change
preview	2025-11-01-preview	Available on free tiers.

Change logs for Azure SDKs

Azure SDKs are on an independent release schedule. You should check the change logs to determine which packages provide semantic features and whether any APIs have been renamed.

- [Azure SDK for .NET change log ↗](#)
- [Azure SDK for Python change log ↗](#)
- [Azure SDK for Java change log ↗](#)
- [Azure SDK for JavaScript change log ↗](#)

2024-11-01-preview

- Adds [query rewrite](#) to Search Documents.
- Requires `queryLanguage` for query rewrite workloads. For a list of valid values, see the [REST API](#).

2024-09-01-preview

No changes to semantic ranking syntax from the 2024-07-01 stable version.

2024-07-01

No changes to semantic ranking syntax from the 2024-05-01-preview version.

Don't use this API version. It implements a vector query syntax that's incompatible with any newer API version.

2024-05-01-preview

No changes to semantic ranking syntax from the 2024-03-01-preview version.

2024-03-01-preview

No changes to semantic ranking syntax from the 2023-10-01-preview version, but vector queries are introduced. Semantic ranking now applies to responses from hybrid and vector queries. You can apply reranking on any human-readable text fields in the response, assuming the fields are listed in `prioritizedFields`.

2023-11-01

- Excludes `SemanticDebug` and `semanticQuery`, otherwise the same as the 2023-10-01-preview version.

2023-10-01-preview

- Adds `semanticQuery`

2023-07-01-preview

- Adds `semanticErrorHandling`, `semanticMaxWaitInMilliseconds`.
- Adds numerous semantic-related fields to the response, such as `SemanticDebug` and `SemanticErrorMode`.
- Ignores `queryLanguage`, it's no longer used in semantic ranking.

Starting on July 14, 2023, semantic ranker is language agnostic. In preview versions, semantic ranking would deprioritize results differing from the `querylanguage` specified by the field analyzer. However, the `queryLanguage` property is still applicable to [spell correction](#) and the short list of languages supported by that feature.

2021-04-30-preview

- Semantic support is through [Search Documents](#) and [Create or Update Index](#) preview API calls.
- Adds `semanticConfiguration` to a search index. A semantic configuration has a name and a prioritized field list.
- Adds ``prioritizedFields`.

The `searchFields` property is no longer used to prioritize fields. In all versions moving forward, `semanticConfiguration.prioritizedFields` replaces `searchFields` as the mechanism for specifying which fields to use for L2 ranking.

2020-06-30-preview

- Semantic support is through a [Search Documents](#) preview API call.
- Adds `queryType=semantic` to the query request.
- Adapts `searchFields` so that if the query type is semantic, the `searchFields` property determines the priority order of field inputs to the semantic ranker.
- Adds `captions`, `answers`, and `highlights` to the query response.

Next steps

Test your semantic configuration migration by running a semantic query.

[Create a semantic query](#)

Use scoring profiles with semantic ranker in Azure AI Search

09/28/2025

You can apply a [scoring profile](#) over [semantically ranked search results](#), where the scoring profile is processed last.

To ensure the scoring profile provides the determining score, the semantic ranker adds a response field, `@search.rerankerBoostedScore`, that applies scoring profile logic on semantically ranked results. In search results that include `@search.score` from level 1 ranking, `@search.rerankerScore` from semantic ranker, and `@search.reRankerBoostedScore`, results are sorted by `@search.reRankerBoostedScore`.

Prerequisites

- [Azure AI Search](#), Basic pricing tier or higher, with [semantic ranker](#) enabled.
- A search index with a semantic configuration that specifies `"rankingOrder": "boostedRerankerScore"` and a scoring profile that specifies [functions](#).

Limitations

Boosting of semantically ranked results applies to scoring profile functions only. There's no boosting if the scoring profile consists only of weighted text fields.

How does semantic configuration with scoring profiles work?

When you execute a semantic query associated with a scoring profile, a third search score, `@search.rerankerBoostedScore` value, is generated for every document in your search results. This boosted score, calculated by applying the scoring profile to the existing reranker score, doesn't have a guaranteed range (0–4) like a normal reranker score, and scores can be significantly higher than 4.

Semantic results are sorted by `@search.rerankerBoostedScore` by default if a scoring profile exists. If the `rankingOrder` property isn't specified, then `BoostedRerankerScore` is the default value in the semantic configuration.

In this scenario, a scoring profile is used twice.

1. First, the scoring profile defined in your index is used during the initial L1 ranking phase, boosting results from:
 - Text-based queries (BM25 or RRF)
 - The text portion of vector queries
 - Hybrid queries that combine both types
2. Next, the semantic ranker rescores the top 50 results, promoting more semantically relevant matches to the top. This step can erase the benefit of the scoring profile. For example, if you boosted based on freshness, then semantic reordering replaces that boost with its own logic of what is most relevant.
3. Finally, the scoring profile is applied again, after reranking, restoring the boosts influence over the final order of results. If you boost by freshness, the semantically ranked results are rescored based on freshness.

Enable scoring profiles in semantic configuration

To enable scoring profiles for semantically ranked results, [update an index](#) by setting the `rankingOrder` property of its semantic configuration. Use the PUT method to update the index with your revisions. No index rebuild is required.

JSON

```
PUT https://{{service-name}}.search.windows.com/indexes/{{index-name}}?api-version=2025-09-01
{
  "semantic": {
    "configurations": [
      {
        "name": "mySemanticConfig",
        "rankingOrder": "boostedRerankerScore"
      }
    ]
  }
}
```

Disable scoring profiles in semantic configuration

To opt out of sorting by semantic reranker boosted score, set the `rankingOrder` field to `reRankerScore` value in the semantic configuration.

JSON

```
PUT /indexes/{index-name}?api-version=2025-09-01
{
  "semantic": {
    "configurations": [
      {
        "name": "mySemanticConfig",
        "rankingOrder": "reRankerScore"
      }
    ]
  }
}
```

Even if you opt out of sorting by `@search.rerankerBoostedScore`, the `boostedRerankerScore` field is still produced in the response, but it's no longer used to sort results.

Example query and response

Start with a [semantic query](#) that specifies a scoring profile. This query targets a search index that has `rankingOrder` set to `boostedRerankerScore`.

JSON

```
POST /indexes/{index-name}/docs/search?api-version=2025-09-01
{
  "search": "my query to be boosted",
  "scoringProfile": "myScoringProfile",
  "queryType": "semantic"
}
```

The response includes the new `rerankerBoostedScore`, alongside the L1 `@search.score` and the L2 `@search.rerankerScore`. Results are ordered by `@search.rerankerBoostedScore`.

JSON

```
{
  "value": [
    {
      "@search.score": 0.63,
      "@search.rerankerScore": 2.98,
      "@search.rerankerBoostedScore": 7.68,
      "content": "boosted content 2"
    },
    {
      "@search.score": 1.12,
      "@search.rerankerScore": 3.12,
      "@search.rerankerBoostedScore": 5.61,
    }
  ]
}
```

```
"content": "boosted content 1"
```

```
}
```

```
]
```

```
}
```

Configure network access and firewall rules for Azure AI Search

This article explains how to restrict network access to a search service's public endpoint. To block *all* data plane access to the public endpoint, use [private endpoints](#) and connect from within an Azure virtual network.

This article assumes the Azure portal for configuring network access options. You can also use the [Management REST API](#), [Azure PowerShell](#), or the [Azure CLI](#).

Prerequisites

- A search service, any region, at the Basic tier or higher
- Owner or Contributor permissions

Limitations

There are drawbacks to locking down the public endpoint:

- It takes time to fully identify IP ranges and set up firewalls, and if you're in early stages of proof-of-concept testing and investigation and using sample data, you might want to defer network access controls until you actually need them.
- Some workflows require access to a public endpoint. Specifically, the [indexing wizards](#) in the Azure portal connect to built-in (hosted) sample data and embedding models over the public endpoint. You can switch to code or script to complete the same tasks when firewall rules in place, but if you want to run the wizards, the public endpoint must be available. For more information, see [Secure connections in the import wizards](#).

When to configure network access

By default, Azure AI Search is configured to allow connections over a public endpoint. Access to a search service *through* the public endpoint is protected by authentication and authorization protocols, but the endpoint itself is open to the internet at the network layer for data plane requests.

If you aren't hosting a public web site, you might want to configure network access to automatically refuse requests unless they originate from an approved set of devices and cloud services.

There are two mechanisms for restricting access to the public endpoint:

- Inbound rules listing the IP addresses, ranges, or subnets from which requests are admitted
- Exceptions to network rules, where requests are admitted with no checks, as long as the request originates from a [trusted service](#)

Network rules aren't required, but it's a security best practice to add them if you use Azure AI Search for surfacing private or internal corporate content.

Network rules are scoped to data plane operations against the search service's public endpoint. Data plane operations include creating or querying indexes, and all other actions described by the [Search REST APIs](#). Control plane operations target service administration. Those operations specify resource provider endpoints, which are subject to the [network protections supported by Azure Resource Manager](#).

Configure network access in Azure portal

1. Sign in to Azure portal and [find your search service](#).
2. Under **Settings**, select **Networking** on the leftmost pane. If you don't see this option, check your service tier. Networking options are available on the Basic tier and higher.
3. Choose **Selected IP addresses**. Avoid the **Disabled** option unless you're configuring a [private endpoint](#).

The screenshot shows the 'Networking' settings page in the Azure portal. The 'IP Firewall' section is selected. At the top, there are three tabs: 'Firewalls and virtual networks' (which is selected), 'Private endpoint connections', and 'Shared private access'. Below the tabs, a note states: 'Public endpoints allow access to this resource through the internet using a public IP address. An application or resource that is granted access with the following network rules still requires proper authorization to access this resource.' Under 'Public network access', there are three options: 'All networks' (radio button is empty), 'Selected IP addresses' (radio button is checked and highlighted with a red box), and 'Disabled' (radio button is empty). To the right of the radio buttons is a magnifying glass icon with a plus sign inside, used for adding new IP addresses.

4. Under **IP Firewall**, select **Add your client IP address**. This step creates an inbound rule for the public IP address of your personal device to Azure AI Search. See [Allow access from the Azure portal IP address](#) for details.

IP firewall

Add IP ranges to restrict access to specific Internet-based services or on-premises networks and block general Internet traffic. [Learn more](#)

 Add your client IP address

Restricted address range

IP address or CIDR

5. Add other client IP addresses for other devices and services that send requests to a search service.

Specify IP addresses and ranges in the CIDR format. An example of CIDR notation is 8.8.8.0/24, which represents the IPs that range from 8.8.8.0 to 8.8.8.255.

To get the public IP addresses of Azure services, see [Azure IP Ranges and Service Tags](#). If your search client is hosted within an Azure function, see [IP addresses in Azure Functions](#).

6. Under **Exceptions**, select **Allow Azure services on the trusted services list to access this search service**.

Exceptions

Allow Azure services on the trusted services list to access this search service.

The trusted service list includes:

- `Microsoft.CognitiveServices` for Azure OpenAI and Foundry Tools
- `Microsoft.MachineLearningServices` for Azure Machine Learning

When you enable this exception, you take a dependency on Microsoft Entra ID authentication, managed identities, and role assignments. Any Foundry Tool or AML feature that has a valid role assignment on your search service can bypass the firewall. See [Grant access to trusted services](#) for more details.

7. Save your changes.

After you enable the IP access control policy for your Azure AI Search service, all requests to the data plane from machines outside the allowed list of IP address ranges are rejected.

When requests originate from IP addresses that aren't in the allowed list, a generic **403 Forbidden** response is returned with no other details.

Important

It can take several minutes for changes to take effect. Wait at least 15 minutes before troubleshooting any problems related to network configuration.

Allow access from the Azure portal IP address

The Azure portal has its own connection to Azure AI Search, separate from your local device and browser. If you use the Azure portal to manage your search service, you need to add the portal IP address as described in this section, and your client IP address as described in the previous section.

When IP rules are configured, some features of the Azure portal are disabled. For example, you can view and manage service level information, but portal access to the import wizards, indexes, indexers, and other top-level resources are restricted.

You can restore the Azure portal's access to the full range of search service operations by adding the Azure portal IP address to the restricted address range.

To get the Azure portal's IP address, perform `nslookup` (or `ping`) on:

- `stamp2.ext.search.windows.net`, which is the domain of the traffic manager for the Azure public cloud.
- `stamp2.ext.search.azure.us` for Azure Government cloud.

For `nslookup`, the IP address is visible in the "Non-authoritative answer" portion of the response. In the following example, the IP address that you should copy is `52.252.175.48`.

Bash

```
$ nslookup stamp2.ext.search.windows.net
Server: ZenWiFi_ET8-0410
Address: 192.168.50.1

Non-authoritative answer:
Name: azsyrie.northcentralus.cloudapp.azure.com
Address: 52.252.175.48
Aliases: stamp2.ext.search.windows.net
          azs-ux-prod.trafficmanager.net
          azspncuux.management.search.windows.net
```

When services run in different regions, they connect to different traffic managers. Regardless of the domain name, the IP address returned from the ping is the correct one to use when defining an inbound firewall rule for the Azure portal in your region.

For ping, the request times out, but the IP address is visible in the response. For example, in the message "Pinging azsyrie.northcentralus.cloudapp.azure.com [52.252.175.48]", the IP address is 52.252.175.48.

A banner informs you that IP rules affect the Azure portal experience. This banner remains visible even after you add the Azure portal's IP address. Remember to wait several minutes for network rules to take effect before testing.

ⓘ **Restricted access:** When IP rules are configured, some features of the Azure portal may be disabled. You can view and manage service level information, but portal access to indexes, indexers, and other top-level resources is restricted. You can restore portal access to the full range of search service operations by allowing access from your client IP address. [Learn how to continue using your service fully through the portal](#)

Grant access to trusted Azure services

Did you select the trusted services exception? If yes, your search service admits requests and responses from a trusted Azure resource without checking for an IP address. A trusted resource must have a managed identity (either system or user-assigned, but usually system). A trusted resource must have a role assignment on Azure AI Search that gives it permission to data and operations.

The trusted service list for Azure AI Search includes:

- Microsoft.CognitiveServices for Azure OpenAI and Foundry Tools
- Microsoft.MachineLearningServices for Azure Machine Learning

Workflows for this network exception are requests originating from Microsoft Foundry or other AML features to Azure AI Search. The trusted services exception is typically for [Azure OpenAI On Your Data](#) scenarios for retrieval augmented generation (RAG) and playground environments.

Trusted resources must have a managed identity

To set up managed identities for Azure OpenAI and Azure Machine Learning:

- [How to configure Azure OpenAI in Foundry Models with managed identities](#)
- [How to set up authentication between Azure Machine Learning and other services.](#)

To set up a managed identity for a Foundry resource:

1. [Find your Foundry resource](#).
2. From the left pane, select **Resource management > Identity**.
3. Set **System assigned** to **On**.

Trusted resources must have a role assignment

Once your Azure resource has a managed identity, [assign roles on Azure AI Search](#) to grant permissions to data and operations.

The trusted services are used for vectorization workloads: generating vectors from text and image content, and sending payloads back to the search service for query execution or indexing. Connections from a trusted service are used to deliver payloads to Azure AI search.

1. [Find your search service](#).
2. On the leftmost pane, under **Access control (IAM)**, select **Identity**.
3. Select **Add** and then select **Add role assignment**.
4. On the **Roles** page:
 - Select **Search Index Data Contributor** to load a search index with vectors generated by an embedding model. Choose this role if you intend to use integrated vectorization during indexing.
 - Or, select **Search Index Data Reader** to provide queries containing a vector generated by an embedding model at query time. The embedding used in a query isn't written to an index, so no write permissions are required.
5. Select **Next**.
6. On the **Members** page, select **Managed identity** and **Select members**.
7. Filter by system-managed identity and then select the managed identity of your Foundry resource.

(!) Note

This article covers the trusted exception for admitting requests to your search service, but Azure AI Search is itself on the trusted services list of other Azure resources. Specifically, you can use the trusted service exception for [connections from Azure AI Search to Azure Storage](#).

Next steps

Once a request is allowed through the firewall, it must be authenticated and authorized. You have two options:

- [Key-based authentication](#), where an admin or query API key is provided on the request. This option is the default.
- [Role-based access control](#) using Microsoft Entra ID, where the caller is a member of a security role on a search service. This is the most secure option. It uses Microsoft Entra ID for authentication and role assignments on Azure AI Search for permissions to data and operations.

[Enable RBAC on your search service](#)

Last updated on 11/18/2025

Create a private endpoint for a secure connection to Azure AI Search

09/23/2025

This article explains how to configure a private connection to Azure AI Search so that it admits requests from clients in a virtual network instead of over a public internet connection:

- [Create an Azure virtual network](#), or use an existing one
- [Configure a search service to use a private endpoint](#)
- [Create an Azure virtual machine \(client\) in the same virtual network](#)
- [Test using a browser session on the virtual machine](#)

Other Azure resources that might privately connect to Azure AI Search include Azure OpenAI for "use your own data" scenarios. Azure AI Foundry doesn't run in a virtual network, but it can be configured on the backend to send requests over the Microsoft backbone network. Configuration for this traffic pattern is enabled by Microsoft when your request is submitted and approved. For this scenario:

- Follow the instructions in this article to set up the private endpoint.
- [Enable trusted service](#) of your search resource from the Azure portal.
- Optionally, [disable public network access](#) if connections should only originate from clients in virtual network or from Azure OpenAI over a private endpoint connection.

Key points about private endpoints

Private endpoints are provided by [Azure Private Link](#), as a separate billable service. For more information about costs, see [Azure Private Link pricing](#).

Once a search service has a private endpoint, portal access to that service must be initiated from a browser session on a virtual machine inside the virtual network. See [this step](#) for details.

You can create a private endpoint for a search service in the Azure portal, as described in this article. Alternatively, you can use the [Management REST API](#), [Azure PowerShell](#), or the [Azure CLI](#).

Why use a private endpoint?

[Private endpoints](#) for Azure AI Search allow a client on a virtual network to securely access data in a search index over a [Private Link](#). The private endpoint uses an IP address from the [virtual network address space](#) for your search service. Network traffic between the client and the

search service traverses over the virtual network and a private link on the Microsoft backbone network, eliminating exposure from the public internet. For a list of other PaaS services that support Private Link, check the [availability section](#) in the product documentation.

Private endpoints for your search service allow you to:

- Block all connections on the public endpoint for your search service.
- Increase security for the virtual network, by letting you block exfiltration of data from the virtual network.
- Securely connect to your search service from on-premises networks that connect to the virtual network using [VPN](#) or [ExpressRoutes](#) with private-peering.

Create the virtual network

In this section, you create a virtual network and subnet to host the VM that will be used to access your search service's private endpoint.

1. From the Azure portal home tab, select **Create a resource > Networking > Virtual network**.
2. In **Create virtual network**, enter or select the following values:

 [Expand table](#)

Setting	Value
Subscription	Select your subscription
Resource group	Select Create new , enter a name, such as <i>myResourceGroup</i> , then select OK
Name	Enter a name, such as <i>MyVirtualNetwork</i>
Region	Select a region

3. Accept the defaults for the rest of the settings. Select **Review + create** and then **Create**.

Create a search service with a private endpoint

In this section, you create a new Azure AI Search service with a private endpoint.

1. On the upper-left side of the screen in the Azure portal, select **Create a resource > AI + machine learning > AI Search**.
2. In **Create a search service - Basics**, enter or select the following values:

[+] Expand table

Setting	Value
PROJECT DETAILS	
Subscription	Select your subscription
Resource group	Use the resource group that you created in the previous step
INSTANCE DETAILS	
URL	Enter a unique name
Location	Select your region
Pricing tier	Select Change Pricing Tier and choose your desired service tier. Private endpoints aren't supported on the Free tier. You must select Basic or higher.

3. Select **Next: Scale**.

4. Accept the defaults and select **Next: Networking**.

5. In **Create a search service - Networking**, select **Private** for **Endpoint connectivity (data)**.

6. Select **+ Add** under **Private endpoint**.

7. In **Create private endpoint**, enter or select values that associate your search service with the virtual network you created:

[+] Expand table

Setting	Value
Subscription	Select your subscription
Resource group	Use the resource group that you created in the previous step
Location	Select a region
Name	Enter a name, such as <i>myPrivateEndpoint</i>
Target subresource	Accept the default searchService
NETWORKING	
Virtual network	Select the virtual network you created in the previous step
Subnet	Select the default

Setting	Value
PRIVATE DNS INTEGRATION	
Enable Private DNS Integration	Select the checkbox
Private DNS zone	Accept the default (New) <code>privatelink.search.windows.net</code>

8. Select **Add**.
9. Select **Review + create**. You're taken to the **Review + create** page where Azure validates your configuration.
10. When you see the **Validation passed** message, select **Create**.
11. Once provisioning of your new service is complete, browse to the resource that you created.
12. Select **Settings > Keys** from the left content menu.
13. Copy the **Primary admin key** for later, when connecting to the service.

Create a virtual machine

1. On the upper-left side of the screen in the Azure portal, select **Create a resource > Compute > Virtual machine**.
2. In **Create a virtual machine - Basics**, enter or select the following values:

[] [Expand table](#)

Setting	Value
PROJECT DETAILS	
Subscription	Select your subscription
Resource group	Use the resource group that you created in the previous section
INSTANCE DETAILS	
Virtual machine name	Enter a name, such as <i>my-vm</i>
Region	Select your region
Availability options	You can choose No infrastructure redundancy required , or select another option if you need the functionality

Setting	Value
Image	Select Windows Server 2022 Datacenter: Azure Edition - Gen2
VM architecture	Accept the default x64
Size	Accept the default Standard D2S v3
ADMINISTRATOR ACCOUNT	
Username	Enter the user name of the administrator. Use an account that's valid for your Azure subscription. Sign in to the Azure portal from the VM so that you can manage your search service.
Password	Enter the account password. The password must be at least 12 characters long and meet the defined complexity requirements .
Confirm Password	Reenter password
INBOUND PORT RULES	
Public inbound ports	Accept the default Allow selected ports
Select inbound ports	Accept the default RDP (3389)

3. Select **Next: Disks**.

4. In **Create a virtual machine - Disks**, accept the defaults and select **Next: Networking**.

5. In **Create a virtual machine - Networking**, provide the following values:

[] [Expand table](#)

Setting	Value
Virtual network	Select the virtual network you created in a previous step
Subnet	Accept the default 10.1.0.0/24
Public IP	Accept the default
NIC network security group	Accept the default Basic
Public inbound ports	Select the default Allow selected ports
Select inbound ports	Select HTTP 80, HTTPS (443), and RDP (3389)

! **Note**

IPv4 addresses can be expressed in [CIDR](#) format. Remember to avoid the IP range reserved for private networking, as described in [RFC 1918](#):

- 10.0.0.0 - 10.255.255.255 (10/8 prefix)
- 172.16.0.0 - 172.31.255.255 (172.16/12 prefix)
- 192.168.0.0 - 192.168.255.255 (192.168/16 prefix)

6. Select **Review + create** for a validation check.

7. When you see the **Validation passed** message, select **Create**.

Connect to the VM

Download and then connect to the virtual machine as follows:

1. In the Azure portal's search bar, search for the virtual machine created in the previous step.
2. Select **Connect**. After selecting the **Connect** button, **Connect to virtual machine** opens.
3. Select **Download RDP File**. Azure creates a Remote Desktop Protocol (.rdp) file and downloads it to your computer.
4. Open the downloaded .rdp file.
 - a. If prompted, select **Connect**.
 - b. Enter the username and password you specified when creating the VM.

Note

You might need to select **More choices > Use a different account**, to specify the credentials you entered when you created the VM.

5. Select **OK**.

6. You might receive a certificate warning during the sign-in process. If you receive a certificate warning, select **Yes** or **Continue**.
7. Once the VM desktop appears, minimize it to go back to your local desktop.

Test connections

In this section, you verify private network access to the search service and connect privately to the using the Private Endpoint.

When the search service endpoint is private, some portal features are disabled. You can view and manage service level settings, but portal access to index data and various other components in the service, such as the index, indexer, and skillset definitions, is restricted for security reasons.

1. In the Remote Desktop of *myVM*, open PowerShell.
2. Enter `nslookup [search service name].search.windows.net`.

You'll receive a message similar to this:

```
Server: UnKnown
Address: 168.63.129.16
Non-authoritative answer:
Name: [search service name].privatelink.search.windows.net
Address: 10.0.0.5
Aliases: [search service name].search.windows.net
```

3. From the VM, connect to the search service and create an index. You can follow this [quickstart](#) to create a new search index in your service using the REST API. Setting up requests from a Web API test tool requires the search service endpoint (`https://[search service name].search.windows.net`) and the admin api-key you copied in a previous step.
4. Completing the quickstart from the VM is your confirmation that the service is fully operational.
5. Close the remote desktop connection to *myVM*.
6. To verify that your service isn't accessible on a public endpoint, open a REST client on your local workstation and attempt the first several tasks in the quickstart. If you receive an error that the remote server doesn't exist, you successfully configured a private endpoint for your search service.

Use the Azure portal to access a private search service

When the search service endpoint is private, some portal features are disabled. You can view and manage service level information, but index, indexer, and skillset information are hidden for security reasons.

To work around this restriction, connect to Azure portal from a browser on a virtual machine inside the virtual network. the Azure portal uses the private endpoint on the connection and gives you visibility into content and operations.

1. Follow the [steps to provision a VM that can access the search service through a private endpoint](#).
2. On a virtual machine in your virtual network, open a browser and sign in to the Azure portal. the Azure portal uses the private endpoint attached to the virtual machine to connect to your search service.

Disable public network access

You can lock down a search service to prevent it from admitting any request from the public internet. You can use the Azure portal for this step.

1. In the Azure portal, on the leftmost pane of your search service page, select **Networking**.
2. Select **Disabled** on the **Firewalls and virtual networks** tab.

You can also use the [Azure CLI](#), [Azure PowerShell](#), or the [Management REST API](#), by setting `public-access` or `public-network-access` to `disabled`.

Clean up resources

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money.

You can delete individual resources or the resource group to delete everything you created in this exercise. Select the resource group on any resource's overview page, and then select **Delete**.

Next step

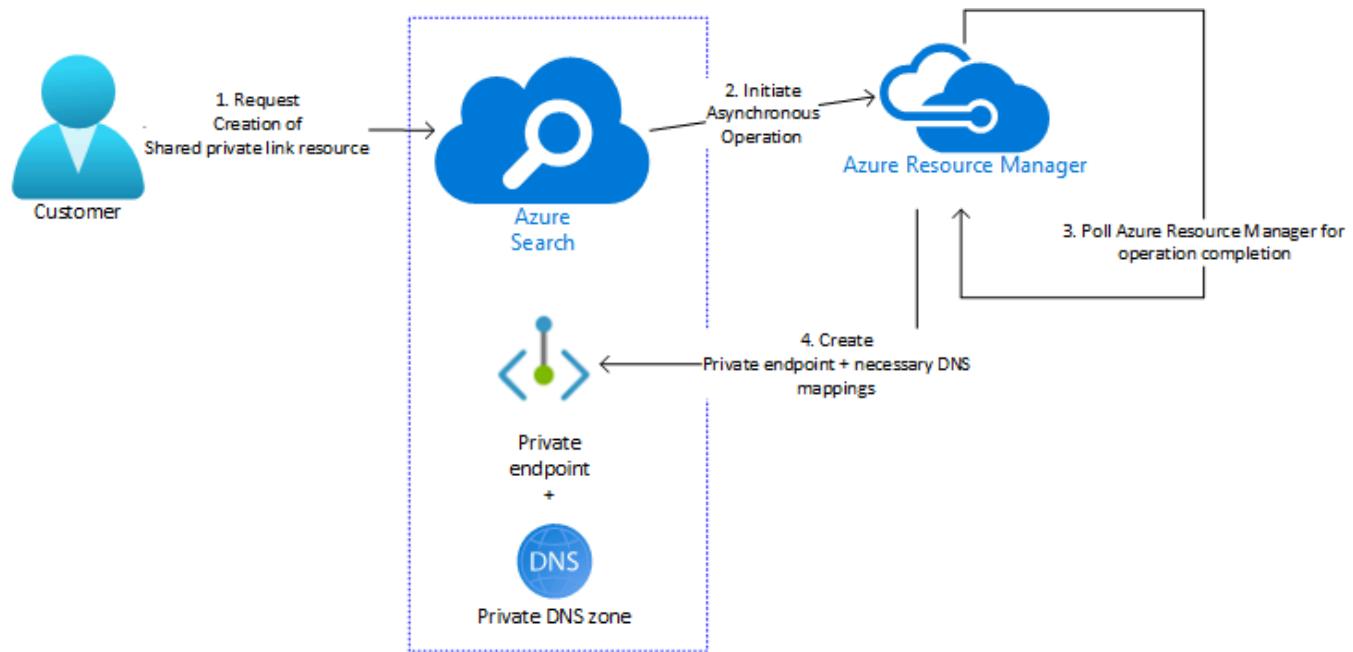

In this article, you created a VM on a virtual network and a search service with a private endpoint. You connected to the VM from the internet and securely communicated to the search service using Private Link. To learn more about private endpoints, see [What is a private endpoint?](#)

Troubleshoot issues with shared private links in Azure AI Search

06/04/2025

A shared private link allows Azure AI Search to make secure outbound connections over a private endpoint when accessing customer resources in a virtual network. This article can help you resolve errors that might occur.

Creating a shared private link is a search service control plane operation. You can [create a shared private link](#) using either the Azure portal or a [Management REST API](#). During provisioning, the state of the request is `Updating`. After the operation completes successfully, status is `Succeeded`. A private endpoint to the resource, along with any DNS zones and mappings, is created. This endpoint is used exclusively by your search service instance and is managed through Azure AI Search.

The following are common errors that occur during the creation phase.

Request validation failures

- **Unsupported SKU:** Shared private links are supported on the Basic tier and higher. For indexers with skillsets, the minimum tier is Standard 1 (S1). For more information, see [Shared private link resource limits](#).
- **Invalid name:** Naming rules for a shared private link are:
 - Length should be between 1 to 60 characters
 - Alphanumeric characters

- Names can include underscore `_`, period `.`, and hyphen `-` as long as it's not the first character in the name
- Invalid group ID: Group IDs are case-sensitive and must be one of the following values.

[\[+\] Expand table](#)

Azure resource	Group ID	First available API version
Azure Storage - Blob (or) ADLS Gen 2	<code>blob</code>	<code>2020-08-01</code>
Azure Storage - Tables	<code>table</code>	<code>2020-08-01</code>
Azure Cosmos DB for NoSQL	<code>Sql</code>	<code>2020-08-01</code>
Azure SQL Database	<code>sqlServer</code>	<code>2020-08-01</code>
Azure Database for MySQL (preview)	<code>mysqlServer</code>	<code>2020-08-01-Preview</code>
Azure Key Vault	<code>vault</code>	<code>2020-08-01</code>
Azure Functions (preview)	<code>sites</code>	<code>2020-08-01-Preview</code>

Resources marked with "(preview)" must be created using a preview version of the Management REST API versions.

- `privateLinkResourceId` type validation: Similar to `groupId`, Azure AI Search validates that the "correct" resource type is specified in the `privateLinkResourceId`. The following are valid resource types:

[\[+\] Expand table](#)

Azure resource	Resource type	First available API version
Azure Storage	<code>Microsoft.Storage/storageAccounts</code>	<code>2020-08-01</code>
Azure Cosmos DB	<code>Microsoft.DocumentDb/databaseAccounts</code>	<code>2020-08-01</code>
Azure SQL Database	<code>Microsoft.Sql/servers</code>	<code>2020-08-01</code>
Azure Key Vault	<code>Microsoft.KeyVault/vaults</code>	<code>2020-08-01</code>
Azure Database for MySQL (preview)	<code>Microsoft.DBforMySQL/servers</code>	<code>2020-08-01-Preview</code>
Azure Functions (preview)	<code>Microsoft.Web/sites</code>	<code>2020-08-01-Preview</code>

Azure resource	Resource type	First available API version
Azure SQL Managed Instance (preview)	Microsoft.Sql/managedInstance	2020-08-01-Preview

In addition, the specified `groupId` needs to be valid for the specified resource type. For example, `groupId` "blob" is valid for type `Microsoft.Storage/storageAccounts`, it can't be used with any other resource type. For a given search management API version, customers can find out the supported `groupId` and resource type details by utilizing the [List supported API](#).

- Quota limit enforcement: Search services have quotas imposed on the distinct number of shared private link resources that can be created and the number of various target resource types that are being used (based on `groupId`). For more information, see [Shared private link resource limits](#).

Deployment failures

A search service initiates the request to create a shared private link, but Azure Resource Manager performs the actual work. You can [check the deployment's status](#) in the Azure portal or by query, and address any errors that might occur.

Shared private link resources that fail Azure Resource Manager deployment show up in [List](#) and [Get](#) API calls, but they have a "Provisioning State" of `Failed`. Once the reason of the Azure Resource Manager deployment failure is ascertained, delete the `Failed` resource and re-create it after applying the appropriate resolution from the following table.

[] [Expand table](#)

Deployment failure reason	Description	Resolution
"LinkedAuthorizationFailed"	The error message states that the client has permission to create the shared private link on the search service, but doesn't have permission to perform action 'privateEndpointConnectionApproval/action' on the linked scope.	Recheck the private link ID in the request to make sure there are no errors or omissions in the URL. If Azure AI Search and the Azure PaaS resource are in different subscriptions, and if you're using REST or a command line interface, ensure the

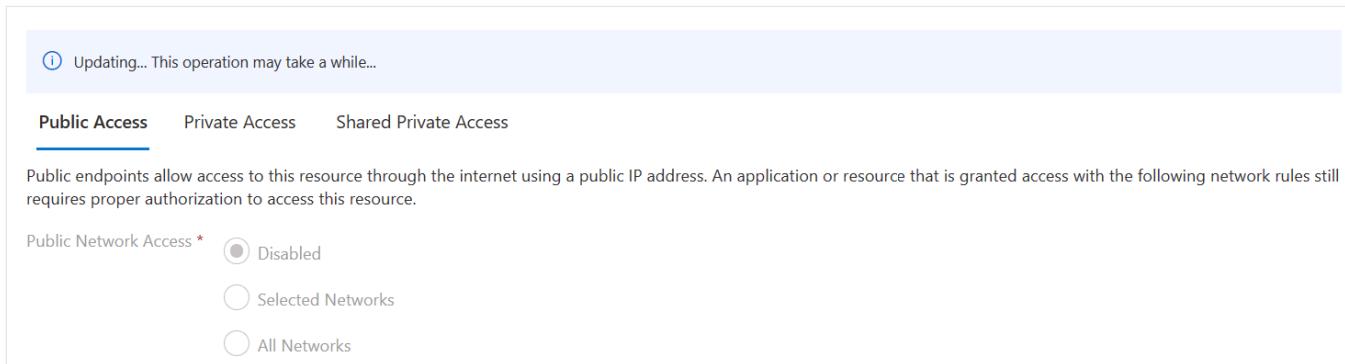

Deployment failure reason	Description	Resolution
		<p>active Azure account is the Azure PaaS resource.</p> <p>For REST clients, make sure you're not using an expired bearer token, and that the token is valid for the active subscription.</p>
Network resource provider not registered on target resource's subscription	<p>A private endpoint (and associated DNS mappings) is created for the target resource (Storage Account, Azure Cosmos DB, Azure SQL) via the <code>Microsoft.Network</code> resource provider (RP). If the subscription that hosts the target resource ("target subscription") isn't registered with <code>Microsoft.Network</code> RP, then the Azure Resource Manager deployment can fail.</p>	<p>You need to register this RP in their target subscription. You can register the resource provider using the Azure portal, PowerShell, or CLI.</p>
Invalid <code>groupId</code> for the target resource	<p>When Azure Cosmos DB accounts are created, you can specify the API type for the database account. While Azure Cosmos DB offers several different API types, Azure AI Search only supports "Sql" as the <code>groupId</code> for shared private link resources. When a shared private link of type "Sql" is created for a <code>privateLinkResourceId</code> pointing to a non-Sql database account, the Azure Resource Manager deployment fails because of the <code>groupId</code> mismatch. The Azure resource ID of an Azure Cosmos DB account isn't sufficient to determine the API type that is being used. Azure AI Search tries to create the private endpoint, which Azure Cosmos DB then denies.</p>	<p>You should ensure that the <code>privateLinkResourceId</code> of the specified Azure Cosmos DB resource is for a database account of "Sql" API type</p>
Target resource not found	<p>Existence of the target resource specified in <code>privateLinkResourceId</code> is checked only during the commencement of the Azure Resource Manager deployment. If the target resource is no longer available, then the deployment fails.</p>	<p>You should ensure that the target resource is present in the specified subscription and resource group and isn't moved or deleted.</p>
Transient/other errors	<p>The Azure Resource Manager deployment can fail if there's an infrastructure outage or because of other unexpected reasons. This should be rare and usually indicates a transient state.</p>	<p>Retry creating this resource at a later time. If the problem persists, reach out to Azure Support.</p>

Issues approving the backing private endpoint

A private endpoint is created to the target Azure resource as specified in the shared private link creation request. This is one of the final steps in the asynchronous Azure Resource Manager deployment operation, but Azure AI Search needs to link the private endpoint's private IP address as part of its network configuration. Once this link is done, the `provisioningState` of the shared private link resource goes to a terminal success state `Succeeded`. Customers should only approve or deny (or in general modify the configuration of the backing private endpoint) after the state transitions to `Succeeded`. Modifying the private endpoint in any way before this could result in an incomplete deployment operation and can cause the shared private link resource to end up (either immediately, or usually within a few hours) in a `Failed` state.

Search service network connectivity change stalled in an "Updating" state

Shared private links and private endpoints are used when search service **Public Network Access is Disabled**. Typically, changing network connectivity should succeed in a few minutes after the request is accepted. In some circumstances, Azure AI Search might take several hours to complete the connectivity change operation.

If you observe that the connectivity change operation is taking a significant amount of time, wait for a few hours. Connectivity change operations involve operations such as updating DNS records which might take longer than expected.

If **Public Network Access** is changed, existing shared private links and private endpoints might not work correctly. If existing shared private links and private endpoints stop working during a connectivity change operation, wait a few hours for the operation to complete. If they're still not working, try deleting and recreating them.

Shared private link resource stalled in an "Updating" or "Incomplete" state

Typically, a shared private link resource should go a terminal state (`Succeeded` or `Failed`) in a few minutes after the request is accepted.

In rare circumstances, Azure AI Search can fail to correctly mark the state of the shared private link resource to a terminal state (`Succeeded` or `Failed`). This usually occurs due to an unexpected failure. Shared private link resources are automatically transitioned to a `Failed` state if it's "stuck" in a nonterminal state for more than a few hours.

If the shared private link resource doesn't transition to a terminal state, wait for a few hours to ensure that it becomes `Failed` before you can delete it and re-create it. Alternatively, instead of waiting you can try to create another shared private link resource with a different name (keeping all other parameters the same).

Updating a shared private link resource

An existing shared private link resource can be updated using the [Create or Update API](#). Search only allows for narrow updates to the shared private link resource - only the request message can be modified via this API.

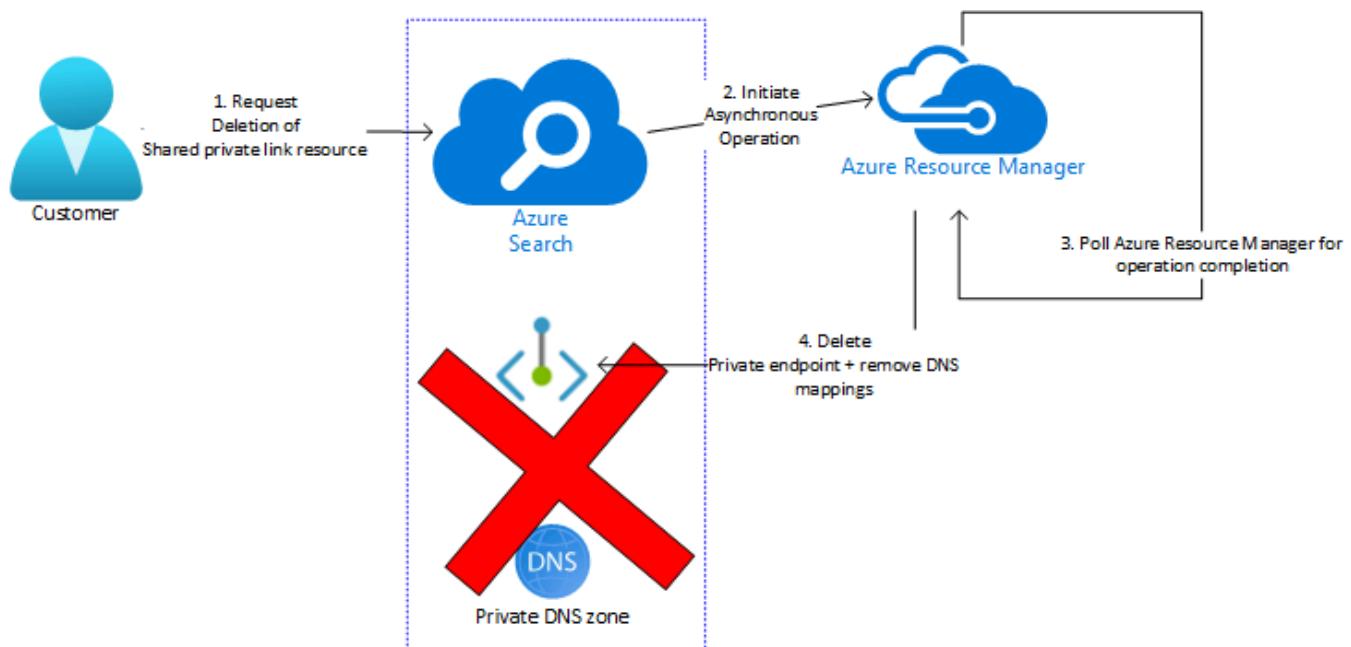

- It isn't possible to update any of the "core" properties of an existing shared private link resource (such as `privateLinkResourceId` or `groupId`) and this will always be unsupported. If any other property besides the request message needs to be changed, we advise customers to delete and re-create the shared private link resource.
- Updating the request message of a shared private link resource is only possible if it reaches the provisioning state of `Succeeded`.

Deleting a shared private link resource

Customers can delete an existing shared private link resource via the [Delete API](#). Similar to the process of creation (or update), this is also an asynchronous operation with four steps:

1. You request a search service to delete the shared private link resource.
2. The search service validates that the resource exists and is in a state valid for deletion. If so, it initiates an Azure Resource Manager delete operation to remove the resource.
3. Search queries for the completion of the operation (which usually takes a few minutes). At this point, the shared private link resource would have a provisioning state of `Deleting`.
4. Once the operation completes successfully, the backing private endpoint and any associated DNS mappings are removed. The resource doesn't show up as part of [List](#)

operation and attempting a [Get](#) operation on this resource results in a 404 Not Found.

The following are common errors that occur during the deletion phase.

 Expand table

Failure Type	Description	Resolution
Resource is in nonterminal state	A shared private link resource that's not in a terminal state (Succeeded or Failed) can't be deleted. It's possible (rare) for a shared private link resource to be stuck in a nonterminal state for up to 8 hours.	Wait until the resource reaches a terminal state and retry the delete request.
Delete operation failed with error "Conflict"	The Azure Resource Manager operation to delete a shared private link resource reaches out to the resource provider of the target resource specified in <code>privateLinkId</code> ("target RP") before it can remove the private endpoint and DNS mappings. Customers can utilize Azure resource locks to prevent any changes to their resources. When Azure Resource Manager reaches out to the target RP, it requires the target RP to modify the state of the target resource (to remove details about the private endpoint from its metadata). When the target resource has a lock configured on it (or its resource group/subscription), the Azure Resource Manager operation fails with a "Conflict" (and appropriate details). The shared private link resource won't be deleted.	Customers should remove the lock on the target resource before retrying the deletion operation. Note: This problem can also occur when customers try to delete a search service with shared private link resources that point to "locked" target resources
Delete operation failed	The asynchronous Azure Resource Manager delete operation can fail in rare cases. When this operation fails, querying the state of the asynchronous operation presents an error message and appropriate details.	Retry the operation at a later time, or reach out to Azure Support if the problem persists.

Failure Type	Description	Resolution
Resource stuck in "Deleting" state	In rare cases, a shared private link resource might be stuck in "Deleting" state for up to 8 hours, likely due to some catastrophic failure on the search RP.	Wait for 8 hours, after which the resource would transition to <code>Failed</code> state and then reissue the request.

Add a search service to a network security perimeter

08/18/2025

A network security perimeter is a logical network boundary around your platform-as-a-service (PaaS) resources that are deployed outside of a virtual network. It establishes a perimeter for controlling public network access to resources like Azure AI Search, [Azure Storage](#), and [Azure OpenAI](#).

This article explains how to join an Azure AI Search service to a [network security perimeter](#) to control network access to your search service. By joining a network security perimeter, you can:

- Log all access to your search service in context with other Azure resources in the same perimeter.
- Block any data exfiltration from a search service to other services outside the perimeter.
- Allow access to your search service using inbound and outbound access capabilities of the network security perimeter.

You can add a search service to a network security perimeter in the Azure portal, as described in this article. Alternatively, you can use the [Azure Virtual Network Manager REST API](#) to join a search service, and use the [Search Management REST APIs](#) to view and synchronize the configuration settings.

Limitations and considerations

- For search services within a network security perimeter, indexers must use a [system or user-assigned managed identity](#) and have a role assignment that permits read-access to data sources.
- Supported indexer data sources are currently limited to [Azure Blob Storage](#), [Azure Cosmos DB for NoSQL](#), and [Azure SQL Database](#).
- Currently, within the perimeter, indexer connections to Azure PaaS for data retrieval is the primary use case. For outbound skills-driven API calls to Azure AI services, Azure OpenAI, or the Azure AI Foundry model catalog, or for inbound calls from the Azure AI Foundry for "chat with your data" scenarios you must [configure inbound and outbound rules](#) to allow the requests through the perimeter. If you require private connections for [structure-aware chunking](#) and vectorization, you should [create a shared private link](#) and a private network.

Prerequisites

- An existing network security perimeter. You can [create one to associate with your search service](#).
- [Azure AI Search](#), any billable tier, in any region.

Assign a search service to a network security perimeter

Azure Network Security Perimeter allows administrators to define a logical network isolation boundary for PaaS resources (for example, Azure Storage and Azure SQL Database) that are deployed outside virtual networks. It restricts communication to resources within the perimeter, and it allows non-perimeter public traffic through inbound and outbound access rules.

You can add Azure AI Search to a network security perimeter so that all indexing and query requests occur within the security boundary.

1. In the Azure portal, find the network security perimeter service for your subscription.
2. From the left pane, select **Settings > Associated resources**.

> Help

3. Select Add > Associate resources with an existing profile.

The screenshot shows the Azure portal interface for managing network security perimeter profiles. At the top, there are navigation links: '+ Add', 'Refresh', 'View details', 'Configure public network access', 'Move to another profile', 'Change access mode', and 'Remove'. Below these are two buttons: 'Associate resources with a new profile' (highlighted with a red box) and 'Associate resources with an existing profile'. A search bar labeled 'Search' is also present. The main area displays a table with columns: 'Associated resources' (checkbox), 'Resource type', 'Access mode', 'Profile', 'Access logs', and 'Public network acce...'. A message at the bottom states 'No Resources to display.' and 'Create or edit profiles to add resources'. A 'Create' button is located at the bottom right.

4. Select the profile you created when you created the network security perimeter for **Profile**.
5. Select **Add**, and then select your search service.

The screenshot shows the 'Select resources' dialog box. At the top, there is a search bar containing 'mysearchservice' and several filter buttons: 'Subscription equals 2 of 192 selected', 'Resource group equals all', 'Type equals 104 selected', 'Add filter', and 'More (1)'. Below the filters is a checkbox for 'Show hidden types'. The main table lists a single resource: 'mysearchservice' (Search service, Type: Search service, Resource group: MyResourceGroup, Location: West Central US, Subscription: MySubscription). The table has columns: 'Name ↑↓', 'Type ↑↓', 'Resource group ↑↓', 'Location ↑↓', and 'Subscription ↑↓'. At the bottom of the dialog are 'Select' and 'Cancel' buttons.

6. Select **Associate** in the lower-left corner to create the association.

Network security perimeter access modes

Network security perimeter supports two different access modes for associated resources:

Expand table

Mode	Description
Learning mode	This is the default access mode. In <i>learning</i> mode, network security perimeter logs all traffic to the search service that would have been denied if the perimeter was in enforced mode. This allows network administrators to understand the existing access patterns of the search service before implementing enforcement of access rules.
Enforced mode	In <i>Enforced</i> mode, network security perimeter logs and denies all traffic that isn't explicitly allowed by access rules.

Network security perimeter and search service networking settings

The `publicNetworkAccess` setting determines search service association with a network security perimeter.

- In Learning mode, the `publicNetworkAccess` setting controls public access to the resource.
- In Enforced mode, the `publicNetworkAccess` setting is overridden by the network security perimeter rules. For example, if a search service with a `publicNetworkAccess` setting of `enabled` is associated with a network security perimeter in Enforced mode, access to the search service is still controlled by network security perimeter access rules.

Change the network security perimeter access mode

1. Go to your network security perimeter resource in the Azure portal.
2. From the left pane, select **Settings > Associated resources**.

> Help

3. Select **Add diagnostic setting**.

4. Enter any name, such as "diagnostic," for **Diagnostic setting name**.

5. Under **Logs**, select **allLogs**. **allLogs** ensures all inbound and outbound network access to resources in your network security perimeter is logged.

6. Under **Destination details**, select **Archive to a storage account** or **Send to Log Analytics workspace**. The storage account must be in the same region as the network security

perimeter. You can either use an existing storage account or create a new one. A Log Analytics workspace can be in a different region than the one used by the network security perimeter. You can also select any of the other applicable destinations.

The screenshot shows the 'Diagnostic setting' configuration page. At the top, there are buttons for Save, Discard, Delete, and Feedback. Below that, a description explains what a diagnostic setting is: 'A diagnostic setting specifies a list of categories of platform logs and/or metrics that you want to collect from a resource, and one or more destinations that you would stream them to. Normal usage charges for the destination will occur.' A link to 'Learn more about the different log categories and contents of those logs' is provided. The 'Diagnostic setting name' is set to 'diagnostic'. In the 'Logs' section, under 'Category groups', 'allLogs' is selected. Under 'Categories', several checkboxes are checked: 'Public inbound access allowed by NSP access rules.', 'Public inbound access denied by NSP access rules.', 'Public outbound access allowed by NSP access rules.', 'Public outbound access denied by NSP access rules.', 'Inbound access allowed within same perimeter.', and 'Public inbound access allowed by PaaS resource rules.'. In the 'Destination details' section, 'Send to Log Analytics workspace' is unchecked, while 'Archive to a storage account' is checked. A note states: 'You'll be charged normal data rates for storage and transactions when you send diagnostics to a storage account.' Another note says: 'Showing all storage accounts including classic storage accounts'. The 'Location' is set to 'West Central US', 'Subscription' is 'MySubscription', and 'Storage account' is 'mystorageaccount'.

7. Select **Save** to create the diagnostic setting and start logging network access.

Reading network access logs

Log Analytics workspace

The `network-security-perimeterAccessLogs` table contains all the logs for every log category (for example `network-security-perimeterPublicInboundResourceRulesAllowed`). Every log contains a record of the network security perimeter network access that matches the log category.

Here's an example of the `network-security-perimeterPublicInboundResourceRulesAllowed` log format:

[] Expand table

Column Name	Meaning	Example Value
ResultDescription	Name of the network access operation	POST /indexes/my-index/docs/search

Column Name	Meaning	Example Value
Profile	Which network security perimeter the search service was associated with	defaultProfile
ServiceResourceId	Resource ID of the search service	search-service-resource-id
Matched Rule	JSON description of the rule that was matched by the log	{ "accessRule": "IP firewall" }
SourceIPAddress	Source IP of the inbound network access, if applicable	1.1.1.1
AccessRuleVersion	Version of the network-security-perimeter access rules used to enforce the network access rules	0

Storage Account

The storage account has containers for every log category (for example `insights-logs-network-security-perimeterpublicinboundperimeterrulesallowed`). The folder structure inside the container matches the resource ID of the network security perimeter and the time the logs were taken. Each line on the JSON log file contains a record of the network security perimeter network access that matches the log category.

For example, the inbound perimeter rules allowed category log uses the following format:

```
JSON

"properties": {
    "ServiceResourceId": "/subscriptions/00000000-0000-0000-0000-000000000000/resourceGroups/network-security-
perimeter/providers/Microsoft.Search/searchServices/network-security-perimeter-
search",
    "Profile": "defaultProfile",
    "MatchedRule": {
        "AccessRule": "myaccessrule"
    },
    "Source": {
        "IpAddress": "255.255.255.255",
    }
}
```

Add an access rule for your search service

A network security perimeter profile specifies rules that allow or deny access through the perimeter.

Within the perimeter, all resources have mutual access at the network level. You must still set up authentication and authorization, but at the network level, connection requests from inside the perimeter are accepted.

For resources outside of the network security perimeter, you must specify inbound and outbound access rules. Inbound rules specify which connections to allow in, and outbound rules specify which requests are allowed out.

A search service accepts inbound requests from apps like [Azure AI Foundry portal](#), Azure Machine Learning prompt flow, and any app that sends indexing or query requests. A search service sends outbound requests during indexer-based indexing and skillset execution. This section explains how to set up inbound and outbound access rules for Azure AI Search scenarios.

Note

Any service associated with a network security perimeter implicitly allows inbound and outbound access to any other service associated with the same network security perimeter when that access is authenticated using [managed identities and role assignments](#). Access rules only need to be created when allowing access outside of the network security perimeter, or for access authenticated using API keys.

Add an inbound access rule

Inbound access rules can allow the internet and resources outside the perimeter to connect with resources inside the perimeter.

Network security perimeter supports two types of inbound access rules:

- IP address ranges. IP addresses or ranges must be in the Classless Inter-Domain Routing (CIDR) format. An example of CIDR notation is 192.0.2.0/24, which represents the IPs that range from 192.0.2.0 to 192.0.2.255. This type of rule allows inbound requests from any IP address within the range.
- Subscriptions. This type of rule allows inbound access authenticated using any managed identity from the subscription.

To add an inbound access rule in the Azure portal:

1. Go to your network security perimeter resource in the Azure portal.
2. From the left pane, select **Settings > Profiles**.

Add an outbound access rule

A search service makes outbound calls during indexer-based indexing and skillset execution. If your indexer data sources, Azure AI services, or custom skill logic is outside of the network security perimeter, you should create an outbound access rule that allows your search service to make the connection.

Recall that in public preview, Azure AI Search can only connect to Azure Storage or Azure Cosmos DB within the security perimeter. If your indexers use other data sources, you need an outbound access rule to support that connection.

Network security perimeter supports outbound access rules based on the Fully Qualified Domain Name (FQDN) of the destination. For example, you can allow outbound access from any service associated with your network security perimeter to an FQDN such as `mystorageaccount.blob.core.windows.net`.

To add an outbound access rule in the Azure portal:

1. Go to your network security perimeter resource in the Azure portal.
2. From the left pane, select **Settings > Profiles**.

Test your connection through network security perimeter

In order to test your connection through network security perimeter, you need access to a web browser, either on a local computer with an internet connection or an Azure VM.

1. Change your network security perimeter association to [enforced mode](#) to start enforcing network security perimeter requirements for network access to your search service.
2. Decide if you want to use a local computer or an Azure VM.
 - a. If you're using a local computer, you need to know your public IP address.
 - b. If you're using an Azure VM, you can either use [private link](#) or [check the IP address using the Azure portal](#).
3. Using the IP address, you can create an [inbound access rule](#) for that IP address to allow access. You can skip this step if you're using private link.
4. Finally, try navigating to the search service in the Azure portal. If you can view the indexes successfully, then the network security perimeter is configured correctly.

View and manage network security perimeter configuration

You can use the [Network Security Perimeter Configuration REST APIs](#) to review and reconcile perimeter configurations.

Be sure to use `2025-05-01`, which is the latest stable REST API version. [Learn how to call the Search Management REST APIs](#).

Related content

- [Use Azure role-based access control in Azure AI Search](#)

Enable or disable role-based access control in Azure AI Search

07/31/2025

Azure AI Search supports both identity-based and [key-based authentication](#) for all data plane operations. You can use Microsoft Entra ID authentication and role-based authorization to enable identity-based access to operations and content.

Important

When you create a search service, key-based authentication is the default, but it's not the most secure option. We recommend that you replace it with role-based access as described in this article.

Before you can assign roles for authorized data plane access to Azure AI Search, you must enable role-based access control on your search service. Roles for service administration (control plane) are built in and can't be enabled or disabled.

Data plane refers to operations against the search service endpoint, such as indexing or queries, or any other operation specified in the [Search Service REST APIs](#) or equivalent Azure SDK client libraries.

Control plane refers to Azure resource management, such as creating or configuring a search service, or any other operation specified in the [Search Management REST APIs](#).

You can only enable or disable role-based access control for data plane operations. Control plane operations always use Owner, Contributor, or Reader roles. If you observe key-related activity, such as Get Admin Keys, in the [Activity Log](#) on a roles-only search service, those actions are initiated on the control plane and don't affect your content or content-related operations.

Prerequisites

- A search service in any region, on any tier, including free.
- Owner, User Access Administrator, or a custom role with [Microsoft.Authorization/roleAssignments/write](#) permissions.

Enable role-based access for data plane operations

Configure your search service to recognize an **authorization** header on data requests that provide an OAuth2 access token.

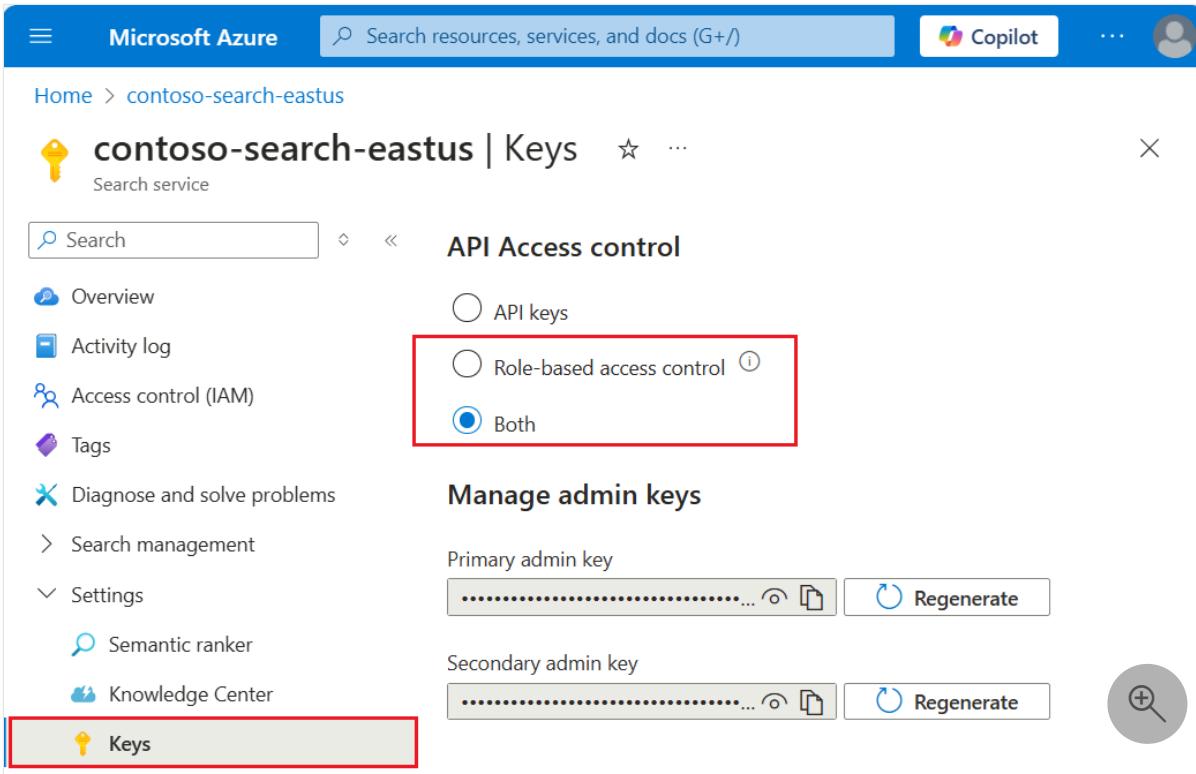

When you enable roles for the data plane, the change is effective immediately, but wait a few seconds before assigning roles.

The default failure mode for unauthorized requests is `http401WithBearerChallenge`.

Alternatively, you can set the failure mode to `http403`.

Azure portal

1. Sign in to the [Azure portal](#) and navigate to your search service.
2. Select **Settings** and then select **Keys** in the left pane.

3. Choose **Role-based control**. Only choose **Both** if you're currently using keys and need time to transition clients to role-based access control.

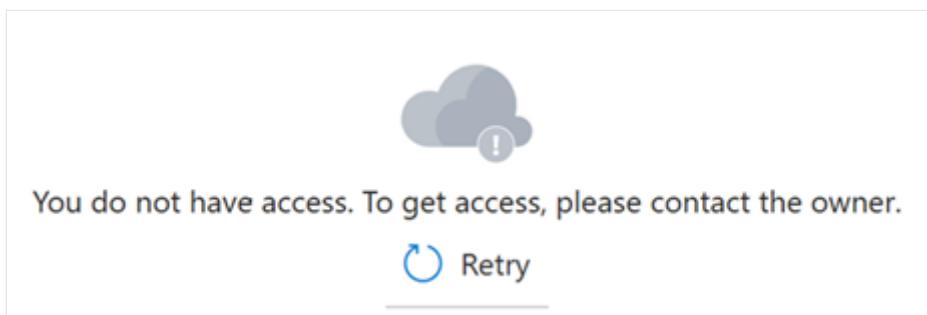

[Expand table](#)

Option	Description
API Key (default)	Requires API keys on the request header for authorization.
Role-based access control (recommended)	Requires membership in a role assignment to complete the task. It also requires an authorization header on the request.

Option	Description
Both	Requests are valid using either an API key or role-based access control, but if you provide both in the same request, the API key is used.

4. As an administrator, if you choose a roles-only approach, [assign data plane roles](#) to your user account to restore full administrative access over data plane operations in the Azure portal. Roles include Search Service Contributor, Search Index Data Contributor, and Search Index Data Reader. You need the first two roles if you want equivalent access.

Sometimes it can take five to ten minutes for role assignments to take effect. Until that happens, the following message appears in the Azure portal pages used for data plane operations.

Disable role-based access control

It's possible to disable role-based access control for data plane operations and use key-based authentication instead. You might do this as part of a test workflow, for example to rule out permission issues.

To disable role-based access control in the Azure portal:

1. Sign in to the [Azure portal](#) and open the search service page.
2. Select **Settings** and then select **Keys** in the left pane.
3. Select **API Keys**.

Disable API key authentication

[Key access](#), or local authentication, can be disabled on your service if you're exclusively using the built-in roles and Microsoft Entra authentication. Disabling API keys causes the search

service to refuse all data-related requests that pass an API key in the header.

Admin API keys can be disabled, but not deleted. Query API keys can be deleted.

Owner or Contributor permissions are required to disable security features.

Azure portal

1. In the Azure portal, navigate to your search service.
2. In the left-navigation pane, select **Keys**.
3. Select **Role-based access control**.

The change is effective immediately, but wait a few seconds before testing. Assuming you have permission to assign roles as a member of Owner, service administrator, or coadministrator, you can use portal features to test role-based access.

Next steps

[Set up roles for access to a search service](#)

Connect to Azure AI Search using roles

Azure provides a global authentication and [role-based access control](#) through Microsoft Entra ID for all services running on the platform. In this article, learn which roles provide access to search content and administration on Azure AI Search.

In Azure AI Search, you can assign Azure roles for:

- [Service administration](#)
- [Development or write-access to a search service](#)
- [Read-only access for queries](#)
- [Scoped access to a single index](#)

Per-user access over search results (sometimes referred to as *row-level security* or *document-level access*) is supported through permission inheritance for Azure Data Lake Storage (ADLS) Gen2 and Azure blob indexes and through security filters for all other platforms (see [Document-level access control](#)).

Role assignments are cumulative and pervasive across all tools and client libraries. You can assign roles using any of the [supported approaches](#) described in Azure role-based access control documentation.

Role-based access is optional, but recommended. The alternative is [key-based authentication](#), which is the default.

Prerequisites

- A search service in any region, on any tier, [enabled for role-based access](#).
- Owner, User Access Administrator, Role-based Access Control Administrator, or a custom role with [Microsoft.Authorization/roleAssignments/write](#) permissions.

How to assign roles in the Azure portal

The following steps work for all role assignments.

1. Sign in to the [Azure portal](#) ↗ .
2. Navigate to your search service.
3. [Enable role-based access](#).
4. Select **Access Control (IAM)** in the left pane.

5. Select + Add > Add role assignment to start the Add role assignment wizard.

The screenshot shows the Microsoft Azure portal interface. At the top, there's a blue header bar with the Microsoft Azure logo, a search bar, and a Copilot button. Below the header, the URL 'contoso-search-eastus' is shown. The main content area has a title 'contoso-search-eastus | Access control (IAM)'. On the left, there's a sidebar with links like Overview, Activity log, and Access control (IAM), which is currently selected and highlighted with a red box. The main pane has tabs for Check access, Role assignments, Roles, Deny assignments, and Classic administrators. Under the 'Check access' tab, there are sections for 'My access' (with a 'View my access' button) and 'Check access' (with a 'Check access' button). At the bottom, there are two boxes: 'Grant access to this resource' (with a 'Learn more' link) and 'View access to this resource' (with a 'Learn more' link).

6. Select a role. You can assign multiple security principals, whether users or managed identities to a role in one pass through the wizard, but you have to repeat these steps for each role you define.
7. On the **Members** tab, select the Microsoft Entra user or group identity. If you're setting up permissions for another Azure service, select a system or user-managed identity.
8. On the **Review + assign** tab, select **Review + assign** to assign the role.

Built-in roles used in search

Roles are a collection of permissions on specific operations affecting either data plane or control plane layers.

Data plane refers to operations against the search service endpoint, such as indexing or queries, or any other operation specified in the [Search Service REST APIs](#) or equivalent Azure SDK client libraries.

Control plane refers to Azure resource management, such as creating or configuring a search service.

The following roles are built in. If these roles are insufficient, [create a custom role](#).

Role	Plane	Description
Owner	Control & Data	<p>Full access to the control plane of the search resource, including the ability to assign Azure roles. Only the Owner role can enable or disable authentication options or manage roles for other users. Subscription administrators are members by default.</p> <p>On the data plane, this role has the same access as the Search Service Contributor role. It includes access to all data plane actions except the ability to query documents.</p>
Contributor	Control & Data	<p>Same level of control plane access as Owner, minus the ability to assign roles or change authentication options.</p> <p>On the data plane, this role has the same access as the Search Service Contributor role. It includes access to all data plane actions except the ability to query or index documents.</p>
Reader	Control & Data	<p>Read access across the entire service, including search metrics, content metrics (storage consumed, number of objects), and the object definitions of data plane resources (indexes, indexers, and so on). However, it can't read API keys or read content within indexes.</p>
Search Service Contributor	Control & Data	<p>Read-write access to object definitions (indexes, aliases, synonym maps, indexers, data sources, and skillsets). This role is for developers who create objects, and for administrators who manage a search service and its objects, but without access to index content. Use this role to create, delete, and list indexes, get index definitions, get service information (statistics and quotas), test analyzers, create and manage synonym maps, indexers, data sources, and skillsets. See Microsoft.Search/searchServices/* for the permissions list.</p>
Search Index Data Contributor	Data	<p>Read-write access to content in indexes. This role is for developers or index owners who need to import, refresh, or query the documents collection of an index. This role doesn't support index creation or management. By default, this role is for all indexes on a search service. See Grant access to a single index to narrow the scope.</p>
Search Index Data Reader	Data	<p>Read-only access for querying search indexes. This role is for apps and users who run queries. This role doesn't support read access to object definitions. For example, you can't read a search index definition or get search service statistics. By default, this role is for all indexes on a search service. See Grant access to a single index to narrow the scope.</p>

Combine these roles to get sufficient permissions for your use case.

(!) Note

If you disable Azure role-based access, built-in roles for the control plane (Owner, Contributor, Reader) continue to be available. Disabling role-based access removes just

the data-related permissions associated with those roles. If data plane roles are disabled, Search Service Contributor is equivalent to control-plane Contributor.

Summary

[Expand table](#)

Permissions	Search Index Reader	Search Data Contributor	Search Service Contributor	Owner/Contributor	Reader
View the resource in Azure portal	✗	✗	✓	✓	✓
View resource properties/metrics/endpoint	✗	✗	✓	✓	✓
List all objects on the resource	✗	✗	✓	✓	✓
Access quotas and service statistics	✗	✗	✓	✓	✗

Create or manage deployments	✗	✗	✓	✓	✗
Create or configure Azure AI Search resources	✗	✗	✓	✓	✗
View/Copy/Regenerate keys under Keys	✗	✗	✓	✓	✗

Permissions	Search	Search	Search	Owner/Contributor	Reader
	Index	Index Data	Service		
	Data	Contributor	Contributor		
	Reader				
View roles/policies/definitions	✗	✗	✓	✓	✗
Set authentication options	✗	✗	✓	✓	✗
Configure private connections	✗	✗	✓	✓	✗
Configure network security	✗	✗	✓	✓	✗

¹ In the Azure portal, an Owner or Contributor can run the Import data wizards that create and load indexes, even though they can't upload documents in other clients. Data connections in the wizard are made by the search service itself and not individual users. The wizards have the `Microsoft.Search/searchServices/indexes/documents/*` permission necessary for completing this task.

Owners and Contributors grant the same permissions, except that only Owners can assign roles.

Assign roles

In this section, assign roles for:

- Service administration
- Development or write-access to a search service
- Read-only access for queries

Assign roles for service administration

As a service administrator, you can create and configure a search service, and perform all control plane operations described in the [Management REST API](#) or equivalent client libraries. If you're an Owner or Contributor, you can also perform most data plane [Search REST API](#) tasks in the Azure portal.

[] [Expand table](#)

Role	ID
Owner	8e3af657-a8ff-443c-a75c-2fe8c4bcb635

Role	ID
Contributor	b24988ac-6180-42a0-ab88-20f7382dd24c
Reader	acdd72a7-3385-48ef-bd42-f606fba81ae7

Azure portal

1. Sign in to the [Azure portal](#).

2. Assign these roles:

- Owner (full access to all data plane and control plane operations, except for query permissions)
- Contributor (same as Owner, except for permissions to assign roles)
- Reader (acceptable for monitoring and viewing metrics)

Assign roles for development

Role assignments are global across the search service. To [scope permissions to a single index](#), use PowerShell or the Azure CLI to create a custom role.

[Expand table](#)

Task	Role	ID
Create or manage objects	Search Service Contributor	7ca78c08-252a-4471-8644-bb5ff32d4ba0
Load documents, run indexing jobs	Search Index Data Contributor	8ebe5a00-799e-43f5-93ac-243d3dce84a7
Query an index	Search Index Data Reader	1407120a-92aa-4202-b7e9-c0e197c71c8f

Another combination of roles that provides full access is Contributor or Owner, plus Search Index Data Reader.

Important

If you configure role-based access for a service or index and you also provide an API key on the request, the search service uses the API key to authenticate.

Azure portal

1. Sign in to the [Azure portal](#).

2. Assign these roles:

- Search Service Contributor (create-read-update-delete operations on indexes, indexers, skillsets, and other top-level objects)
- Search Index Data Contributor (load documents and run indexing jobs)
- Search Index Data Reader (query an index)

Assign roles for read-only queries

Use the Search Index Data Reader role for apps and processes that only need read-access to an index.

 [Expand table](#)

Role	ID
Search Index Data Reader with PowerShell	1407120a-92aa-4202-b7e9-c0e197c71c8f

This is a very specific role. It grants [GET or POST access](#) to the *documents collection of a search index* for search, autocomplete, and suggestions. It doesn't support GET or LIST operations on an index or other top-level objects, or GET service statistics.

This section provides basic steps for setting up the role assignment and is here for completeness, but we recommend [Use Azure AI Search without keys](#) for comprehensive instructions on configuring your app for role-based access.

Azure portal

1. Sign in to the [Azure portal](#).

2. Assign the **Search Index Data Reader** role.

Test role assignments

Use a client to test role assignments. Remember that roles are cumulative and inherited roles that are scoped to the subscription or resource group level can't be deleted or denied at the resource (search service) level.

Configure your application for keyless connections and have role assignments in place before testing.

Azure portal

1. Sign in to the [Azure portal](#).
2. Navigate to your search service.
3. On the Overview page, select the **Indexes** tab:
 - Search Service Contributors can view and create any object, but can't load documents or query an index. To verify permissions, [create a search index](#).
 - Search Index Data Contributors can load documents. There's no load documents option in the Azure portal outside of Import data wizard, but you can [reset and run an indexer](#) to confirm document load permissions.
 - Search Index Data Readers can query the index. To verify permissions, use [Search explorer](#). You should be able to send queries and view results, but you shouldn't be able to view the index definition or create one.

Test as current user

If you're already a Contributor or Owner of your search service, you can present a bearer token for your user identity for authentication to Azure AI Search.

1. Get a bearer token for the current user using the Azure CLI:

Azure CLI

```
az account get-access-token --scope https://search.azure.com/.default
```

Or by using PowerShell:

PowerShell

```
Get-AzAccessToken -ResourceUrl https://search.azure.com
```

2. Paste these variables into a new text file in Visual Studio Code.

HTTP

```
@baseUrl = PASTE-YOUR-SEARCH-SERVICE-URL-HERE  
@index-name = PASTE-YOUR-INDEX-NAME-HERE  
@token = PASTE-YOUR-TOKEN-HERE
```

3. Paste in and then send a request to confirm access. Here's one that queries the hotels-quickstart index

HTTP

```
POST https://{{baseUrl}}/indexes/{{index-name}}/docs/search?api-version=2025-09-01 HTTP/1.1  
Content-type: application/json  
Authorization: Bearer {{token}}  
  
{  
    "queryType": "simple",  
    "search": "motel",  
    "filter": "",  
    "select": "HotelName,Description,Category,Tags",  
    "count": true  
}
```

Grant access to a single index

In some scenarios, you might want to limit an application's access to a single resource, such as an index.

The Azure portal doesn't currently support role assignments at this level of granularity, but it can be done with [PowerShell](#) or the [Azure CLI](#).

In PowerShell, use [New-AzRoleAssignment](#), providing the Azure user or group name, and the scope of the assignment.

1. Load the `Azure` and `AzureAD` modules and connect to your Azure account:

PowerShell

```
Import-Module -Name Az  
Import-Module -Name AzureAD  
Connect-AzAccount
```

2. Add a role assignment scoped to an individual index:

PowerShell

```
New-AzRoleAssignment -ObjectId <objectId> `  
    -RoleDefinitionName "Search Index Data Contributor" `  
    -Scope "/subscriptions/<subscription>/resourceGroups/<resource-  
group>/providers/Microsoft.Search/searchServices/<search-  
service>/indexes/<index-name>"
```

Create a custom role

If [built-in roles](#) don't provide the right combination of permissions, you can create a [custom role](#) to support the operations you require.

This example clones **Search Index Data Reader** and then adds the ability to list indexes by name. Normally, listing the indexes on a search service is considered an administrative right.

Azure portal

These steps are derived from [Create or update Azure custom roles using the Azure portal](#). Cloning from an existing role is supported in a search service page.

These steps create a custom role that augments search query rights to include listing indexes by name. Typically, listing indexes is considered an admin function.

1. In the Azure portal, navigate to your search service.
2. In the left-navigation pane, select **Access Control (IAM)**.
3. In the action bar, select **Roles**.
4. Right-click **Search Index Data Reader** (or another role) and select **Clone** to open the **Create a custom role** wizard.
5. On the Basics tab, provide a name for the custom role, such as "Search Index Data Explorer", and then select **Next**.
6. On the Permissions tab, select **Add permission**.
7. On the Add permissions tab, search for and then select the **Microsoft Search** tile.
8. Set the permissions for your custom role. At the top of the page, using the default **Actions** selection:
 - Under Microsoft.Search/operations, select **Read : List all available operations**.
 - Under Microsoft.Search/searchServices/indexes, select **Read : Read Index**.

9. On the same page, switch to **Data actions** and under Microsoft.Search/searchServices/indexes/documents, select **Read : Read Documents**.

The JSON definition looks like the following example:

JSON

```
{  
  "properties": {  
    "roleName": "search index data explorer",  
    "description": "",  
    "assignableScopes": [  
      "/subscriptions/00000000000000000000000000000000/resourceGroups/free-search-svc/providers/Microsoft.Search/searchServices/demo-search-svc"  
    ],  
    "permissions": [  
      {  
        "actions": [  
          "Microsoft.Search/operations/read",  
          "Microsoft.Search/searchServices/indexes/read"  
        ],  
        "notActions": [],  
        "dataActions": [  
          "Microsoft.Search/searchServices/indexes/documents/read"  
        ],  
        "notDataActions": []  
      }  
    ]  
  }  
}
```

10. Select **Review + create** to create the role. You can now assign users and groups to the role.

Conditional Access

We recommend [Microsoft Entra Conditional Access](#) if you need to enforce organizational policies, such as multifactor authentication.

To enable a Conditional Access policy for Azure AI Search, follow these steps:

1. [Sign in](#) to the Azure portal.
2. Search for **Microsoft Entra Conditional Access**.
3. Select **Policies**.

4. Select **New policy**.
5. In the **Cloud apps or actions** section of the policy, add **Azure AI Search** as a cloud app depending on how you want to set up your policy.
6. Update the remaining parameters of the policy. For example, specify which users and groups this policy applies to.
7. Save the policy.

 **Important**

If your search service has a managed identity assigned to it, the specific search service will show up as a cloud app that can be included or excluded as part of the Conditional Access policy. Conditional Access policies can't be enforced on a specific search service. Instead make sure you select the general **Azure AI Search** cloud app.

Troubleshooting role-based access control issues

When developing applications that use role-based access control for authentication, some common issues might occur:

- If the authorization token came from a [managed identity](#) and the appropriate permissions were recently assigned, it [might take several hours](#) for these permissions assignments to take effect.
- The default configuration for a search service is [key-based authentication](#). If you didn't change the default key setting to **Both** or **Role-based access control**, then all requests using role-based authentication are automatically denied regardless of the underlying permissions.

Last updated on 11/21/2025

Connect your app to Azure AI Search using identities

06/17/2025

In your application code, you can set up a keyless connection to Azure AI Search that uses Microsoft Entra ID and roles for authentication and authorization. Application requests to most Azure services must be authenticated with keys or keyless connections. Developers must be diligent to never expose the keys in an unsecure location. Anyone who gains access to the key is able to authenticate to the service. Keyless authentication offers improved management and security benefits over the account key because there's no key (or connection string) to store.

Keyless connections are enabled with the following steps:

- Enable role-based access on your search service
- Set environment variables, as needed.
- Use an Azure Identity library credential type to create an Azure AI Search client object.

Prerequisites

The following steps need to be completed for both local development and production workloads:

- [Create an AI Search resource](#)
- [Enable role-based access on your search service](#)
- [Install Azure Identity client library](#)

Install Azure Identity client library

To use a keyless approach, update your AI Search enabled code with the Azure Identity client library.

.NET

Install the [Azure Identity client library for .NET](#):

.NET CLI

```
dotnet add package Azure.Identity
```

Update source code to use DefaultAzureCredential

The Azure Identity library's `DefaultAzureCredential` allows you to run the same code in the local development environment and in the Azure cloud. Create a single credential and reuse the credential instance as needed to take advantage of token caching.

.NET

For more information on `DefaultAzureCredential` for .NET, see [Azure Identity client library for .NET](#).

C#

```
using Azure;
using Azure.Search.Documents;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;
using Azure.Search.Documents.Models;
using Azure.Identity;
using System;
using static System.Environment;

string endpoint = GetEnvironmentVariable("AZURE_SEARCH_ENDPOINT");
string indexName = "my-search-index";

DefaultAzureCredential credential = new();
SearchClient searchClient = new(new Uri(endpoint), indexName, credential);
SearchIndexClient searchIndexClient = new(endpoint, credential);
```

Local development

Local development using roles includes these steps:

- Assign your personal identity to RBAC roles on the specific resource.
- Use a tool like the Azure CLI or Azure PowerShell to authenticate with Azure.
- Establish environment variables for your resource.

Roles for local development

As a local developer, your Azure identity needs full control over data plane operations. These are the suggested roles:

- Search Service Contributor, create and manage objects
- Search Index Data Contributor, load and query an index

Find your personal identity with one of the following tools. Use that identity as the `<identity-id>` value.

Azure CLI

1. Sign in to Azure CLI.

```
Azure CLI
```

```
az login
```

2. Get your personal identity.

```
Azure CLI
```

```
az ad signed-in-user show \
--query id -o tsv
```

3. Assign the role-based access control (RBAC) role to the identity for the resource group.

```
Azure CLI
```

```
az role assignment create \
--role "<role-name>" \
--assignee "<identity-id>" \
--scope "/subscriptions/<subscription-id>/resourceGroups/<resource-group-name>"
```

Where applicable, replace `<identity-id>`, `<subscription-id>`, and `<resource-group-name>` with your actual values.

Authentication for local development

Use a tool in your local development environment to authentication to Azure identity. Once you're authenticated, the `DefaultAzureCredential` instance in your source code finds and uses the authentication.

.NET

Select a tool for [authentication during local development](#).

Configure environment variables for local development

To connect to Azure AI Search, your code needs to know your resource endpoint.

Create an environment variable named `AZURE_SEARCH_ENDPOINT` for your Azure AI Search endpoint. This URL generally has the format `https://<YOUR-RESOURCE-NAME>.search.windows.net/`.

Production workloads

Deploy production workloads includes these steps:

- Choose RBAC roles that adhere to the principle of least privilege.
- Assign RBAC roles to your production identity on the specific resource.
- Set up environment variables for your resource.

Roles for production workloads

To create your production resources, you need to create a [user-assigned managed identity](#) then assign that identity to your resources with the correct roles.

The following role is suggested for a production application:

[] [Expand table](#)

Role name	Id
Search Index Data Reader	1407120a-92aa-4202-b7e9-c0e197c71c8f

Authentication for production workloads

Use the following Azure AI Search [Bicep template](#) to create the resource and set the authentication for the `identityId`. Bicep requires the role ID. The `name` shown in this Bicep snippet isn't the Azure role; it's specific to the Bicep deployment.

Bicep

```
// main.bicep
param environment string = 'production'
```

```

param roleGuid string = ''

module aiSearchRoleUser 'core/security/role.bicep' = {
    scope: aiSearchResourceGroup
    name: 'aiSearch-role-user'
    params: {
        principalId: (environment == 'development') ? principalId :
userAssignedManagedIdentity.properties.principalId
        principalType: (environment == 'development') ? 'User' :
'ServicePrincipal'
        roleDefinitionId: roleGuid
    }
}

```

The `main.bicep` file calls the following generic Bicep code to create any role. You have the option to create multiple RBAC roles, such as one for the user and another for production. This allows you to enable both development and production environments within the same Bicep deployment.

Bicep

```

// core/security/role.bicep
metadata description = 'Creates a role assignment for an identity.'
param principalId string // passed in from main.bicep

@allowed([
    'Device'
    'ForeignGroup'
    'Group'
    'ServicePrincipal'
    'User'
])
param principalType string = 'ServicePrincipal'
param roleDefinitionId string // Role ID

resource role 'Microsoft.Authorization/roleAssignments@2022-04-01' = {
    name: guid(subscription().id, resourceGroup().id, principalId,
roleDefinitionId)
    properties: {
        principalId: principalId
        principalType: principalType
        roleDefinitionId: resourceId('Microsoft.Authorization/roleDefinitions',
roleDefinitionId)
    }
}

```

Configure environment variables for production workloads

To connect to Azure AI Search, your code needs to know your resource endpoint, and the ID of the managed identity.

Create environment variables for your deployed and keyless Azure AI Search resource:

- `AZURE_SEARCH_ENDPOINT`: This URL is the access point for your Azure AI Search resource. This URL generally has the format `https://<YOUR-RESOURCE-NAME>.search.windows.net/`.
- `AZURE_CLIENT_ID`: This is the identity to authenticate as.

- [Set environment variables](#)

Connect to Azure AI Search using keys

Azure AI Search supports both identity-based and key-based authentication for connections to your search service. An API key is a unique string composed of 52 randomly generated numbers and letters.

In your source code, you can directly specify the API key in a request header. Alternatively, you can store it as an [environment variable](#) or app setting in your project and then reference the variable in the request.

 **Important**

When you create a search service, key-based authentication is the default, but it's not the most secure option. We recommend that you replace it with [role-based access](#).

Enabled by default

Key-based authentication is the default for new search services. A request made to a search service endpoint is accepted if both the request and the API key are valid and if the search service is configured to allow API keys on a request.

In the Azure portal, you specify authentication on the [Settings > Keys](#) page. Either **API keys** or **Both** provides key support.

Types of keys

There are two kinds of keys used for authenticating a request:

[Expand table](#)

Type	Permission level	How it's created	Maximum
Admin	Full access (read-write) for all content operations	Two admin keys, referred to as <i>primary</i> and <i>secondary</i> keys in the Azure portal, are generated when the service is created and can be individually regenerated on demand.	2 ¹
Query	Read-only access, scoped to the documents collection of a search index	One query key is generated with the service. More can be created on demand by a search service administrator.	50

¹ Having two allows you to roll over one key while using the second key for continued access to the service.

Visually, there's no distinction between an admin key or query key. Both keys are strings composed of 52 randomly generated alpha-numeric characters. If you lose track of what type of key is specified in your application, you can [check the key values in the Azure portal](#).

Key-to-role mapping

This article is about API keys. However, if you want to transition to role-based access, it's helpful to understand how keys map to [built-in roles in Azure AI Search](#):

- An admin key corresponds to the **Search Service Contributor** and **Search Index Data Contributor** roles.
- A query key corresponds to the **Search Index Data Reader** role.

Permissions to view or manage keys

Permissions for viewing and managing API keys are conveyed through [role assignments](#). Members of the following roles can view and regenerate keys:

- Owner
- Contributor
- [Search Service Contributor](#)
- Administrator and co-administrator (classic)

The following roles don't have access to API keys:

- Reader
- Search Index Data Contributor
- Search Index Data Reader

Find existing keys

You can view and manage API keys using the [Azure portal](#), [PowerShell](#), [Azure CLI](#), or [REST API](#).

Portal

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. From the left pane, select **Settings > Keys** to view admin and query keys.

The screenshot shows the Azure portal interface for managing a search service named 'my-demo-search-svc'. The left sidebar contains a navigation menu with various service management options like Semantic search, Knowledge Center, Keys, Scale, Search traffic analytics, Identity, Networking, Properties, Locks, Monitoring, Alerts, Metrics, Diagnostic settings, and Logs. The 'Keys' option is currently selected. The main content area is titled 'API access control' and includes three radio button options: 'API keys' (selected), 'Role-based access control', and 'Both'. Below this are two sections: 'Manage admin keys' and 'Manage query keys'. The 'Manage admin keys' section shows a primary key placeholder '<your-primary-admin-key>' with a regenerate button. The 'Manage query keys' section shows a single entry with a placeholder key '<your-autogenerated-query-key>'.

Use keys on connections

API keys are used for data plane (content) requests, such as creating or accessing an index or any other request that's represented in the [Search Service REST APIs](#).

You can use either an API key or [roles](#) for control plane (service) requests. When you use an API key:

- Admin keys are used for creating, modifying, or deleting objects. Admin keys are also used to GET object definitions and system information, such as [LIST Indexes](#) or [GET Service Statistics](#).
- Query keys are typically distributed to client applications that issue queries.

REST API

Set an admin key in the request header. You can't pass admin keys on the URI or in the body of the request.

Here's an example of admin API key usage on a create index request:

HTTP

```

@baseUrl=https://my-demo-search-service.search.windows.net
@adminApiKey=aaaabbbb-0000-cccc-1111-dddd2222eeee

### Create an index
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{adminApiKey}}

{
    "name": "my-new-index",
    "fields": [
        {"name": "docId", "type": "Edm.String", "key": true, "filterable": true},
        {"name": "Name", "type": "Edm.String", "searchable": true }
    ]
}

```

Set a query key in a request header for POST, or on the URI for GET. Query keys are used for operations that target the `index/docs` collection: [Search Documents](#), [Autocomplete](#), [Suggest](#), or [GET Document](#).

Here's an example of query API key usage on a Search Documents (GET) request:

HTTP

```

### Query an index
GET /indexes/my-new-index/docs?search=*&api-version=2025-09-01&api-key={{queryApiKey}}

```

ⓘ Note

It's considered a poor security practice to pass sensitive data such as an `api-key` in the request URI. For this reason, Azure AI Search only accepts a query key as an `api-key` in the query string. As a general rule, we recommend passing your `api-key` as a request header.

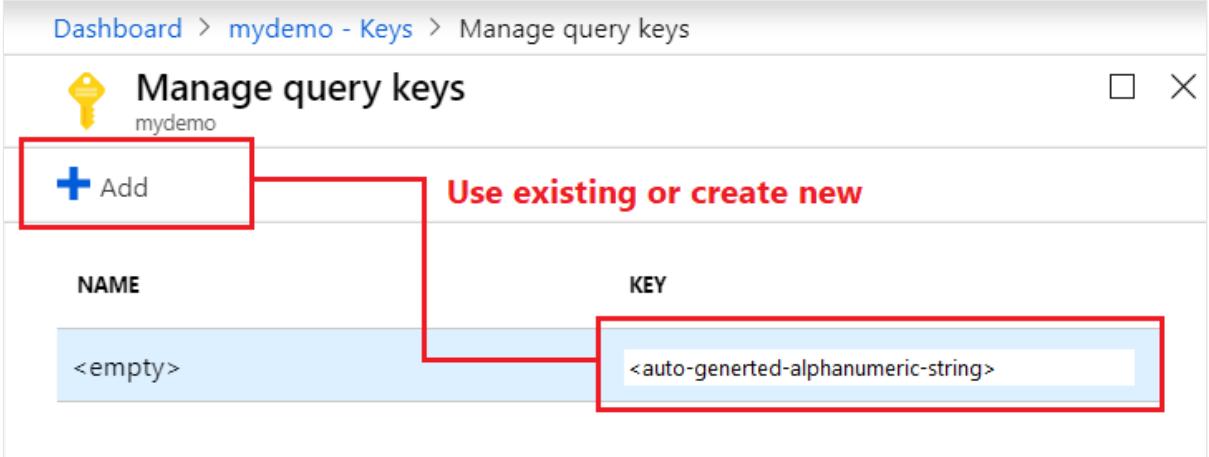

Create query keys

Query keys are used for read-only access to documents within an index for operations targeting a documents collection. Search, filter, and suggestion queries are all operations that take a query key. Any read-only operation that returns system data or object definitions, such as an index definition or indexer status, requires an admin key.

Restricting access and operations in client apps is essential to safeguarding the search assets on your service. Always use a query key rather than an admin key for any query originating from a client app.

Portal

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. From the left pane, select **Settings > Keys** to view API keys.
3. Under **Manage query keys**, use the query key already generated for your service, or create new query keys. The default query key isn't named, but other generated query keys can be named for manageability.

Regenerate admin keys

Two admin keys are created for each service so that you can rotate a primary key while using the secondary key for business continuity.

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. From the left pane, select **Settings > Keys**.
3. Copy the secondary key.
4. For all applications, update the API key settings to use the secondary key.
5. Regenerate the primary key.
6. Update all applications to use the new primary key.

If you inadvertently regenerate both keys at the same time, all client requests using those keys will fail with HTTP 403 Forbidden. However, content isn't deleted and you aren't locked out permanently.

You can still access the service through the Azure portal or programmatically. Management functions are operative through a subscription ID not a service API key, and are thus still available even if your API keys aren't.

After you create new keys via portal or management layer, access is restored to your content (indexes, indexers, data sources, synonym maps) once you provide those keys on requests.

Secure keys

Use role assignments to restrict access to API keys.

It's not possible to use [customer-managed key encryption](#) to encrypt API keys. Only sensitive data within the search service itself (for example, index content or connection strings in data source object definitions) can be CMK-encrypted.

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. From the left pane, select **Access control (IAM)**, and then select the **Role assignments** tab.
3. In the **Role** filter, select the roles that have permission to view or manage keys (Owner, Contributor, Search Service Contributor). The resulting security principals assigned to those roles have key permissions on your search service.
4. As a precaution, also check the **Classic administrators** tab to determine whether administrators and co-administrators have access.

Best practices

- For production workloads, switch to [Microsoft Entra ID and role-based access](#). Alternatively, if you want to continue using API keys, be sure to always monitor [who has access to your API keys](#) and [regenerate API keys](#) on a regular cadence.
- Only use API keys if data disclosure isn't a risk (for example, when using sample data) and if you're operating behind a firewall. Exposing API keys puts both your data and your search service at risk of unauthorized use.
- If you use an API key, store it securely somewhere else, such as in [Azure Key Vault](#). Don't include the API key directly in your code, and never post it publicly.

- Always check code, samples, and training material before publishing to make sure you don't inadvertently expose an API key.

Indexer access to content protected by Azure network security

Article • 05/12/2025

If your Azure resources are deployed in an Azure virtual network, this concept article explains how a search indexer can access content that's protected by network security. It describes the outbound traffic patterns and indexer execution environments. It also covers the network protections supported by Azure AI Search and factors that might influence your security strategy. Finally, because Azure Storage is used for both data access and persistent storage, this article also covers network considerations that are specific to [search and storage connectivity](#).

Looking for step-by-step instructions instead? See [How to configure firewall rules to allow indexer access](#) or [How to make outbound connections through a private endpoint](#).

Resources accessed by indexers

Azure AI Search indexers can make outbound calls to various Azure resources in three situations:

- Connections to external data sources during indexing
- Connections to external, encapsulated code through a skillset that includes custom skills
- Connections to Azure Storage during skillset execution to cache enrichments, save debug session state, or write to a knowledge store

A list of all possible Azure resource types that an indexer might access in a typical run are listed in the table below.

 Expand table

Resource	Purpose within indexer run
Azure Storage (blobs, ADLS Gen 2, files, tables)	Data source
Azure Storage (blobs, tables)	Skillsets (caching enrichments, debug sessions, knowledge store projections)
Azure Cosmos DB (various APIs)	Data source
Azure SQL Database	Data source
OneLake (Microsoft Fabric)	Data source

Resource	Purpose within indexer run
SQL Server on Azure virtual machines	Data source
SQL Managed Instance	Data source
Azure Functions	Attached to a skillset and used to host for custom web API skills

 **Note**

An indexer also connects to Azure AI services for built-in skills. However, that connection is made over the internal network and isn't subject to any network provisions under your control.

Indexers connect to resources using the following approaches:

- A public endpoint with credentials
- A private endpoint, using Azure Private Link
- Connect as a trusted service
- Connect through IP addressing

If your Azure resource is on a virtual network, you should use either a private endpoint or IP addressing to admit indexer connections to the data.

Supported network protections

Your Azure resources could be protected using any number of the network isolation mechanisms offered by Azure. Depending on the resource and region, Azure AI Search indexers can make outbound connections through IP firewalls and private endpoints, subject to the limitations indicated in the following table.

 Expand table

Resource	IP restriction	Private endpoint
Azure Storage for text-based indexing (blobs, ADLS Gen 2, files, tables)	Supported only if the storage account and search service are in different regions.	Supported
Azure Storage for AI enrichment (caching, debug sessions, knowledge store)	Supported only if the storage account and search service are in different regions.	Supported
Azure Cosmos DB for NoSQL	Supported	Supported

Resource	IP restriction	Private endpoint
Azure Cosmos DB for MongoDB	Supported	Unsupported
Azure Cosmos DB for Apache Gremlin	Supported	Unsupported
Azure SQL Database	Supported	Supported
SQL Server on Azure virtual machines	Supported	N/A
SQL Managed Instance	Supported	N/A
Azure Functions	Supported	Supported, only for certain tiers of Azure functions

Network access and indexer execution environments

Azure AI Search has the concept of an *indexer execution environment* that optimizes processing based on the characteristics of the job. There are two environments. If you're using an IP firewall to control access to Azure resources, knowing about execution environments will help you set up an IP range that is inclusive of both environments.

For any given indexer run, Azure AI Search determines the best environment in which to run the indexer. Depending on the number and types of tasks assigned, the indexer will run in one of two environments/

[] Expand table

Execution environment	Description
Private	Internal to a search service. Indexers running in the private environment share computing resources with other indexing and query workloads on the same search service. If you set up a private connection between an indexer and your data, such as a shared private link, this is the only execution environment you can use and it's used automatically.
multitenant	Managed and secured by Microsoft at no extra cost. It isn't subject to any network provisions under your control. This environment is used to offload computationally intensive processing, leaving service-specific resources available for routine operations. Examples of resource-intensive indexer jobs include skillsets, processing large documents, or processing a high volume of documents.

Setting up IP ranges for indexer execution

This section explains IP firewall configuration for admitting requests from either execution environment.

If your Azure resource is behind a firewall, set up [inbound rules that admit indexer connections](#) for all of the IPs from which an indexer request can originate. This includes the IP address used by the search service, and the IP addresses used by the multitenant environment.

- To obtain the IP address of the search service (and the private execution environment), use `nslookup` (or `ping`) to find the fully qualified domain name (FQDN) of your search service. The FQDN of a search service in the public cloud would be `<service-name>.search.windows.net`.
- To obtain the IP addresses of the multitenant environments within which an indexer might run, use the `AzureCognitiveSearch` service tag.

[Azure service tags](#) have a published range of IP addresses of the multitenant environments for each region. You can find these IPs using the [discovery API](#) or a [downloadable JSON file](#). IP ranges are allocated by region, so check your search service region before you start.

Setting up IP rules for Azure SQL

When setting the IP rule for the multitenant environment, certain SQL data sources support a simple approach for IP address specification. Instead of enumerating all of the IP addresses in the rule, you can create a [Network Security Group rule](#) that specifies the `AzureCognitiveSearch` service tag.

You can specify the service tag if your data source is either:

- [SQL Server on Azure virtual machines](#)
- [SQL Managed Instances](#)

Notice that if you specified the service tag for the multitenant environment IP rule, you'll still need an explicit inbound rule for the private execution environment (meaning the search service itself), as obtained through `nslookup`.

Choose a connectivity approach

A search service can't be provisioned into a specific virtual network, running natively on a virtual machine. Although some Azure resources offer [virtual network service endpoints](#), this

functionality won't be offered by Azure AI Search. You should plan on implementing one of the following approaches.

[] [Expand table](#)

Approach	Details
Secure the inbound connection to your Azure resource	Configure an inbound firewall rule on your Azure resource that admits indexer requests for your data. Your firewall configuration should include the service tag for multitenant execution and the IP address of your search service. See Configure firewall rules to allow indexer access .
Private connection between Azure AI Search and your Azure resource	Configure a shared private link used exclusively by your search service for connections to your resource. Connections travel over the internal network and bypass the public internet. If your resources are fully locked down (running on a protected virtual network, or otherwise not available over a public connection), a private endpoint is your only choice. See Make outbound connections through a private endpoint .

Connections through a private endpoint must originate from the search service's private execution environment.

Configuring an IP firewall is free. A private endpoint, which is based on Azure Private Link, has a billing impact. See [Azure Private Link pricing](#) for details.

After you configure network security, follow up with role assignments that specify which users and groups have read and write access to your data and operations.

Considerations for using a private endpoint

This section narrows in on the private connection option.

- A shared private link requires a billable search service, where the minimum tier is either Basic for text-based indexing or Standard 2 (S2) for skills-based indexing. See [tier limits on the number of private endpoints](#) for details.
- Once a shared private link is created, the search service always uses it for every indexer connection to that specific Azure resource. The private connection is locked and enforced internally. You can't bypass the private connection for a public connection.
- Requires a billable Azure Private Link resource.
- Requires that a subscription owner approve the private endpoint connection.
- Requires that you turn off the multitenant execution environment for the indexer.

You do this by setting the `executionEnvironment` of the indexer to "Private". This step ensures that all indexer execution is confined to the private environment provisioned within the search service. This setting is scoped to an indexer and not the search service. If you want all indexers to connect over private endpoints, each one must have the following configuration:

JSON

```
{  
  "name" : "myindexer",  
  ... other indexer properties  
  "parameters" : {  
    ... other parameters  
    "configuration" : {  
      ... other configuration properties  
      "executionEnvironment": "Private"  
    }  
  }  
}
```

Once you have an approved private endpoint to a resource, indexers that are set to be *private* attempt to obtain access via the private link that was created and approved for the Azure resource.

Azure AI Search will validate that callers of the private endpoint have appropriate role assignments. For example, if you request a private endpoint connection to a storage account with read-only permissions, this call will be rejected.

If the private endpoint isn't approved, or if the indexer didn't use the private endpoint connection, you'll find a `transientFailure` error message in indexer execution history.

Supplement network security with token authentication

Firewalls and network security are a first step in preventing unauthorized access to data and operations. Authorization should be your next step.

We recommend role-based access, where Microsoft Entra ID users and groups are assigned to roles that determine read and write access to your service. See [Connect to Azure AI Search using role-based access controls](#) for a description of built-in roles and instructions for creating custom roles.

If you don't need key-based authentication, we recommend that you disable API keys and use role assignments exclusively.

Access to a network-protected storage account

A search service stores indexes and synonym lists. For other features that require storage, Azure AI Search takes a dependency on Azure Storage. Enrichment caching, debug sessions, and knowledge stores fall into this category. The location of each service, and any network protections in place for storage, will determine your data access strategy.

Same-region services

In Azure Storage, access through a firewall requires that the request originates from a different region. If Azure Storage and Azure AI Search are in the same region, you can bypass the IP restrictions on the storage account by accessing data under the system identity of the search service.

There are two options for supporting data access using the system identity:

- Configure search to run as a [trusted service](#) and use the [trusted service exception](#) in Azure Storage.
- Configure a [resource instance rule](#) in Azure Storage that admits inbound requests from an Azure resource.

The above options depend on Microsoft Entra ID for authentication, which means that the connection must be made with a Microsoft Entra login. Currently, only an Azure AI Search [system-assigned managed identity](#) is supported for same-region connections through a firewall.

Services in different regions

When search and storage are in different regions, you can use the previously mentioned options or set up IP rules that admit requests from your service. Depending on the workload, you might need to set up rules for multiple execution environments as described in the next section.

Next steps

Now that you're familiar with indexer data access options for solutions deployed in an Azure virtual network, review either of the following how-to articles as your next step:

- [How to make indexer connections to a private endpoint](#)
- [How to make indexer connections through an IP firewall](#)

Configure a search service to connect using a managed identity

08/27/2025

You can use Microsoft Entra ID security principals and role assignments for outbound connections from Azure AI Search to other Azure resources providing data, applied AI, or vectorization during indexing or queries.

To use roles on an outbound connection, first configure your search service to use either a [system-assigned or user-assigned managed identity](#) as the security principal for your search service in a Microsoft Entra tenant. Once you have a managed identity, you can assign roles for authorized access. Managed identities and role assignments eliminate the need for passing secrets and credentials in a connection string or code.

Prerequisites

- A search service at the [Basic tier or higher](#), any region.
- An Azure resource that accepts incoming requests from a Microsoft Entra security principal that has a valid role assignment.
- To create a managed identity, you must be an Owner or User Access Administrator roles. To assign roles, you must be an Owner, User Access Administrator, Role-based Access Control Administrator, or a member of a custom role with Microsoft.Authorization/roleAssignments/write permissions.

Supported scenarios

You can use managed identities for these scenarios.

 Expand table

Scenario	System	User-assigned
Connect to indexer data sources ¹	Yes	Yes ²
Connect to embedding and chat completion models in Azure OpenAI, Azure AI Foundry, and Azure Functions via skills/vectorizers ³	Yes	Yes
Connect to Azure Key Vault for customer-managed keys	Yes	Yes

Scenario	System	User-assigned
Connect to Debug sessions (hosted in Azure Storage) ¹	Yes	No
Connect to an enrichment cache (hosted in Azure Storage) ^{1, 4}	Yes	Yes ²
Connect to a Knowledge Store (hosted in Azure Storage) ¹	Yes	Yes ²

¹ For connectivity between search and storage, network security imposes constraints on which type of managed identity you can use. Only a system managed identity can be used for a same-region connection to Azure Storage, and that connection must be via the *trusted service exception* or resource instance rule. See [Access to a network-protected storage account](#) for details.

² User-assigned managed identities can be used in data source connection strings. However, only the newer preview REST APIs and preview packages support a user-assigned managed identity in a connection string. Be sure to switch to a preview API if you set `SearchIndexerDataUserAssignedIdentity` as the `identity` in a data source connection.

³ Connections to Azure OpenAI, Azure AI Foundry, and Azure Functions via skills/vectorizers include: [Custom skill](#), [Custom vectorizer](#), [Azure OpenAI embedding skill](#), [Azure OpenAI vectorizer](#), [AML skill](#) and [Azure AI Foundry model catalog vectorizer](#).

⁴ AI search service currently can't connect to tables on a storage account that has [shared key access turned off](#).

Create a system managed identity

A system-assigned managed identity is a Microsoft Entra ID security principal that's automatically created and linked to an Azure resource, such as an Azure AI Search service.

You can have one system-assigned managed identity for each search service. It's unique to your search service and bound to the service for its lifetime.

When you enable a system-assigned managed identity, Microsoft Entra ID creates a security principal for your search service that's used to authenticate to other Azure resources. You can then use this identity in role assignments for authorized access to data and operations.

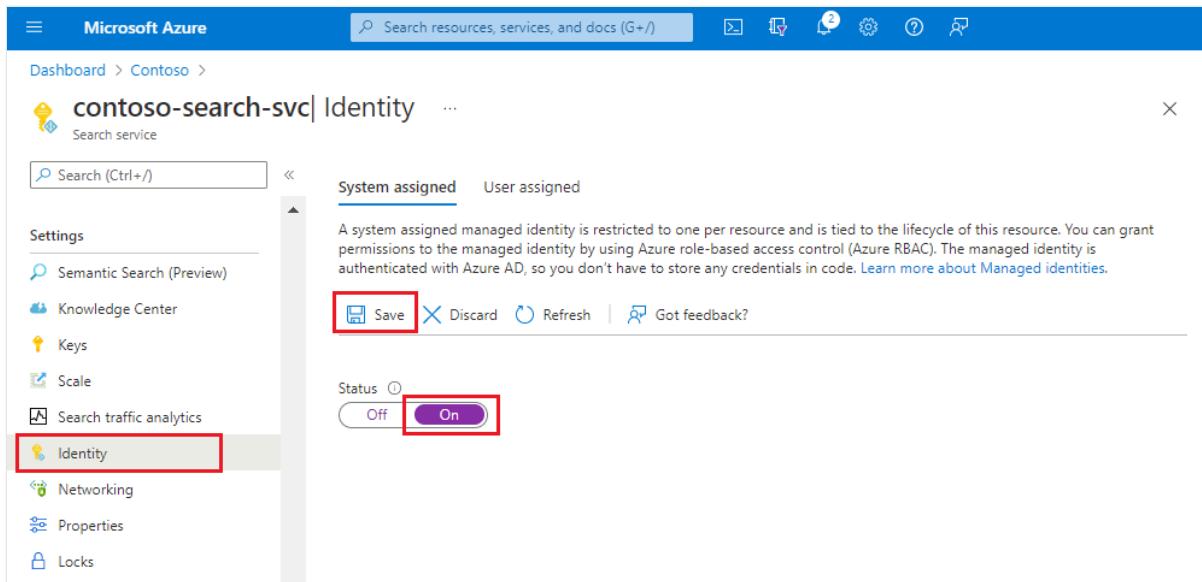

Azure portal

1. Sign in to the [Azure portal](#) and [find your search service](#).

2. From the left pane, select **Settings** > **Identity**.

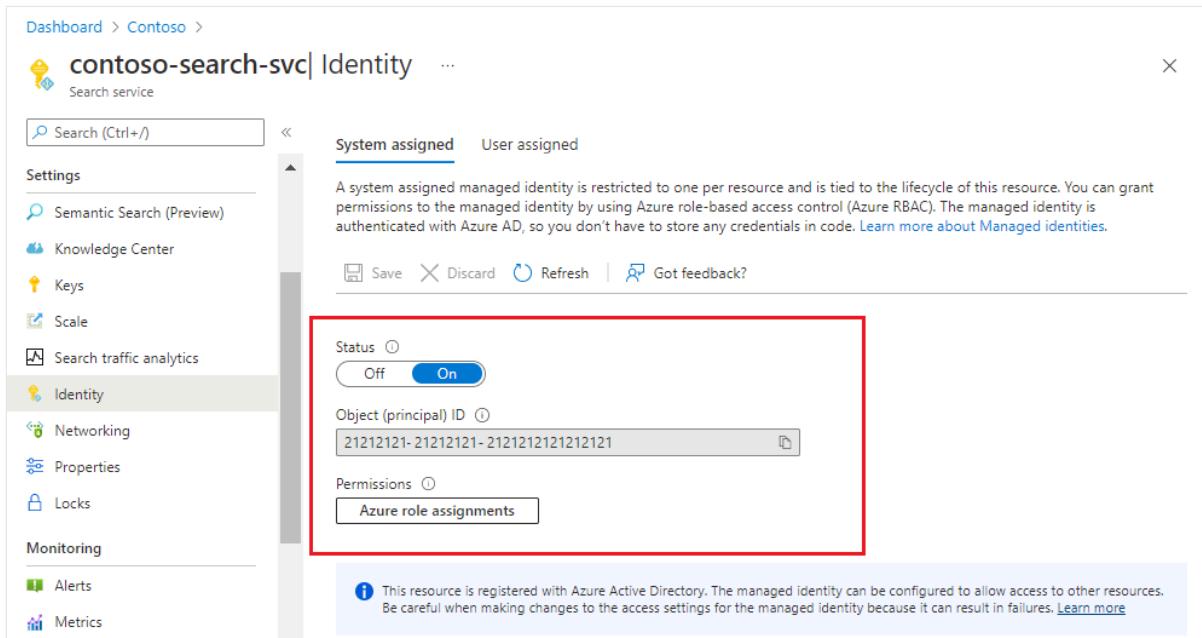

3. On the **System assigned** tab, under **Status**, select **On**.

4. Select **Save**.

The screenshot shows the Azure portal interface for managing a search service. The top navigation bar includes the Microsoft Azure logo, a search bar, and various navigation icons. Below the navigation bar, the page title is "contoso-search-svc | Identity". The left sidebar contains a "Settings" section with several options: Semantic Search (Preview), Knowledge Center, Keys, Scale, Search traffic analytics, **Identity** (which is highlighted with a red box), Networking, Properties, and Locks. The main content area is titled "System assigned". It contains a brief description of system assigned identities and a status switch. The "Status" switch is currently set to "On" (highlighted with a red box). At the bottom of the main content area are "Save", "Discard", "Refresh", and "Got feedback?" buttons.

After you save the settings, the page updates to show an object identifier that's assigned to your search service.

The screenshot shows the Azure portal interface for managing a search service. The top navigation bar and sidebar are identical to the previous screenshot. The main content area is titled "System assigned". It contains a brief description of system assigned identities and a status switch. The "Status" switch is currently set to "On". Below the status switch, there is a section labeled "Object (principal) ID" which displays the value "21212121-21212121-212121212121". There is also a section labeled "Permissions" with the sub-section "Azure role assignments". A callout message at the bottom right of the main content area states: "This resource is registered with Azure Active Directory. The managed identity can be configured to allow access to other resources. Be careful when making changes to the access settings for the managed identity because it can result in failures." The "Identity" option in the left sidebar is highlighted with a red box.

Create a user-assigned managed identity

A user-assigned managed identity is an Azure resource that can be scoped to subscriptions, resource groups, or resource types.

You can create multiple user-assigned managed identities for more granularity in role assignments. For example, you might want separate identities for different applications and scenarios. As an independently created and managed resource, it's not bound to the service itself.

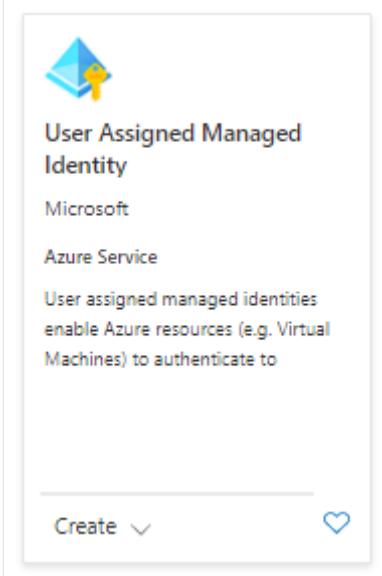

The steps for setting up a user-assigned managed identity are as follows:

- In your Azure subscription, create a user-assigned managed identity.
- On your search service, associate the user-assigned managed identity with your search service.
- On other Azure services you want to connect to, create a role assignment for the identity.

Associating a user-assigned managed identity with an Azure AI Search service is supported in the Azure portal, Search Management REST APIs, and SDK packages that provide the feature.

Azure portal

1. Sign in to the [Azure portal](#).
2. In the upper-left corner of your dashboard, select **Create a resource**.
3. Use the search box to find **User Assigned Managed Identity**, and then select **Create**.

4. Select the subscription, resource group, and region. Give the identity a descriptive name.
5. Select **Create** and wait for the resource to finish deploying.

It takes several minutes before you can use the identity.

6. On your search service page, select **Settings > Identity**.
7. On the **User assigned** tab, select **Add**.
8. Select the subscription and the user-assigned managed identity you previously created.

Assign a role

Once you have a managed identity, assign roles that determine search service permissions on the Azure resource.

- Read permissions are needed for indexer data connections and for accessing a customer-managed key in Azure Key Vault.
- Write permissions are needed for AI enrichment features that use Azure Storage for hosting debug session data, enrichment caching, and long-term content storage in a knowledge store.

The following steps illustrate the role assignment workflow. This example is for Azure OpenAI. For other Azure resources, see [Connect to Azure Storage](#), [Connect to Azure Cosmos DB](#), or [Connect to Azure SQL](#).

1. Sign in to the [Azure portal](#) with your Azure account, and go to your Azure OpenAI resource.
2. Select **Access control** from the left menu.
3. Select **Add** and then select **Add role assignment**.
4. Under **Job function roles**, select [Cognitive Services OpenAI User](#) and then select **Next**.
5. Under **Members**, select **Managed identity** and then select **Members**.
6. Filter by subscription and resource type (Search services), and then select the managed identity of your search service.
7. Select **Review + assign**.

Connection string examples

Recall from the scenarios description that you can use managed identities in connection strings to other Azure resources. This section provides examples. You can use generally available REST

API versions and Azure SDK packages for connections using a system-assigned managed identity.

💡 Tip

You can create most of these objects in the Azure portal, specifying either a system or user-assigned managed identity, and then view the JSON definition to get the connection string.

Here are some examples of connection strings for various scenarios.

Blob data source (system managed identity):

An indexer data source includes a `credentials` property that determines how the connection is made to the data source. The following example shows a connection string specifying the unique resource ID of a storage account.

A system managed identity is indicated when a connection string is the unique resource ID of a Microsoft Entra ID-aware service or application. A user-assigned managed identity is specified through an `identity` property.

JSON

```
"credentials": {  
    "connectionString": "ResourceId=/subscriptions/{subscription-  
ID}/resourceGroups/{resource-group-  
name}/providers/Microsoft.Storage/storageAccounts/{storage-account-name};"  
}
```

Blob data source (user managed identity):

User-assigned managed identities can also be used in indexer data source connection strings. However, only the newer preview REST APIs and preview packages support a user-assigned managed identity in a data source connection string. Be sure to switch to a preview version if you set `SearchIndexerDataUserAssignedIdentity` as the identity in a data source connection.

A search service user identity is specified in the `identity` property.

JSON

```
"credentials": {  
    "connectionString": "ResourceId=/subscriptions/{subscription-  
ID}/resourceGroups/{resource-group-  
name}/providers/Microsoft.Storage/storageAccounts/{storage-account-name};"  
},
```

```
    ...
  "identity": {
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
    "userAssignedIdentity": "/subscriptions/{subscription-
ID}/resourceGroups/{resource-group-
name}/providers/Microsoft.ManagedIdentity/userAssignedIdentities/{user-assigned-
managed-identity-name}"
  }
```

Knowledge store:

A knowledge store definition includes a connection string to Azure Storage. The connection string is the unique resource ID of your storage account. Notice that the string doesn't include containers or tables in the path. These are defined in the embedded projection definition, not the connection string.

JSON

```
"knowledgeStore": {
  "storageConnectionString": "ResourceId=/subscriptions/{subscription-
ID}/resourceGroups/{resource-group-
name}/providers/Microsoft.Storage/storageAccounts/storage-account-name};"
}
```

Enrichment cache:

An indexer creates, uses, and remembers the container used for the cached enrichments. It's not necessary to include the container in the cache connection string. You can find the object ID on the **Identity** page of your search service in the Azure portal.

JSON

```
"cache": {
  "enableReprocessing": true,
  "storageConnectionString": "ResourceId=/subscriptions/{subscription-
ID}/resourceGroups/{resource-group-
name}/providers/Microsoft.Storage/storageAccounts/{storage-account-name};"
}
```

Debug session:

A debug session runs in the Azure portal and takes a connection string when you start the session. You can paste a string similar to the following example.

JSON

```
"ResourceId=/subscriptions/{subscription-ID}/resourceGroups/{resource-group-name}/providers/Microsoft.Storage/storageAccounts/{storage-account-name}/{container-name};",
```

Custom skill:

A [custom skill](#) targets the endpoint of an Azure function or app hosting custom code.

- `uri` is the endpoint of the function or app.
- `authResourceId` tells the search service to connect using a managed identity, passing the application ID of the target function or app in the property.

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",  
    "description": "A custom skill that can identify positions of different phrases  
in the source text",  
    "uri": "https://contoso.count-things.com",  
    "authResourceId": "<Azure-AD-registered-application-ID>",  
    "batchSize": 4,  
    "context": "/document",  
    "inputs": [ ... ],  
    "outputs": [ ... ]  
}
```

Connection examples for models

For connections made using managed identities, this section shows examples of connection information used by a search service to connect to a model on another resource. A connection through a system managed identity is transparent; the identity and roles are in place, and the connection succeeds if they are properly configured. In contrast, a user managed identity requires extra connection properties.

[Azure OpenAI embedding skill](#) and [Azure OpenAI vectorizer](#):

An Azure OpenAI embedding skill and vectorizer in AI Search target the endpoint of an Azure OpenAI hosting an embedding model. The endpoint is specified in the [Azure OpenAI embedding skill definition](#) and/or in the [Azure OpenAI vectorizer definition](#).

The system-managed identity is used automatically if `"apikey"` and `"authIdentity"` are empty, as demonstrated in the following example. The `"authIdentity"` property is used for user-assigned managed identity only.

System-managed identity example:

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill",  
  "description": "Connects a deployed embedding model.",  
  "resourceUri": "https://url.openai.azure.com/",  
  "deploymentId": "text-embedding-ada-002",  
  "modelName": "text-embedding-ada-002",  
  "inputs": [  
    {  
      "name": "text",  
      "source": "/document/content"  
    }  
  ],  
  "outputs": [  
    {  
      "name": "embedding"  
    }  
  ]  
}
```

Here's a [vectorizer example](#) configured for a system-assigned managed identity. A vectorizer is specified in a search index.

JSON

```
"vectorizers": [  
  {  
    "name": "my_azure_open_ai_vectorizer",  
    "kind": "azureOpenAI",  
    "azureOpenAIParameters": {  
      "resourceUri": "https://url.openai.azure.com",  
      "deploymentId": "text-embedding-ada-002",  
      "modelName": "text-embedding-ada-002"  
    }  
  }  
]
```

User-assigned managed identity example:

A user-assigned managed identity is used if `"apiKey"` is empty and a valid `"authIdentity"` is provided.

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill",  
  "description": "Connects a deployed embedding model.",
```

```

"resourceUri": "https://url.openai.azure.com/",
"deploymentId": "text-embedding-ada-002",
"modelName": "text-embedding-ada-002",
"inputs": [
  {
    "name": "text",
    "source": "/document/content"
  }
],
"outputs": [
  {
    "name": "embedding"
  }
],
"authIdentity": {
  "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
  "userAssignedIdentity":
  "/subscriptions/<subscription_id>/resourcegroups/<resource_group>/providers/Microsoft.ManagedIdentity/userAssignedIdentities/<user-assigned-managed-identity-name>"
}
}

```

Here's a [vectorizer example](#) configured for a user-assigned managed identity. A vectorizer is specified in a search index.

JSON

```

"vectorizers": [
  {
    "name": "my_azure_open_ai_vectorizer",
    "kind": "azureOpenAI",
    "azureOpenAIParameters": {
      "resourceUri": "https://url.openai.azure.com",
      "deploymentId": "text-embedding-ada-002",
      "modelName": "text-embedding-ada-002"
      "authIdentity": {
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
        "userAssignedIdentity":
        "/subscriptions/<subscription_id>/resourcegroups/<resource_group>/providers/Microsoft.ManagedIdentity/userAssignedIdentities/<user-assigned-managed-identity-name>"
      }
    }
  }
]

```

Check for firewall access

If your Azure resource is behind a firewall, make sure there's an inbound rule that admits requests from your search service and from the Azure portal.

- For same-region connections to Azure Blob Storage or Azure Data Lake Storage Gen2, use a system managed identity and the [trusted service exception](#). Optionally, you can configure a [resource instance rule](#) to admit requests.
- For all other resources and connections, [configure an IP firewall rule](#) that admits requests from Azure AI Search. See [Indexer access to content protected by Azure network security features](#) for details.

- [About managed identities \(Microsoft Entra ID\)](#)

Connect to Azure Storage using a managed identity (Azure AI Search)

08/27/2025

This article explains how to configure a search service connection to an Azure Storage account using a managed identity instead of providing credentials in the connection string.

You can use a system-assigned managed identity or a user-assigned managed identity.

Managed identities are Microsoft Entra logins and require role assignments for access to Azure Storage.

Prerequisites

- Azure AI Search, Basic tier or higher, with a [managed identity](#).

 Note

If storage is network-protected and in the same region as your search service, you must use a system-assigned managed identity and either one of the following network options: [connect as a trusted service](#), or [connect using the resource instance rule](#).

Create a role assignment in Azure Storage

1. Sign in to Azure portal and find your storage account.
2. Select **Access control (IAM)**.
3. Select **Add** and then select **Role assignment**.
4. From the list of job function roles, select the roles needed for your search service:

 Expand table

Task	Role assignment
Blob indexing using an indexer	Add Storage Blob Data Reader
ADLS Gen2 indexing using an indexer	Add Storage Blob Data Reader

Task	Role assignment
Table indexing using an indexer	Add Storage Table Data Reader
File indexing using an indexer	Add Reader and Data Access
Write to a knowledge store	Add Storage Blob Data Contributor for object and file projections, and Reader and Data Access for table projections.
Write to an enrichment cache	Add Storage Blob Data Contributor and Storage Table Data Contributor
Save debug session state	Add Storage Blob Data Contributor

5. Select **Next**.

6. Select **Managed identity** and then select **Members**.

7. Filter by system-assigned managed identities or user-assigned managed identities. You should see the managed identity that you previously created for your search service. If you don't have one, see [Configure search to use a managed identity](#). If you already set one up but it's not available, give it a few minutes.

8. Select the identity and save the role assignment.

Specify a managed identity in a connection string

Once you have a role assignment, you can set up a connection to Azure Storage that operates under that role.

[Indexers](#) use a data source object for connections to an external data source. This section explains how to specify a system-assigned managed identity or a user-assigned managed identity on a data source connection string. You can find more [connection string examples](#) in the managed identity article.

Tip

You can create a data source connection to Azure Storage in the Azure portal, specifying either a system or user-assigned managed identity, and then view the JSON definition to see how the connection string is formulated.

System-assigned managed identity

You must have a [system-assigned managed identity already configured](#), and it must have a role-assignment on Azure Storage.

For connections made using a system-assigned managed identity, the only change to the [data source definition](#) is the format of the `credentials` property.

Provide a connection string that contains a `ResourceId`, with no account key or password. The `ResourceId` must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01

{
    "name" : "blob-datasource",
    "type" : "azureblob",
    "credentials" : {
        "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-0000-
00000000/resourceGroups/MY-DEMO-RESOURCE-
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/;"
    },
    "container" : {
        "name" : "my-container", "query" : "<optional-virtual-directory-name>"
    }
}
```

User-assigned managed identity (preview)

You must have a [user-assigned managed identity already configured](#) and associated with your search service, and the identity must have a role-assignment on Azure Storage.

Connections made through user-assigned managed identities use the same credentials as a system-assigned managed identity, plus an extra `identity` property that contains the collection of user-assigned managed identities. Only one user-assigned managed identity should be provided when creating the data source.

Provide a connection string that contains a `ResourceId`, with no account key or password. The `ResourceId` must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name.

Provide an `identity` using the syntax shown in the following example. Set `userAssignedIdentity` to the user-assigned managed identity.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-08-01-preview

{
    "name" : "blob-datasource",
    "type" : "azureblob",
    "credentials" : {
        "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-0000-00000000/resourceGroups/MY-DEMO-RESOURCE-
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/;"
    },
    "container" : {
        "name" : "my-container", "query" : "<optional-virtual-directory-name>"
    },
    "identity" : {
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
        "userAssignedIdentity" : "/subscriptions/00000000-0000-0000-0000-00000000/resourcegroups/MY-DEMO-RESOURCE-
GROUP/providers/Microsoft.ManagedIdentity/userAssignedIdentities/MY-DEMO-USER-
MANAGED-IDENTITY"
    }
}
```

Connection information and permissions on the remote service are validated at run time during indexer execution. If the indexer is successful, the connection syntax and role assignments are valid. For more information, see [Run or reset indexers, skills, or documents](#).

Accessing network secured data in storage accounts

Azure storage accounts can be further secured using firewalls and virtual networks. If you want to index content from a storage account that is secured using a firewall or virtual network, see [Make indexer connections to Azure Storage as a trusted service](#).

Connect to Azure Cosmos DB using a managed identity (Azure AI Search)

08/27/2025

This article explains how to set up an indexer connection to an Azure Cosmos DB database using a managed identity instead of providing credentials in the connection string.¹

You can use a system-assigned managed identity or a user-assigned managed identity. Managed identities are Microsoft Entra logins and require Azure role assignments to access data in Azure Cosmos DB. You can optionally [enforce role-based access as the only authentication method](#) for data connections by setting `disableLocalAuth` to `true` for your Azure Cosmos DB for NoSQL account.

Prerequisites

- [Create a managed identity](#) for your search service.

Supported approaches for managed identity authentication

Azure AI Search supports two mechanisms to connect to Azure Cosmos DB using managed identity.

- The *legacy* approach requires configuring the managed identity to have reader permissions on the control plane of the target Azure Cosmos DB account. Azure AI Search utilizes that identity to fetch the account keys of Cosmos DB account in the background to access the data. This approach won't work if the Cosmos DB account has `"disableLocalAuth": true`.
- The *modern* approach requires configuring the managed identity appropriate roles on the control and data plane of the target Azure Cosmos DB account. Azure AI Search will then request an access token to access the data in the Cosmos DB account. This approach works even if the Cosmos DB account has `"disableLocalAuth": true`.

Indexers that connect to Azure Cosmos DB for NoSQL support both the *legacy* and the *modern* approach - the *modern* approach is recommended.

Limitations

- Indexers that connect to Azure Cosmos DB for Gremlin and MongoDB (currently in preview) only support the *legacy* approach.

Connect to Azure Cosmos DB for NoSQL

This section outlines the steps to configure connecting to Azure Cosmos DB for NoSQL via the *modern* approach.

Configure control plane role assignments

1. Sign in to Azure portal and find your Cosmos DB for NoSQL account.
2. Select **Access control (IAM)**.
3. Select **Add** and then select **Role assignment**.
4. From the list of job function roles, select **Cosmos DB Account Reader**.
5. Select **Next**.
6. Select **Managed identity** and then select **Members**.
7. Filter by system-assigned managed identities or user-assigned managed identities. You should see the managed identity that you previously created for your search service. If you don't have one, see [Configure search to use a managed identity](#). If you already set one up but it's not available, give it a few minutes.
8. Select the identity and save the role assignment.

For more information, see [Use control plane role-based access control with Azure Cosmos DB for NoSQL](#).

Configure data plane role assignments

The managed identity needs to assigned a role to read from the Cosmos DB account's data plane. The Object (principal) ID for the search service's system/user assigned identity can be found from the search service's "Identity" tab. This step can only be performed via Azure CLI at the moment.

Set variables:

Azure CLI

```
$cosmosdb_acc_name = <cosmos db account name>
$resource_group = <resource group name>
$subsciption = <subscription ID>
$system_assigned_principal = <Object (principal) ID for the search service's
system/user assigned identity>
$readOnlyRoleDefinitionId = "00000000-0000-0000-0000-000000000001"
$scope=$(az cosmosdb show --name $cosmosdb_acc_name --resource-group
$resource_group --query id --output tsv)
```

Define a role assignment for the system-assigned identity:

Azure CLI

```
az cosmosdb sql role assignment create --account-name $cosmosdb_acc_name --
resource-group $resource_group --role-definition-id $readOnlyRoleDefinitionId --
principal-id $system_assigned_principal --scope $scope
```

For more information, see [Use data plane role-based access control with Azure Cosmos DB for NoSQL](#)

Configure the data source definition

Once you have configured **both** control plane and data plane role assignments on the Azure Cosmos DB for NoSQL account, you can set up a connection to it that operates under that role.

Indexers use a data source object for connections to an external data source. This section explains how to specify a system-assigned managed identity or a user-assigned managed identity on a data source connection string. You can find more [connection string examples](#) in the managed identity article.

Tip

You can create a data source connection to Cosmos DB in the Azure portal, specifying either a system or user-assigned managed identity, and then view the JSON definition to see how the connection string is formulated.

The [REST API](#), Azure portal, and the [.NET SDK](#) support using a system-assigned or user-assigned managed identity.

Connect through system-assigned identity

When you're connecting with a system-assigned managed identity, the only change to the data source definition is the format of the "credentials" property. Provide a database name and a ResourceId that has no account key or password. The ResourceId must include the subscription ID of Azure Cosmos DB, the resource group, and the Azure Cosmos DB account name.

Here's an example using the [Create Data Source](#) REST API that exercises the *modern* approach.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
{
    "name": "my-cosmosdb-ds",
    "type": "cosmosdb",
    "credentials": {
        "connectionString": "ResourceId=/subscriptions/[subscription-
id]/resourceGroups/[rg-
name]/providers/Microsoft.DocumentDB/databaseAccounts/[cosmos-account-
name];Database=[cosmos-database];IdentityAuthType=AccessToken"
    },
    "container": { "name": "[my-cosmos-collection]" }
}
```

➊ Note

If the `IdentityAuthType` property isn't part of the connection string, then Azure AI Search defaults to the *legacy* approach to ensure backward compatibility.

Connect through user-assigned identity (preview)

You need to add an "identity" property to the data source definition, where you specify the specific identity (out of several that can be assigned to the search service), that will be used to connect to the Azure Cosmos DB account.

Here's an example using user-assigned identity via the *modern* approach.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-08-01-
preview
{
    "name": "[my-cosmosdb-ds]",
    "type": "cosmosdb",
    "credentials": {
        "connectionString": "ResourceId=/subscriptions/[subscription-
id]/resourceGroups/[rg-
name]/providers/Microsoft.DocumentDB/databaseAccounts/[cosmos-account-
```

```
name];Database=[cosmos-database];IdentityAuthType=AccessToken"
},
"container": { "name": "[my-cosmos-collection]"},  
"identity" : {
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
    "userAssignedIdentity": "/subscriptions/[subscription-
id]/resourcegroups/[rg-
name]/providers/Microsoft.ManagedIdentity/userAssignedIdentities/[my-user-managed-
identity-name]"
}
}
```

Connect to Azure Cosmos DB for Gremlin/MongoDB (preview)

This section outlines the steps to configure connecting to Azure Cosmos DB for Gremlin/Mongo via the *legacy* approach.

Configure control plane role assignments

Follow the same steps as before to assign the appropriate roles on the control plane of the Azure Cosmos DB for Gremlin/MongoDB.

Set the connection string

- For MongoDB collections, add "ApiKind=MongoDb" to the connection string and use a preview REST API.
- For Gremlin graphs, add "ApiKind=Gremlin" to the connection string and use a preview REST API.
- For either kinds, only the **legacy** approach is supported - that is, `IdentityAuthType=AccountKey` or omitting it entirely is the only valid connection string.

Here's an example to connect to MongoDB collections using system-assigned identity via the REST API

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-08-01-
preview
{
    "name": "my-cosmosdb-ds",
    "type": "cosmosdb",
    "credentials": {
        "connectionString": "ResourceId=/subscriptions/[subscription-
id]/resourceGroups/[rg-
```

```
name]/providers/Microsoft.DocumentDB/databaseAccounts/[cosmos-account-name];Database=[cosmos-database];ApiKind=MongoDb"
},
"container": { "name": "[my-cosmos-collection]", "query": null },
"dataChangeDetectionPolicy": null
}
```

Here's an example to connect to Gremlin graphs using user-assigned identity.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-08-01-preview
{
  "name": "[my-cosmosdb-ds]",
  "type": "cosmosdb",
  "credentials": {
    "connectionString": "ResourceId=/subscriptions/[subscription-id]/resourceGroups/[rg-name]/providers/Microsoft.DocumentDB/databaseAccounts/[cosmos-account-name];Database=[cosmos-database];ApiKind=Gremlin"
  },
  "container": { "name": "[my-cosmos-collection]" },
  "identity": {
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
    "userAssignedIdentity": "/subscriptions/[subscription-id]/resourcegroups/[rg-name]/providers/Microsoft.ManagedIdentity/userAssignedIdentities/[my-user-managed-identity-name]"
  }
}
```

Run the indexer to verify permissions

Connection information and permissions on the remote service are validated at run time during indexer execution. If the indexer is successful, the connection syntax and role assignments are valid. For more information, see [Run or reset indexers, skills, or documents](#).

Troubleshoot connections

- For Azure Cosmos DB for NoSQL, check whether the account has its access restricted to select networks. You can rule out any firewall issues by trying the connection without restrictions in place. Refer to [Indexer access to content protected by Azure network security](#) for more information

- For Azure Cosmos DB for NoSQL, if the indexer fails due to authentication issues, ensure that the role assignments have been done **both** on the control plane and data plane of the Cosmos DB account.
- For Gremlin or MongoDB, if you recently rotated your Azure Cosmos DB account keys, you need to wait up to 15 minutes for the managed identity connection string to work.

Set up an indexer connection to Azure SQL using a managed identity

08/27/2025

This article explains how to set up an indexer connection to Azure SQL Database using a managed identity instead of providing credentials in the connection string.

You can use a system-assigned managed identity or a user-assigned managed identity (preview). Managed identities are Microsoft Entra logins and require Azure role assignments to access data in Azure SQL.

Prerequisites

- [Create a managed identity](#) for your search service.
- [Assign an Azure admin role on SQL](#). The identity used on the indexer connection needs read permissions. You must be a Microsoft Entra admin with a server in SQL Database or SQL Managed Instance to grant read permissions on a database.
- You should be familiar with [indexer concepts](#) and [configuration](#).

1 - Assign permissions to read the database

Follow the below steps to assign the search service or user-assigned managed identity permission to read the database.

1. Connect to Visual Studio.

sql-database (contoso /sql-database)

SQL database

Search (Ctrl+ /) Copy Restore Export Set server firewall Delete Connect with... Feedback

Visual Studio

Overview Activity log Tags Diagnose and solve problems Quick start Query editor (preview)

Power Platform Power BI (preview) Power Apps (preview) Power Automate (preview)

Settings Configure Geo-Replication Connection strings Sync to other databases

Resource group (change) : Status Online Location East US Subscription (change) : Subscription ID : Tags (change) Click here to add tags

Show data for last: 1 hour 24 hours 7 days

Compute utilization

2. Authenticate with your Microsoft Entra account.

Connect

History Browse

Type here to filter the list

Local Network Azure

Server Name: sql-server-search-demo.database.windows.net

Authentication: Active Directory Interactive Authentication

User Name:

Password:

Remember Password

Database Name: sql-database

Advanced...

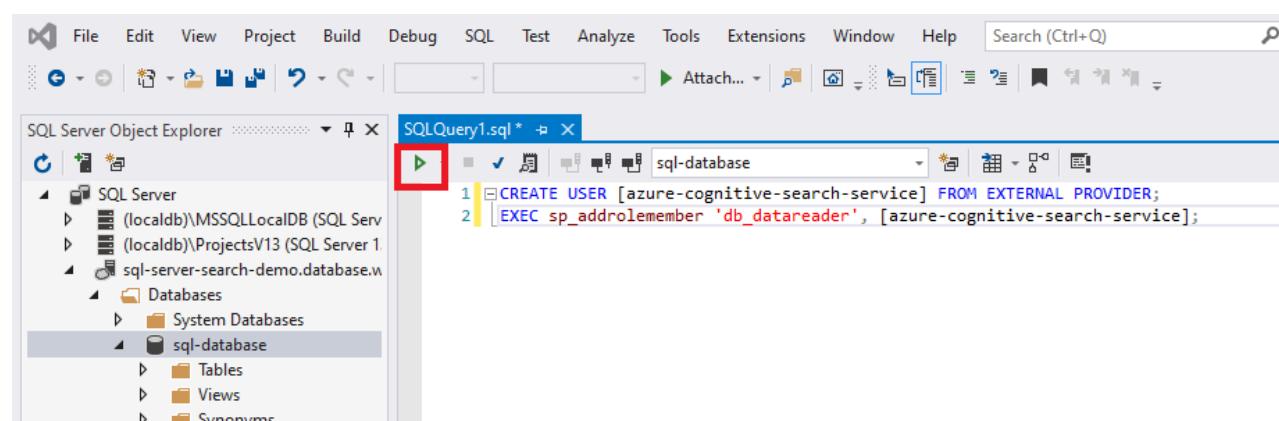

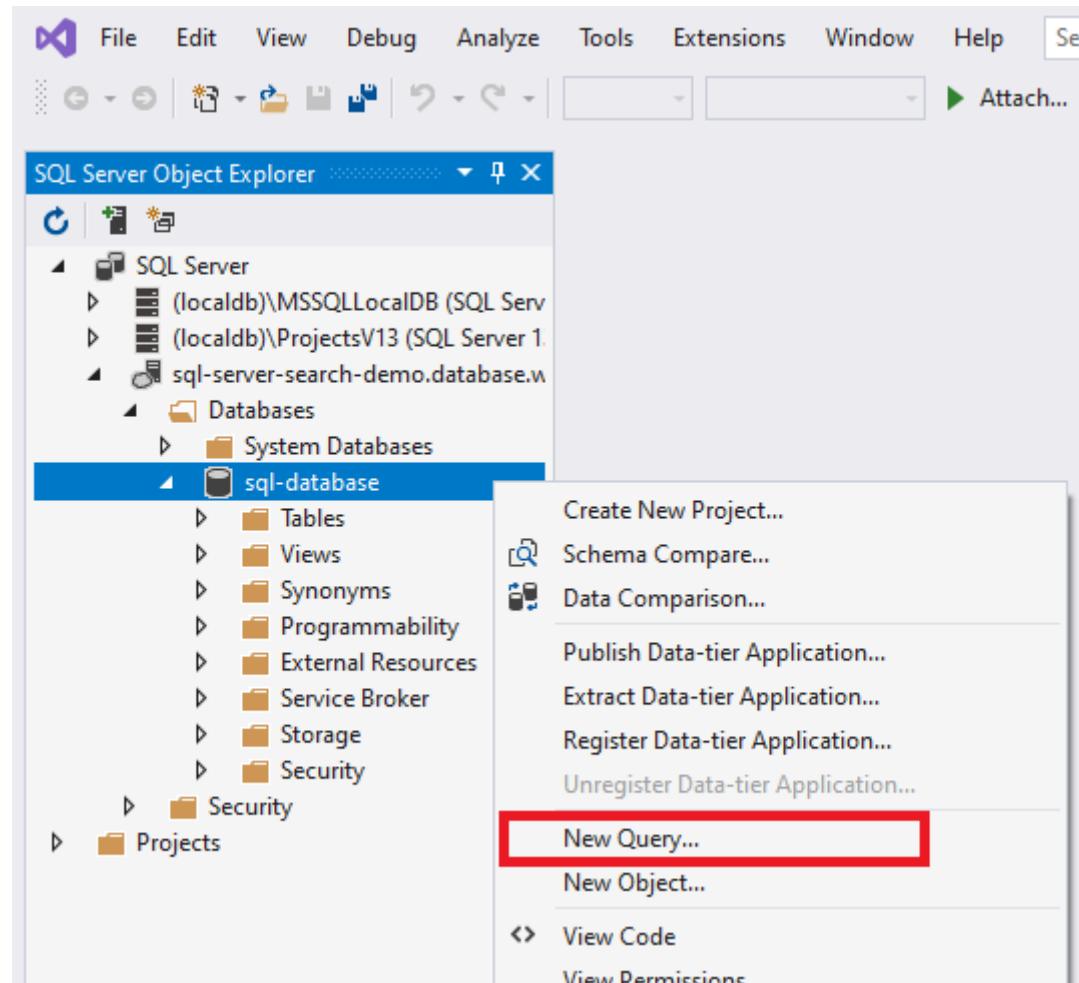

Connect Cancel

3. Execute the following commands:

Include the brackets around your search service name or user-assigned managed identity name.

```
SQL

CREATE USER [insert your search service name here or user-assigned managed identity name] FROM EXTERNAL PROVIDER;
EXEC sp_addrolemember 'db_datareader', [insert your search service name here or user-assigned managed identity name];
```

If you later change the search service identity or user-assigned identity after assigning permissions, you must remove the role membership and remove the user in the SQL database, then repeat the permission assignment. Removing the role membership and user can be accomplished by running the following commands:

SQL

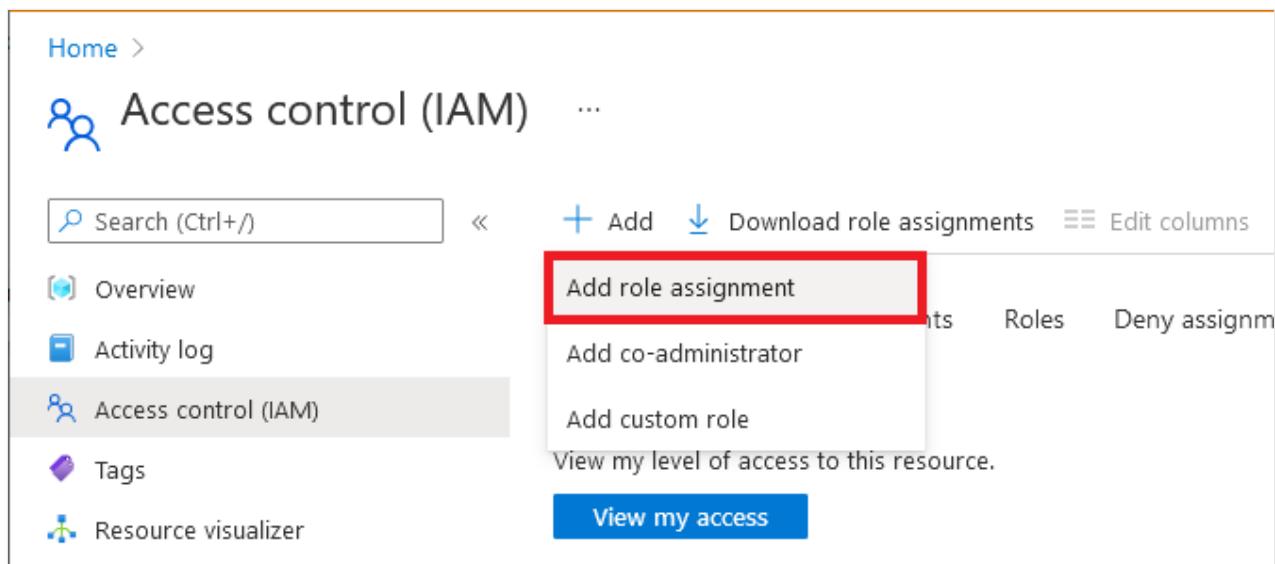

```
sp_droprolemember 'db_datareader', [insert your search service name or user-assigned managed identity name];
```

```
DROP USER IF EXISTS [insert your search service name or user-assigned managed identity name];
```

2 - Add a role assignment

In this section you'll, give your Azure AI Search service permission to read data from your SQL Server. For detailed steps, see [Assign Azure roles using the Azure portal](#).

1. In the Azure portal, navigate to your Azure SQL Server page.
2. Select **Access control (IAM)**.
3. Select **Add > Add role assignment**.

4. On the **Role** tab, select the appropriate **Reader** role.
5. On the **Members** tab, select **Managed identity**, and then select **Select members**.
6. Select your Azure subscription.
7. If you're using a system-assigned managed identity, select **System-assigned managed identity**, search for your search service, and then select it.

8. Otherwise, if you're using a user-assigned managed identity, select **User-assigned managed identity**, search for the name of the user-assigned managed identity, and then select it.
9. On the **Review + assign** tab, select **Review + assign** to assign the role.

3 - Create the data source

Create the data source and provide either a system-assigned managed identity or a user-assigned managed identity (preview).

System-assigned managed identity

The [REST API](#), Azure portal, and the Azure SDKs support system-assigned managed identity.

When you're connecting with a system-assigned managed identity, the only change to the data source definition is the format of the "credentials" property. You'll provide an Initial Catalog or Database name and a ResourceId that has no account key or password. The ResourceId must include the subscription ID of Azure SQL Database, the resource group of SQL Database, and the name of the SQL database.

Here's an example of how to create a data source to index data from a storage account using the [Create Data Source](#) REST API and a managed identity connection string. The managed identity connection string format is the same for the REST API, .NET SDK, and the Azure portal.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sql-datasource",
    "type" : "azuresql",
    "credentials" : {
        "connectionString" : "Database=[SQL database
name];ResourceId=/subscriptions/[subscription ID]/resourceGroups/[resource group
name]/providers/Microsoft.Sql/servers/[SQL Server name];Connection Timeout=30;"
    },
    "container" : {
        "name" : "my-table"
    }
}
```

User-assigned managed identity (preview)

Preview REST APIs support connections based on a user-assigned managed identity. When you're connecting with a user-assigned managed identity, there are two changes to the data source definition:

- First, the format of the "credentials" property is an Initial Catalog or Database name and a ResourceId that has no account key or password. The ResourceId must include the subscription ID of Azure SQL Database, the resource group of SQL Database, and the name of the SQL database. This is the same format as the system-assigned managed identity.
- Second, add an "identity" property that contains the collection of user-assigned managed identities. Only one user-assigned managed identity should be provided when creating the data source. Set it to type "userAssignedIdentities".

Here's an example of how to create an indexer data source object using the most recent preview API version for [Create or Update Data Source](#):

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-08-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sql-datasource",
    "type" : "azuresql",
    "credentials" : {
        "connectionString" : "Database=[SQL database name];ResourceId=/subscriptions/[subscription ID]/resourceGroups/[resource group name]/providers/Microsoft.Sql/servers/[SQL Server name];Connection Timeout=30;"
    },
    "container" : {
        "name" : "my-table"
    },
    "identity" : {
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
        "userAssignedIdentity" : "/subscriptions/[subscription ID]/resourcegroups/[resource group name]/providers/Microsoft.ManagedIdentity/userAssignedIdentities/[managed identity name]"
    }
}
```

4 - Create the index

The index specifies the fields in a document, attributes, and other constructs that shape the search experience.

Here's a [Create Index](#) REST API call with a searchable `booktitle` field:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "my-target-index",
    "fields": [
        { "name": "id", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "booktitle", "type": "Edm.String", "searchable": true,
    "filterable": false, "sortable": false, "facetable": false }
    ]
}
```

5 - Create the indexer

An indexer connects a data source with a target search index, and provides a schedule to automate the data refresh. Once the index and data source have been created, you're ready to create the indexer. If the indexer is successful, the connection syntax and role assignments are valid.

Here's a [Create Indexer](#) REST API call with an Azure SQL indexer definition. The indexer runs when you submit the request.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sql-indexer",
    "dataSourceName" : "sql-datasource",
    "targetIndexName" : "my-target-index"
}
```

If you get an error when the indexer tries to connect to the data source that says that the client isn't allowed to access the server, take a look at [common indexer errors](#).

[Azure SQL indexer](#)

Set up an indexer connection to Azure SQL Managed Instance using a managed identity

10/09/2025

This article describes how to set up an Azure AI Search indexer connection to [SQL Managed Instance](#) using a managed identity instead of providing credentials in the connection string.

You can use a system-assigned managed identity or a user-assigned managed identity (preview). Managed identities are Microsoft Entra logins and require Azure role assignments to access data in SQL Managed Instance.

Before learning more about this feature, we recommended that you understand what an indexer is and how to set up an indexer for your data source. More information can be found at the following links:

- [Indexer overview](#)
- [SQL Managed Instance indexer](#)

Prerequisites

- [Create a managed identity](#) for your search service.
- Microsoft Entra admin role on SQL Managed Instance:

To assign read permissions on SQL Managed Instance, you must be an Azure Global Admin with a SQL Managed Instance. See [Configure and manage Microsoft Entra authentication with SQL Managed Instance](#) and follow the steps to provision a Microsoft Entra admin (SQL Managed Instance).

- [Configure a public endpoint and network security group in SQL Managed Instance](#) to allow connections from Azure AI Search. Connecting through a shared private link when using a managed identity isn't currently supported.

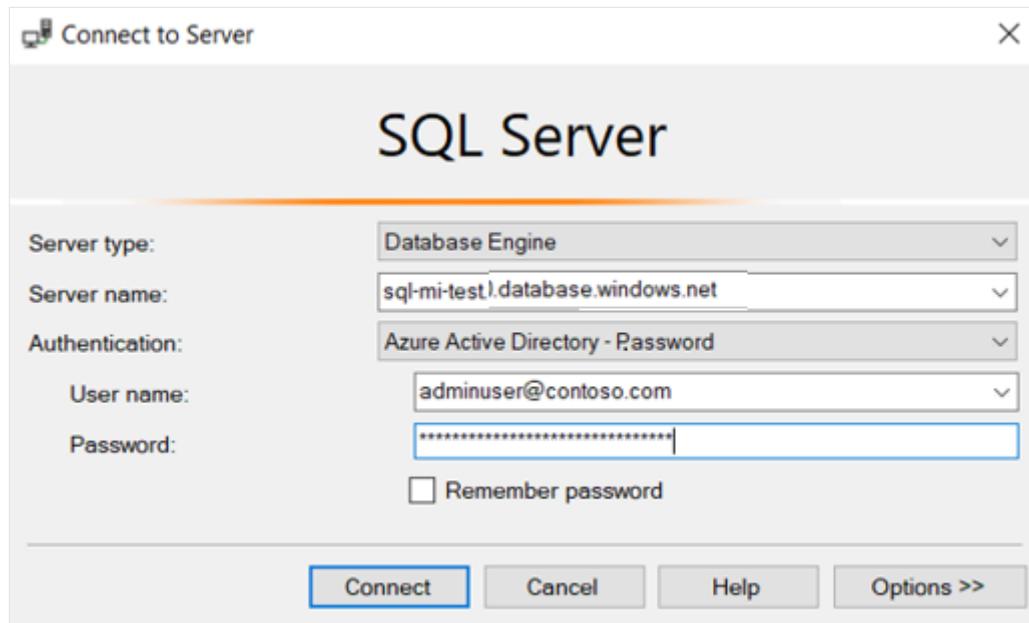

Assign permissions to read the database

Follow these steps to assign the search service system managed identity permission to read the SQL Managed database.

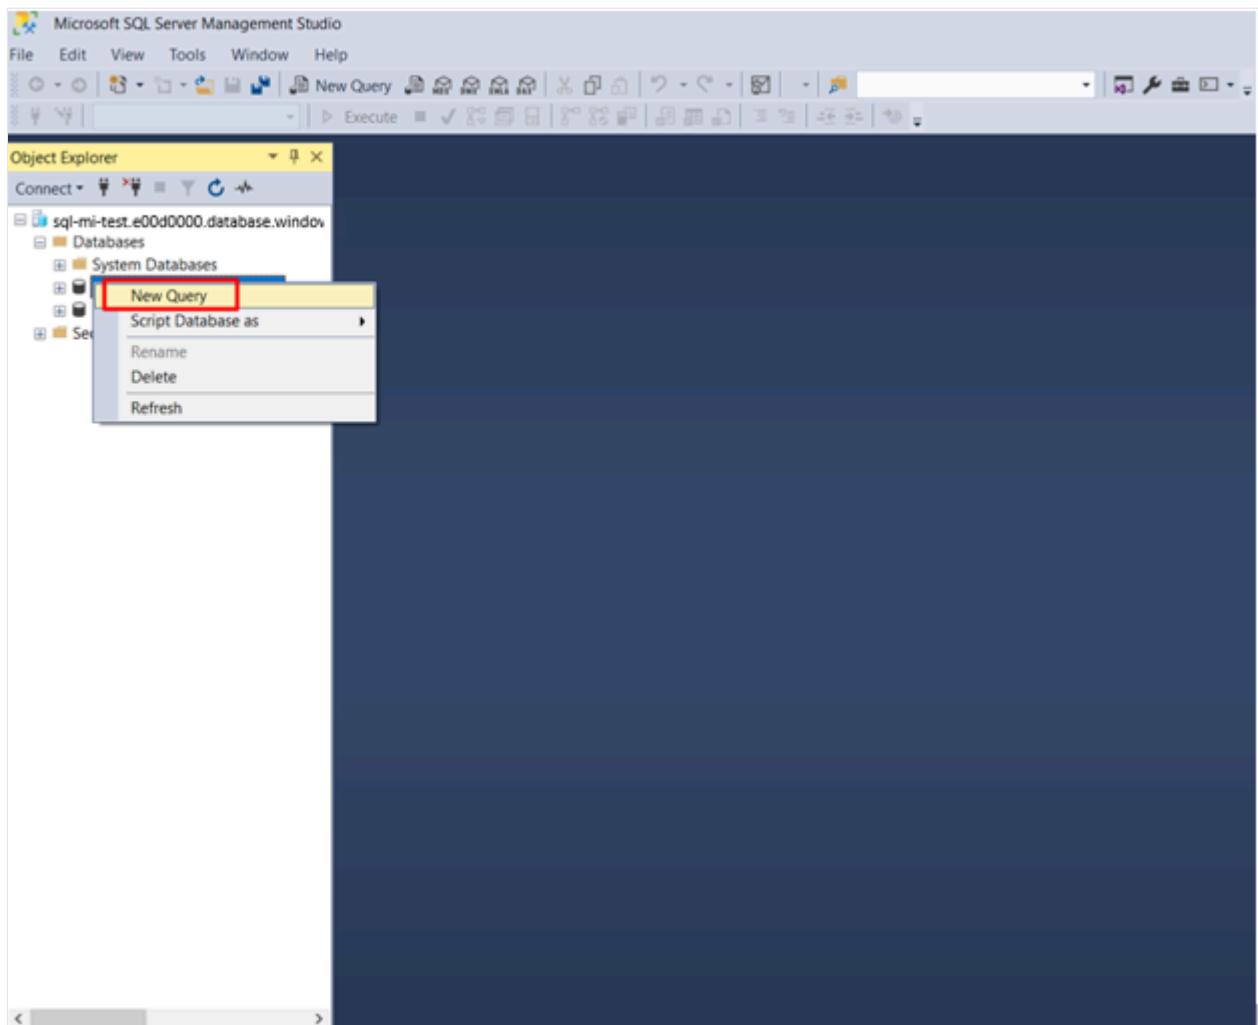

1. Connect to your SQL Managed Instance through SQL Server Management Studio (SSMS) by using one of the following methods:

- [Configure a point-to-site connection from on-premises](#)
- [Configure an Azure virtual machine](#)

2. Authenticate with your Microsoft Entra account.

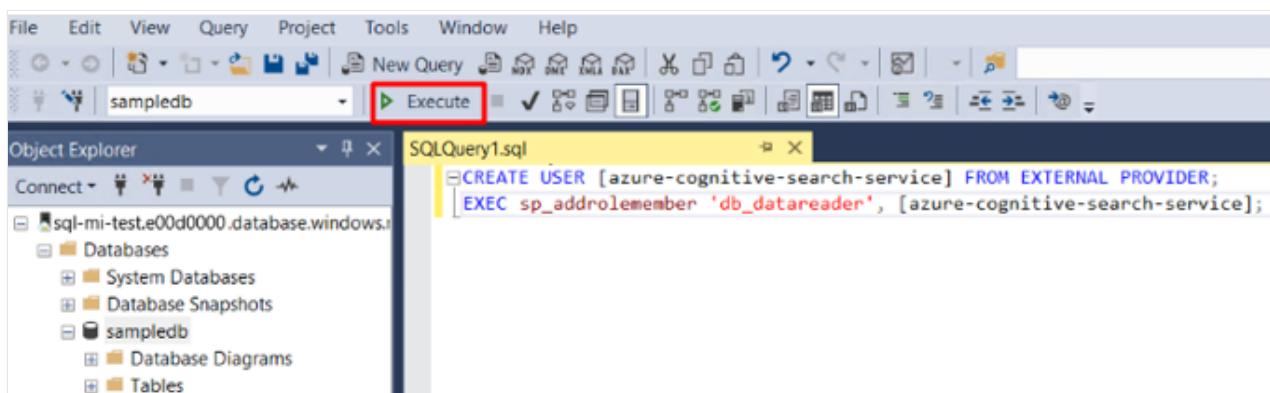

3. From the left pane, locate the SQL database you're using as data source for indexing and right-click it. Select **New Query**.

4. In the T-SQL window, copy the following commands and include the brackets around your search service name. Select **Execute**.

```
SQL

CREATE USER [insert your search service name here or user-assigned managed identity name] FROM EXTERNAL PROVIDER;
EXEC sp_addrolemember 'db_datareader', [insert your search service name here or user-assigned managed identity name];
```

If you later change the search service system identity after assigning permissions, you must remove the role membership and remove the user in the SQL database, then repeat the

permission assignment. Removing the role membership and user can be accomplished by running the following commands:

SQL

```
sp_droprolemember 'db_datareader', [insert your search service name or user-assigned managed identity name];
```

```
DROP USER IF EXISTS [insert your search service name or user-assigned managed identity name];
```

Add a role assignment

In this step, you give your Azure AI Search service permission to read data from your SQL Managed Instance.

1. In the Azure portal, navigate to your SQL Managed Instance page.
2. Select **Access control (IAM)**.
3. Select **Add** then **Add role assignment**.

The screenshot shows the Azure portal's Access control (IAM) blade for a SQL Managed Instance named Contoso. On the left, there's a sidebar with various navigation options like Overview, Activity log, and Resource Management. The main area shows the 'Add role assignment' button highlighted with a red box. Below it, there are sections for 'My access' (with a 'View my access' button), 'Check access' (with a 'Find' dropdown set to 'User, group, or service principal'), and 'Grant access to this resource' (with a 'Add role assignment' button). There's also a 'View deny assignments' section with a 'View' button. A search bar at the bottom allows searching by name or email address.

4. Select **Reader** role.

5. Leave **Assign access to** as Microsoft Entra user, group, or service principal.

6. If you're using a system-assigned managed identity, search for your search service, then select it. If you're using a user-assigned managed identity, search for the name of the user-assigned managed identity, then select it. Select **Save**.

Example for SQL Managed Instance using a system-assigned managed identity:

Create the data source

Create the data source and provide a system-assigned managed identity.

System-assigned managed identity

The [REST API](#), Azure portal, and the [.NET SDK](#) support system-assigned managed identity.

When you're connecting with a system-assigned managed identity, the only change to the data source definition is the format of the "credentials" property. You provide an Initial Catalog or Database name and a `ResourceId` that has no account key or password. The `ResourceId` must include the subscription ID of SQL Managed Instance, the resource group of SQL Managed instance, and the name of the SQL database.

Here's an example of how to create a data source to index data from a storage account using the [Create Data Source REST API](#) and a managed identity connection string. The managed identity connection string format is the same for the REST API, .NET SDK, and the Azure portal.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sql-mi-datasource",
    "type" : "azuresql",
    "credentials" : {
        "connectionString" : "Database=[SQL database
name];ResourceId=/subscriptions/[subscription ID]/resourcegroups/[resource group
name]/providers/Microsoft.Sql/managedInstances/[SQL Managed Instance
name];Connection Timeout=100;"
    },
    "container" : {
        "name" : "my-table"
    }
}
```

Create the index

The index specifies the fields in a document, attributes, and other constructs that shape the search experience.

Here's a [Create Index REST API](#) call with a searchable `booktitle` field:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "my-target-index",
    "fields": [
```

```
        { "name": "id", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "booktitle", "type": "Edm.String", "searchable": true,
"filterable": false, "sortable": false, "facetable": false }
    ]
}
```

Create the indexer

An indexer connects a data source with a target search index, and provides a schedule to automate the data refresh. Once the index and data source are created, you're ready to create the indexer.

Here's a [Create Indexer](#) REST API call with an Azure SQL indexer definition. The indexer runs when you submit the request.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sql-mi-indexer",
    "dataSourceName" : "sql-mi-datasource",
    "targetIndexName" : "my-target-index"
}
```

Troubleshooting

If you get an error when the indexer tries to connect to the data source that says that the client isn't allowed to access the server, see the [common indexer errors](#).

You can also rule out any firewall issues by trying the connection with and without restrictions in place.

Authenticate to an Azure Function App using "Easy Auth" (Azure AI Search)

This article explains how to set up an indexer connection to an Azure Function app using the [built-in authentication capabilities of Azure App Service](#), also known as "Easy Auth." Azure Function apps are a great solution for hosting Custom Web APIs that an Azure AI Search service can use to enrich content ingested during an indexer run or, if you're using a custom embedding model for [integrated vectorization](#), vectorize content in a search query.

You can use a system-assigned or user-assigned managed identity of the search service to authenticate against the Azure Function app. This approach requires setting up a Microsoft Entra ID application registration to use as the authentication provider for the Azure Function app, which is explained in this article.

Prerequisites

- A [managed identity](#) for your search service.

Configure Microsoft Entra ID application as the authentication provider

To use Microsoft Entra ID as an authentication provider to the Azure Function app, an application registration must be created. There are two options: create one automatically via the Azure Function app itself or use an existing application. To learn more about these steps, see the [App Service documentation](#).

Regardless of the option, ensure that the app registration is configured per the following steps to ensure it's compatible with Azure AI Search.

Ensure the app registration has application ID URI configured

The app registration should be configured with an application ID URI, which can be used as the token audience with Azure Function apps and Azure AI Search. Configure it in the format `api://<applicationId>`. This can be done by navigating to the [Overview](#) section of the app registration and setting the [Application ID URI](#) field.

[Screenshot of an app registration configured with application ID URI.](#)

Set supported account types for authentication

Navigate to the **Authentication** section of the app registration and configure the **supported account types** so that only accounts in the same organization directory as the app registration can utilize it for authentication.

[Screenshot of an app registration with supported account types configured.](#)

(Optional) Configure a client secret

App Service recommends using a client secret for the authentication provider application. Authentication still works without client secret, as long as the delegated permissions are set up. To set up a client secret, navigate to the **Certificates & secrets** section of the app registration, and add a **New client secret** as explained [in this article](#).

The screenshot shows the Azure portal interface for managing an app registration named 'contoso-app-registration'. The left sidebar lists various management sections like Overview, Quickstart, Integration assistant, Diagnose and solve problems, Manage, Branding & properties, Authentication, Certificates & secrets (which is currently selected), Token configuration, API permissions, Expose an API, App roles, Owners, Roles and administrators, and Manifest. The right pane displays the 'Certificates & secrets' blade. It shows three tabs: Certificates (0), Client secrets (0, which is underlined in blue), and Federated credentials (0). Below the tabs, a note states: 'A secret string that the application uses to prove its identity when requesting a token. Also can be referred to as application password.' A table lists one client secret entry: Description: 'New client secret', Expires: 'Never', Value: '(redacted)', and Secret ID: 'XXXXXXXX-XXXX-XXXX-XXXX-XXXXXXXXXXXX'. A note at the bottom says: 'No client secrets have been created for this application.'

Add a scope to delegate permissions

Navigate to the section **Expose an API** and configure the app registration to have a scope that delegates admin and user permissions to it, to ensure that it's compatible with the indexer's authentication flow.

The screenshot shows the Azure portal interface for managing an application registration. On the left, a sidebar lists various management options like Overview, Quickstart, Integration assistant, Diagnose and solve problems, Manage, Branding & properties, Authentication, Certificates & secrets, Token configuration, API permissions, and Expose an API. The 'Expose an API' option is currently selected. The main content area displays the 'Application ID URI' as 'api://00000000-0000-0000-0000-000000000000'. A red box highlights the 'Scopes defined by this API' section, which contains a table with one row. The table columns are 'Scopes', 'Who can consent', 'Admin consent display name', and 'User consent display na...'. The single scope listed is 'api://00000000-0000-0000-0000-000000000000/user_impersonation', with 'Admins and users' under 'Who can consent' and 'Accesscontoso-app-registration' under 'Admin consent display name'. Below this table, there's a section for 'Authorized client applications' with a note about trusting the application and a link to 'Add a client application'. A search icon is located in the bottom right corner of the main content area.

Once the delegated permissions scope is set up, you should notice in the **API permissions** section of the app registration that the **User.Read** API on Microsoft.Graph is set.

Screenshot of an app registration with delegated permissions.

Configure Microsoft Entra ID authentication provider in the Azure Function app

With the client application registered with the previous specifications, Microsoft Entra ID authentication for the Azure Function app can be set up by following the [App Service documentation](#). Navigate to the **Authentication** section of the Azure Function app to set up the authentication details.

Ensure the following settings are configured to ensure that Azure AI Search can successfully authenticate to the Azure Function app.

Configure authentication settings

- Ensure that **App Service authentication** is **Enabled**
- Restrict access to the Azure Function app to **Require authentication**
- For **Unauthenticated requests** prefer **HTTP 401: Unauthorized**

The following screenshot highlights these specific settings for a sample Azure Function app.

Screenshot of an Azure Function app that has configured authentication settings.

Add Microsoft Entra ID authentication provider

- Add Microsoft Entra ID as the authentication provider for the Azure Function app.
- Either create a new app registration or choose a previously configured app registration. Ensure that it's configured according to the guidelines in the previous section of this document.
- Ensure that in the **Allowed token audiences** section, the application ID URI of the app registration is specified. It should be in the `api://<applicationId>` format, matching what was configured with the app registration created earlier.
- If you desire, you can configure other checks to restrict access specifically to the indexer.

Screenshot of an Azure Function app with Microsoft Entra ID Authentication provider.

Configure other checks

- Ensure that the **Object (principal) ID** of the specific Azure AI Search service's identity is specified as the **Identity requirement**, by checking the option **Allow requests from specific identities** and entering the **Object (principal) ID** in the identity section.

Screenshot of the identity section for an Azure AI Search service.

- In **Client application requirement**, select the option **Allow requests from specific client application**. You need to look up the Client ID for the Azure AI Search service's identity. To do this, copy over the Object (principal) ID from the previous step and look up in your Microsoft Entra ID tenant. There should be a matching enterprise application whose overview page lists an **Application ID**, which is the GUID that needs to be specified as the client application requirement.

Screenshot of the enterprise application details of an Azure AI Search service's identity.

Note

This step is the most important configuration on the Azure Function app and doing it wrongly can result in the indexer being forbidden from accessing the Azure Function app. Ensure that you perform the lookup of the identity's enterprise application details correctly, and you specify the **Application ID** and **Object (principal) ID** in the right places.

- For the **Tenant requirement**, choose any of the options that aligns with your security posture. For more information, see the [App Service documentation](#).

Set up a connection to the Azure Function app

Depending on whether the connection to the Azure Function app needs to be made in a Custom Web API skill or a Custom Web API vectorizer, the JSON definition is slightly different. In both cases, ensure that you specify the correct URI to the Azure Function app and set the `authResourceId` to be the same value as the **Allowed token audience** configured for the authentication provider.

Depending on whether you choose to connect using a system-assigned identity or user-assigned identity, required properties differ slightly.

Use a system-assigned identity

Here's an example to call into a function named `test` for the sample Azure Function app, where the system assigned identity of the search service is allowed to authenticate via "Easy Auth".

JSON

```
"uri": "https://contoso-function-app.azurewebsites.net/api/test?",  
"authResourceId": "api://00000000-0000-0000-0000-000000000000"
```

Use a user-assigned identity

Here's an example to call into the same function, where the specific user assigned identity is allowed to authenticate via "Easy Auth". You're expected to specify the resource ID of the exact user assigned identity to use in the `identity` property of the configuration.

JSON

```
"uri": "https://contoso-function-app.azurewebsites.net/api/test?",  
"authResourceId": "api://00000000-0000-0000-0000-000000000000",  
"identity" : {  
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",  
    "userAssignedIdentity": "/subscriptions/[subscription-  
id]/resourcegroups/[rg-  
name]/providers/Microsoft.ManagedIdentity/userAssignedIdentities/[my-user-managed-  
identity-name]"  
}
```

! Note

This user assigned identity should actually be assigned to the Azure AI Search service for it to be specified in the Custom Web skill/vectorizer definition.

Run the indexer/vectorizer to verify permissions

For Custom Web API skills, permissions are validated during indexer run-time. For vectorizer, they're validated when a vector query is issued utilizing the Custom Web API vectorizer. To rule out any specific issues with authentication, you can test by disabling the authentication provider on the Azure Function app and ensuring that calls from indexer/vectorizer succeed.

- If authentication issues persist, ensure that the right identity information - namely Application ID, Object (principal) ID for the Azure AI Search service's identity is specified in the Azure Function app's authentication provider.

Configure IP firewall rules to allow indexer connections from Azure AI Search

05/29/2025

On behalf of an indexer, a search service issues outbound calls to an external Azure resource to pull in data during indexing. If your Azure resource uses IP firewall rules to filter incoming calls, you must create an inbound rule in your firewall that admits indexer requests.

This article explains how to find the IP address of your search service and configure an inbound IP rule on an Azure Storage account. While specific to Azure Storage, this approach also works for other Azure resources that use IP firewall rules for data access, such as Azure Cosmos DB and Azure SQL.

! Note

Applicable to Azure Storage only. Your storage account and your search service must be in different regions if you want to define IP firewall rules. If your setup doesn't permit this, try the [trusted service exception](#) or [resource instance rule](#) instead.

For private connections from indexers to any supported Azure resource, we recommend setting up a [shared private link](#). Private connections travel the Microsoft backbone network, bypassing the public internet completely.

Get a search service IP address

1. Get the fully qualified domain name (FQDN) of your search service. This looks like `<search-service-name>.search.windows.net`. You can find the FQDN by looking up your search service on the Azure portal.

The screenshot shows the Azure portal interface for a search service named 'contoso-search-svc'. The left sidebar lists various service management options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Semantic Search (Preview), Knowledge Center, Keys, Scale, Search traffic analytics, Identity, and Properties. The 'Overview' tab is currently selected. In the main content area, there's a 'Create a Standard search service for scalability and greater performance.' button. Below it, under 'Essentials', the 'Url' is listed as <https://contoso-search-svc.search.windows.net>. Other details shown include Status (Running), Location (West US 2), Subscription, and Tags. A red box highlights the 'Url' field.

2. Look up the IP address of the search service by performing a `nslookup` (or a `ping`) of the FQDN on a command prompt. Make sure you remove the `https://` prefix from the FQDN.
3. Copy the IP address so that you can specify it on an inbound rule in the next step. In the following example, the IP address that you should copy is "150.0.0.1".

```
Bash

nslookup contoso.search.windows.net
Server: server.example.org
Address: 10.50.10.50

Non-authoritative answer:
Name: <name>
Address: 150.0.0.1
aliases: contoso.search.windows.net
```

Allow access from your client IP address

Client applications that push indexing and query requests to the search service must be represented in an IP range. On Azure, you can generally determine the IP address by pinging the FQDN of a service (for example, `ping <your-search-service-name>.search.windows.net` returns the IP address of a search service).

Add your client IP address to allow access to the service from the Azure portal on your current computer. Navigate to the **Networking** section on the left pane. Change **Public Network**

Access to Selected networks, and then check Add your client IP address under Firewall.

The screenshot shows a section of the Azure portal's configuration interface. At the top, there are three tabs: 'Firewalls and virtual networks' (which is selected), 'Private endpoint connections', and 'Shared private access'. Below the tabs, a descriptive text states: 'Public endpoints allow access to this resource through the internet using a public IP address. An application or resource that is granted access with the following network rules still requires proper authorization to access this resource.' Underneath this text, there is a configuration section for 'Public network access'. It includes three options: 'All networks' (radio button is empty), 'Selected IP addresses' (radio button is checked and highlighted with a red box), and 'Disabled' (radio button is empty). The 'Selected IP addresses' option is the one being highlighted.

Get the Azure portal IP address

If you're using the Azure portal or the [Import Data wizard](#) to create an indexer, you need an inbound rule for the Azure portal as well.

To get the Azure portal's IP address, perform `nslookup` (or `ping`) on `stamp2.ext.search.windows.net`, which is the domain of the traffic manager. For nslookup, the IP address is visible in the "Non-authoritative answer" portion of the response.

In the following example, the IP address that you should copy is "52.252.175.48".

```
Bash

$ nslookup stamp2.ext.search.windows.net
Server: ZenWiFi_ET8-0410
Address: 192.168.50.1

Non-authoritative answer:
Name: azsyrie.northcentralus.cloudapp.azure.com
Address: 52.252.175.48
Aliases: stamp2.ext.search.windows.net
          azs-ux-prod.trafficmanager.net
          azspncuux.management.search.windows.net
```

Services in different regions connects to different traffic managers. Regardless of the domain name, the IP address returned from the ping is the correct one to use when defining an inbound firewall rule for the Azure portal in your region.

For ping, the request times out, but the IP address is visible in the response. For example, in the message "Pinging azsyrie.northcentralus.cloudapp.azure.com [52.252.175.48]", the IP address is "52.252.175.48".

Get IP addresses for "AzureCognitiveSearch" service tag

You'll also need to create an inbound rule that allows requests from the [multitenant execution environment](#). This environment is managed by Microsoft and it's used to offload processing intensive jobs that could otherwise overwhelm your search service. This section explains how to get the range of IP addresses needed to create this inbound rule.

An IP address range is defined for each region that supports Azure AI Search. Specify the full range to ensure the success of requests originating from the multitenant execution environment.

You can get this IP address range from the `AzureCognitiveSearch` service tag.

1. Use either the [discovery API](#) or the [downloadable JSON file](#). If the search service is in the Azure Public cloud, download the [Azure Public JSON file](#).
2. Open the JSON file and search for "AzureCognitiveSearch". For a search service in WestUS2, the IP addresses for the multitenant indexer execution environment are:

```
JSON

{
  "name": "AzureCognitiveSearch.WestUS2",
  "id": "AzureCognitiveSearch.WestUS2",
  "properties": {
    "changeNumber": 1,
    "region": "westus2",
    "regionId": 38,
    "platform": "Azure",
    "systemService": "AzureCognitiveSearch",
    "addressPrefixes": [
      "20.42.129.192/26",
      "40.91.93.84/32",
      "40.91.127.116/32",
      "40.91.127.241/32",
      "51.143.104.54/32",
      "51.143.104.90/32",
      "2603:1030:c06:1::180/121"
    ],
    "networkFeatures": null
  }
},
```

3. For IP addresses have the "/32" suffix, drop the "/32" (40.91.93.84/32 becomes 40.91.93.84 in the rule definition). All other IP addresses can be used verbatim.

4. Copy all of the IP addresses for the region.

Add IP addresses to IP firewall rules

Now that you have the necessary IP addresses, you can set up the inbound rules. The easiest way to add IP address ranges to a storage account's firewall rule is through the Azure portal.

1. Locate the storage account on the Azure portal and open **Networking** on the left pane.
2. In the **Firewall and virtual networks** tab, choose **Selected networks**.

The screenshot shows the Azure portal interface for a storage account named 'contoso-storage'. The left sidebar has 'Networking' highlighted. The main content area is titled 'contoso-storage | Networking'. It shows the 'Firewalls and virtual networks' tab is selected. Under 'Allow access from', the 'Selected networks' radio button is selected, indicated by a red box. A note below says 'All networks, including the internet, can access this storage account.' At the bottom, there are sections for 'Network Routing' and 'Publish route-specific endpoints'.

3. Add the IP addresses obtained previously in the address range and select **Save**. You should have rules for the search service, Azure portal (optional), plus all of the IP addresses for the "AzureCognitiveSearch" service tag for your region.

The screenshot shows the Azure portal interface for a storage account named 'contoso-storage'. The left sidebar has 'Networking' highlighted. The main content area is titled 'contoso-storage | Networking'. It shows the 'Firewall' section where an IP address range is being added. A red box highlights the 'Address range' input field containing '<YOUR IP ADDRESS HERE>'. Below it is another input field for 'IP address or CIDR'.

It can take five to ten minutes for the firewall rules to be updated, after which indexers should be able to access storage account data behind the firewall.

Supplement network security with token authentication

Firewalls and network security are a first step in preventing unauthorized access to data and operations. Authorization should be your next step.

We recommend role-based access, where Microsoft Entra ID users and groups are assigned to roles that determine read and write access to your service. See [Connect to Azure AI Search using role-based access controls](#) for a description of built-in roles and instructions for creating custom roles.

If you don't need key-based authentication, we recommend that you disable API keys and use role assignments exclusively.

Next Steps

- [Configure Azure Storage firewalls](#)
- [Configure an IP firewall for Azure Cosmos DB](#)
- [Configure IP firewall for Azure SQL Server](#)

Make indexer connections to Azure Storage as a trusted service

In Azure AI Search, indexers that access Azure blobs can use the [trusted service exception](#) to securely access blobs. This mechanism offers customers who are unable to grant [indexer access using IP firewall rules](#) a simple, secure, and free alternative for accessing data in storage accounts.

(!) Note

If Azure Storage is behind a firewall and in the same region as Azure AI Search, you won't be able to create an inbound rule that admits requests from your search service. The solution for this scenario is for search to connect as a trusted service, as described in this article.

Prerequisites

- A search service with a system-assigned managed identity. See [Check service identity](#).
- A storage account with the **Allow trusted Microsoft services to access this storage account** network option. See [Check network settings](#).
- An Azure role assignment in Azure Storage that grants permissions to the search service system-assigned managed identity. See [Check permissions](#).

(!) Note

In Azure AI Search, a trusted service connection is limited to blobs and ADLS Gen2 on Azure Storage. It's unsupported for indexer connections to Azure Table Storage and Azure Files.

A trusted service connection must use a system-assigned managed identity. A user-assigned managed identity isn't currently supported for this scenario.

Check service identity

1. Sign in to the [Azure portal](#)  and [find your search service](#) .
2. From the left pane, select **Settings > Identity**.

3. **Enable a system-assigned identity.** Remember that user-assigned managed identities don't work for a trusted service connection.

my-search-service | Identity

System assigned User assigned

A system assigned managed identity is restricted to one per resource and is tied to the lifecycle of this resource. You can grant permissions to the managed identity by using Azure role-based access control (Azure RBAC). The managed identity is authenticated with Microsoft Entra ID, so you don't have to store any credentials in code.

Status: On

Object (principal) ID: [REDACTED]

Permissions: Azure role assignments

This resource is registered with Microsoft Entra ID. The managed identity can be configured to allow access to other resources. Be careful when making changes to the access settings for the managed identity because it can result in failures. [Learn more](#)

Identity

Check network settings

1. Sign in to the [Azure portal](#) and find your storage account.
2. From the left pane, select **Security + networking > Networking**.
3. On the **Public access** tab, select **Manage**.

my-storage-account | Networking

Public access Private endpoints Network routing Custom domain

Configure access to this storage account using Virtual Networks, IP address ranges, or a network security perimeter. [Learn more](#)

Associate a network security perimeter to secure public network access. [View recommendations](#)

Public network access: Enabled from all networks

Manage

Network security perimeter
Associate a network security perimeter to centrally manage inbound and outbound access rules. [Learn more](#)
No network security perimeter has been associated
Associate

Resource settings: Virtual networks, IP addresses, and exceptions
Configure access rules to specify which networks can access this storage account. [Learn more](#)
Resource settings are not in effect. Public network access is enabled from all networks.

4. Under Public network access scope, select Enable from selected networks.

The screenshot shows the 'Public network access' configuration page. It includes sections for enabling inbound and outbound access, selecting a perimeter, and a note about public access availability. The 'Public network access scope' section is highlighted with a red border around the 'Enable from selected networks' option, indicating it is the correct choice.

5. Under Exceptions, select Allow trusted Microsoft services to access this resource.

Assuming your search service has role-based access to the storage account, it can access data even when connections to Azure Storage are secured by IP firewall rules.

Check permissions

A system-assigned managed identity is a Microsoft Entra service principal. The assignment needs **Storage Blob Data Reader** at a minimum.

1. In the left pane under **Access Control**, view all role assignments and make sure that **Storage Blob Data Reader** is assigned to the search service system identity.
2. Add **Storage Blob Data Contributor** if write access is required.

Features that require write access include [enrichment caching](#), [debug sessions](#), and [knowledge store](#).

Set up and test the connection

The easiest way to test the connection is by running the **Import data** wizard.

1. Start the **Import data** wizard, selecting Azure Blob Storage or Azure Data Lake Storage Gen2.
2. Choose a connection to your storage account, and then select **System-assigned**. Select **Next** to invoke a connection. If the index schema is detected, the connection succeeded.

Make outbound connections through a shared private link

09/26/2025

This article explains how to configure private, outbound calls from Azure AI Search to an Azure resource that runs within an Azure virtual network.

Setting up a private connection allows a search service to connect to a virtual network IP address instead of a port that's open to the internet. The object created for the connection is called a *shared private link*. On the connection, the search service uses the shared private link internally to reach an Azure resource inside the network boundary.

Shared private link is a premium feature that's billed by usage. When you set up a shared private link, charges for the private endpoint are added to your Azure invoice. As you use the shared private link, data transfer rates for inbound and outbound access are also invoiced. For details, see [Azure Private Link pricing](#).

(!) Note

If you're setting up a private indexer connection to a SQL Managed Instance, see [this article](#) instead for steps specific to that resource type.

When to use a shared private link

Azure AI Search makes outbound calls to other Azure resources in the following scenarios:

- Knowledge agent connections to Azure OpenAI for agentic retrieval workflows
- Indexer or query connections to Azure OpenAI or Azure AI Vision for vectorization
- Indexer connections to supported data sources
- Indexer (skillset) connections to Azure Storage for caching enrichments, debug session state, or writing to a knowledge store
- Indexer (skillset) connections to Azure AI services for billing purposes
- Encryption key requests to Azure Key Vault
- Custom skill requests to Azure Functions or similar resource

Shared private links only work for Azure-to-Azure connections. If you're connecting to OpenAI or another external model provider, the connection must be over the public internet.

Shared private links are for operations and data accessed through a [private endpoint](#) for Azure resources or clients that run in an Azure virtual network.

A shared private link is:

- Created using Azure AI Search tooling, APIs, or SDKs
- Approved by the Azure resource owner
- Used internally by Azure AI Search on a private connection to a specific Azure resource

Only your search service can use the private links that it creates, and there can be only one shared private link created on your service for each resource and subresource combination.

Once you set up the private link, it's used automatically whenever the search service connects to that resource. You don't need to modify the connection string or alter the client you're using to issue the requests, although the device used for the connection must connect using an authorized IP in the Azure resource's firewall.

There are two scenarios for using [Azure Private Link](#) and Azure AI Search together.

- Scenario one: create a shared private link when an *outbound* (indexer or knowledge agent) connection to Azure requires a private connection.
- Scenario two: [configure search for a private *inbound* connection](#) from clients that run in a virtual network.

Scenario one is covered in this article.

While both scenarios have a dependency on Azure Private Link, they're independent. You can create a shared private link without having to configure your own search service for a private endpoint.

Limitations

When evaluating shared private links for your scenario, remember these constraints.

- Several of the resource types used in a shared private link are in preview. If you're connecting to a preview resource (Azure Database for MySQL or Azure SQL Managed Instance), use a preview version of the Management REST API to create the shared private link. These versions include `2020-08-01-preview`, `2021-04-01-preview`, `2024-03-01-preview`, `2024-06-01-preview`, and `2025-02-01-preview`. We recommend the latest preview API.
- Indexer execution must use the [private execution environment](#) that's specific to your search service. Private endpoint connections aren't supported from the multitenant content processing environment. The configuration setting for this requirement is covered in this article.

- Review shared private link **resource limits** for each tier.

Prerequisites

- A [supported Azure resource](#), configured to run in a virtual network.
- An Azure AI Search service with tier and region requirements, by workload:

[\[+\] Expand table](#)

Workload	Tier requirements	Region requirements	Service creation requirements
Indexers without skillsets	Basic and higher	None	None
Skillsets with embedding skills (integrated vectorization)	Basic and higher	High capacity regions	After April 3, 2024
Skillsets using other built-in or custom skills	Standard 1 (S1) and higher	None	After April 3, 2024
Knowledge agents calling Azure OpenAI for query planning or passing search results	Basic and higher	None	None

- Permissions on both Azure AI Search and the Azure resource:

[\[+\] Expand table](#)

Resource	Permissions
Azure AI Search	<code>Microsoft.Search/searchServices/sharedPrivateLinkResources/write</code> <code>Microsoft.Search/searchServices/sharedPrivateLinkResources/read</code> <code>Microsoft.Search/searchServices/sharedPrivateLinkResources/operationStatuses/read</code>
Other Azure resource	Permission to approve private endpoint connections. For example, on Azure Storage, you need <code>Microsoft.Storage/storageAccounts/privateEndpointConnectionsApproval/action</code> .

Supported resource types

You can create a shared private link for the following resources.

[\[+\] Expand table](#)

Resource type	Subresource (or Group ID)
Microsoft.Storage/storageAccounts ¹	blob, table, dfs, file
Microsoft.DocumentDB/databaseAccounts ²	Sql
Microsoft.Sql/servers ³	sqlServer
Microsoft.KeyVault/vaults	vault
Microsoft.DBforMySQL/servers (preview)	mysqlServer
Microsoft.Web/sites ⁴	sites
Microsoft.Sql/managedInstances (preview) ⁵	managedInstance
Microsoft.CognitiveServices/accounts ^{6 7}	openai_account
Microsoft.CognitiveServices/accounts ⁸	cognitiveservices_account
Microsoft.Fabric/privateLinkServicesForFabric ⁹	workspace

¹ If Azure Storage and Azure AI Search are in the same region, the connection to storage is made over the Microsoft backbone network, which means a shared private link is redundant for this configuration. However, if you already set up a private endpoint for Azure Storage, you should also set up a shared private link or the connection is refused on the storage side. Also, if you're using multiple storage formats for various scenarios in search, make sure to create a separate shared private link for each subresource.

² The `Microsoft.DocumentDB/databaseAccounts` resource type is used for indexer connections to Azure Cosmos DB for NoSQL. The provider name and group ID are case-sensitive.

³ The `Microsoft.Sql/servers` resource type is used for connections to Azure SQL database. There's currently no support for a shared private link to Azure Synapse SQL.

⁴ The `Microsoft.Web/sites` resource type is used for App service and Azure functions. In the context of Azure AI Search, an Azure function is the more likely scenario. An Azure function is commonly used for hosting the logic of a custom skill. Azure Function has Consumption, Premium, and Dedicated [App Service hosting plans](#). The [App Service Environment \(ASE\)](#), [Azure Kubernetes Service \(AKS\)](#) and [Azure API Management](#) aren't supported at this time.

⁵ See [Create a shared private link for a SQL Managed Instance](#) for instructions.

⁶ The `Microsoft.CognitiveServices/accounts` resource type is used for vectorizer and indexer connections to Azure OpenAI embedding models when implementing [integrated Vectorization](#). As of November 19, 2024, there's now support for shared private link to support the Azure AI Vision multimodal embeddings via [AI Services multi-service account](#).

⁷ Shared private link for Azure OpenAI is only supported in public cloud and [Microsoft Azure Government](#). Other cloud offerings don't have support for shared private links for `openai_account` Group ID.

⁸ Shared private links are now supported (as of November 2024) for connections to Azure AI services multi-service accounts. Azure AI Search connects to Azure AI services multi-service for [billing purposes](#). These connections can now be private through a shared private link. Shared private link is only supported when configuring [a managed identity \(keyless configuration\)](#) in the skillset definition.

⁹ Shared private link is supported for connections to OneLake workspace. To create a `privateLinkServicesForFabric` resource specific to a workspace, [register Microsoft.Fabric](#) namespace to your subscription and refer to step 2 as documented in [Create the private link service in Azure](#). Note that when using a shared private link, the OneLake data source configuration must be defined with a specific connection string as outlined in the [OneLake indexer documentation](#).

1 - Create a shared private link

Use the Azure portal, Management REST API, the Azure CLI, or Azure PowerShell to create a shared private link.

Here are a few tips:

- Give the private link a meaningful name. In the Azure PaaS resource, a shared private link appears alongside other private endpoints. A name like "shared-private-link-for-search" can remind you how it's used.

When you complete the steps in this section, you have a shared private link that's provisioned in a pending state. **It takes several minutes to create the link.** Once it's created, the resource owner must approve the request before it's operational.

Azure portal

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. Under **Settings** on the left pane, select **Networking**.
3. On the Shared Private Access page, select **+ Add Shared Private Access**.
4. Select either **Connect to an Azure resource in my directory** or **Connect to an Azure resource by resource ID**.

5. If you select the first option (recommended), the Azure portal helps you pick the appropriate Azure resource and fills in other properties, such as the group ID of the resource and the resource type.

The screenshot shows the Azure portal interface for creating a new shared private access link. The left sidebar is for the 'contoso | Networking' service, with 'Networking' selected. The main area shows a table of existing shared private access entries. A modal dialog is open on the right titled 'New Shared Private Access'. In the 'Connection method' section, the radio button for 'Connect to an Azure resource in my directory' is selected. The 'Name' field contains 'blob-pe'. The 'Subscription' dropdown is set to 'Contoso Subscription'. Under 'Resource Type', 'Microsoft.Storage/storageAccounts' is chosen, and the specific resource 'contoso-storage' is selected. The 'Target sub-resource' is set to 'blob'. A 'Request Message' field contains the text 'Please approve'. At the bottom of the dialog are 'Cancel' and 'Create' buttons.

6. If you select the second option, enter the Azure resource ID manually and choose the appropriate group ID from the list at the beginning of this article.

This screenshot shows the same 'New Shared Private Access' dialog as the previous one, but with different configuration. The 'Connection method' is now set to 'Connect to an Azure resource by resource ID or alias'. The 'Name' field remains 'blob-pe'. In the 'Private Link Resource Id' field, the full Azure resource ID is entered: '/subscriptions/00000000-0000-0000-0000-00000000...'. The 'Target sub-resource' is set to 'blob', and the 'Request Message' is 'Please approve'. The 'Create' button is at the bottom.

7. Confirm the provisioning status is "Updating".

Access Control Shared Private Access

Azure Cognitive Search supports private access to other resources using Private Links. Click "Add Shared Private Access" to request a private endpoint for accessing protected resources. Your request must be approved by the resource owner before you can connect. [Learn more](#)

+ Add Shared Private Access Refresh Delete

Name	Resource	Sub-Resource	Provisioning state	Connection state	Message
vault-pe	contoso-vault	vault	Succeeded	Pending	please approve
cosmos-pe	contoso-sql	Sql	Succeeded	Pending	please approve
test-pe	contoso-table	blob	Succeeded	Pending	Please approve
blob-pe	contoso-storage	blob	Updating	Pending	Please approve

- Once the resource is successfully created, the provisioning state of the resource changes to "Succeeded".

Shared private link creation workflow

A `202 Accepted` response is returned on success. The process of creating an outbound private endpoint is a long-running (asynchronous) operation. It involves deploying the following resources:

- A private endpoint, allocated with a private IP address in a "Pending" state. The private IP address is obtained from the address space that's allocated to the virtual network of the execution environment for the search service-specific private indexer. Upon approval of

the private endpoint, any communication from Azure AI Search to the Azure resource originates from the private IP address and a secure private link channel.

- A private DNS zone for the type of resource, based on the group ID. By deploying this resource, you ensure that any DNS lookup to the private resource utilizes the IP address that's associated with the private endpoint.

2 - Approve the private endpoint connection

Approval of the private endpoint connection is granted on the Azure PaaS side. Explicit approval by the resource owner is required. The following steps cover approval using the Azure portal, but here are some links to approve the connection programmatically from the Azure PaaS side:

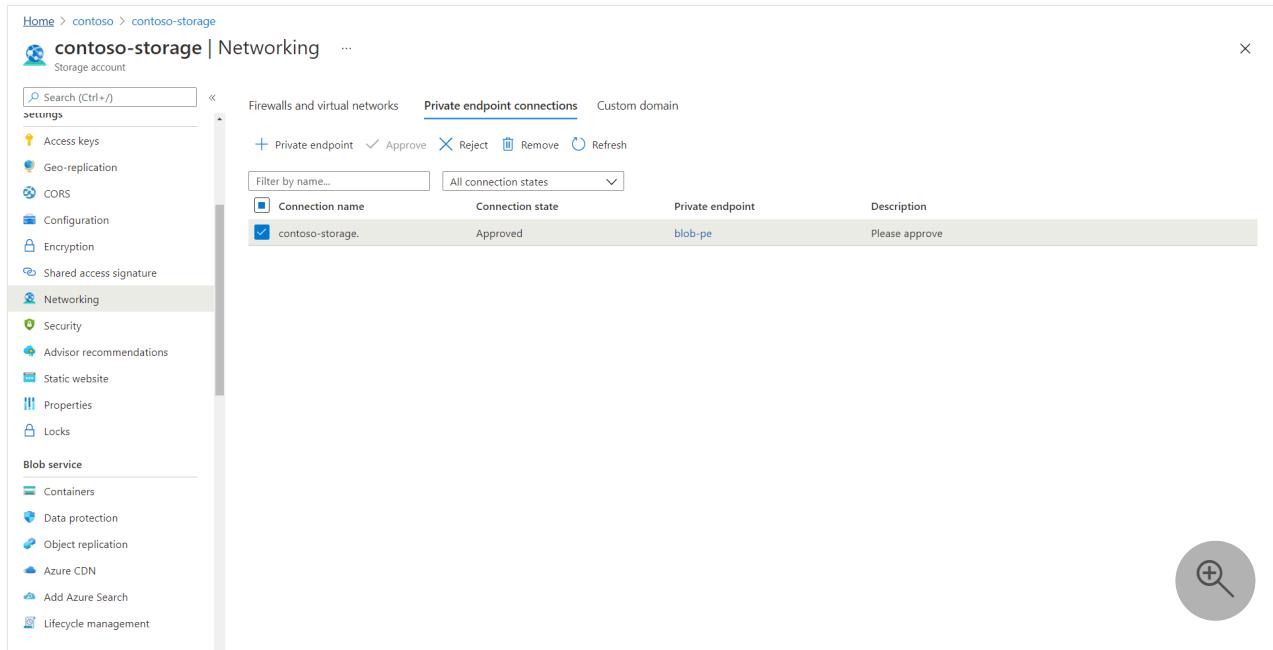

- On Azure Storage, use [Private Endpoint Connections - Put](#)
- On Azure Cosmos DB, use [Private Endpoint Connections - Create Or Update](#)
- On Azure OpenAI, use [Private Endpoint Connections - Create Or Update](#)
- On Microsoft Onelake, use [Private Endpoints - Approve via CLI](#) or [Private Endpoints - Approve via Portal](#)

Using the Azure portal, perform the following steps:

1. Open the **Networking** page of the Azure PaaS resource.[text ↗](#)
2. Find the section that lists the private endpoint connections. The following example is for a storage account.

The screenshot shows the Azure portal interface for a storage account named 'contoso-storage'. The left sidebar has 'Networking' selected under the 'Storage account' category. The main content area is titled 'contoso-storage | Networking'. It displays a table of private endpoint connections. There is one entry: 'contoso-storage.' with a 'Pending' status, a 'blob-pe' private endpoint, and a description 'Please approve'. At the top of the table, there are buttons for '+ Private endpoint', 'Approve', 'Reject', 'Remove', and 'Refresh'. The URL in the browser bar is https://portal.azure.com/#@microsoft.onmicrosoft.com/resource/subscriptions/00000000-0000-0000-0000-000000000000/resourceGroups/contoso/providers/Microsoft.Storage/storageAccounts/contoso-storage/networking.

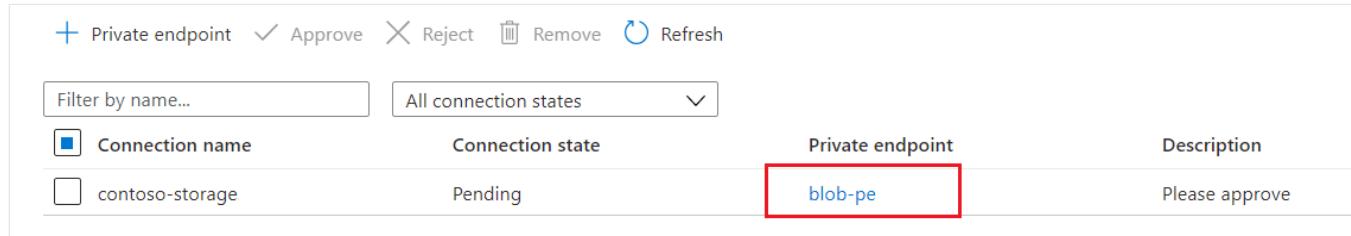

3. Select the connection, and then select **Approve**. It can take a few minutes for the status to be updated in the Azure portal.

The screenshot shows the Azure Storage account 'contoso-storage' Networking page. The left sidebar includes options like Access keys, Geo-replication, CORS, Configuration, Encryption, Shared access signature, and Networking (which is selected). The main area shows a table for 'Private endpoint connections'. A row for 'contoso-storage.' is listed with 'Connection name' checked, 'Connection state' as 'Approved', 'Private endpoint' as 'blob-pe', and 'Description' as 'Please approve'. Action buttons at the top include '+ Private endpoint', 'Approve', 'Reject', 'Remove', and 'Refresh'.

After the private endpoint is approved, Azure AI Search creates the necessary DNS zone mappings in the DNS zone that's created for it.

Although the private endpoint link on the **Networking** page is active, it won't resolve.

The screenshot shows the same Networking page as before, but the connection state for 'contoso-storage.' is now 'Pending'. The 'blob-pe' private endpoint link is highlighted with a red box. The table columns are 'Connection name', 'Connection state', 'Private endpoint', and 'Description'.

Selecting the link produces an error. A status message of "The access token is from the wrong issuer" and "must match the tenant associated with this subscription" appears because the backend private endpoint resource is provisioned by Microsoft in a Microsoft-managed tenant, while the linked resource (Azure AI Search) is in your tenant. It's by design you can't access the private endpoint resource by selecting the private endpoint connection link.

Follow the instructions in the next section to check the status of your shared private link.

3 - Check shared private link status

On the Azure AI Search side, you can confirm request approval by revisiting the Shared Private Access page of the search service **Networking** page. Connection state should be approved.

Search resources, services, and docs (G+)

Home > contoso

contoso | Networking

Access Control Shared Private Access

Azure Cognitive Search supports private access to other resources using Private Links. Click "Add Shared Private Access" to request a private endpoint for accessing protected resources. Your request must be approved by the resource owner before you can connect. [Learn more](#)

+ Add Shared Private Access ⏪ Refresh ⏷ Delete

Filter by name...

Name	Resource	Sub-Resource	Provisioning state	Connection state	Message
vault-pe	contoso-vault	vault	Succeeded	Pending	please approve
cosmos-pe	contoso-sql	Sql	Succeeded	Pending	please approve
test-pe	contoso-table	blob	Succeeded	Pending	Please approve
blob-pe	contoso-storage	blob	Succeeded	Approved	Please approve

Alternatively, you can also obtain connection state by using the [Shared Private Link Resources - Get](#).

.NET CLI

```
az rest --method get --uri https://management.azure.com/subscriptions/aaaa0a0a-bb1b-cc2c-dd3d-eeeeeee4e4e/resourceGroups/contoso/providers/Microsoft.Search/searchServices/contoso-search/sharedPrivateLinkResources/blob-pe?api-version=2025-09-01
```

This would return a JSON, where the connection state shows up as "status" under the "properties" section. Following is an example for a storage account.

JSON

```
{
  "name": "blob-pe",
  "properties": {
    "privateLinkResourceId": "/subscriptions/aaaa0a0a-bb1b-cc2c-dd3d-eeeeeee4e4e/resourceGroups/contoso/providers/Microsoft.Storage/storageAccounts/contoso-storage",
    "groupId": "blob",
    "requestMessage": "please approve",
    "status": "Approved",
    "resourceRegion": null,
    "provisioningState": "Succeeded"
  }
}
```

If the provisioning state (`properties.provisioningState`) of the resource is "Succeeded" and connection state(`properties.status`) is "Approved", it means that the shared private link resource is functional and the indexer can be configured to communicate over the private endpoint.

4 - Configure the indexer to run in the private environment

[Indexer execution](#) occurs in either a private environment that's specific to the search service, or a multitenant environment that's used internally to offload expensive skillset processing for multiple customers.

The execution environment is transparent, but once you start building firewall rules or establishing private connections, you must take indexer execution into account. For a private connection, configure indexer execution to always run in the private environment.

This step shows you how to configure the indexer to run in the private environment using the REST API. You can also set the execution environment using the JSON editor in the Azure portal.

Note

You can perform this step before the private endpoint connection is approved. However, until the private endpoint connection shows as approved, any existing indexer that tries to communicate with a secure resource (such as the storage account) will end up in a transient failure state and new indexers will fail to be created.

1. Create the data source definition, index, and skillset (if you're using one) as you would normally. There are no properties in any of these definitions that vary when using a shared private endpoint.
2. [Create an indexer](#) that points to the data source, index, and skillset that you created in the preceding step. In addition, force the indexer to run in the private execution environment by setting the indexer `executionEnvironment` configuration property to `private`.

JSON

```
{  
  "name": "indexer",  
  "dataSourceName": "blob-datasource",  
  "targetIndexName": "index",  
  "parameters": {
```

```
        "configuration": {
            "executionEnvironment": "private"
        }
    },
    "fieldMappings": []
}
```

After the indexer is created successfully, it should connect to the Azure resource over the private endpoint connection. You can monitor the status of the indexer by using the [Indexer Status API](#).

 **Note**

If you already have existing indexers, you can update them via the [PUT API](#) by setting the `executionEnvironment` to `private` or using the JSON editor in the Azure portal.

5 - Test the shared private link

1. If you haven't done so already, verify that your Azure PaaS resource refuses connections from the public internet. If connections are accepted, review the DNS settings in the [Networking](#) page of your Azure PaaS resource.
2. Choose a tool that can invoke an outbound request scenario, such as an indexer connection to a private endpoint. An easy choice is using an [import wizard](#), but you can also try a REST client and REST APIs for more precision. Assuming that your search service isn't also configured for a private connection, the REST client connection to search can be over the public internet.
3. Set the connection string to the private Azure PaaS resource. The format of the connection string doesn't change for shared private link. The search service invokes the shared private link internally.

For indexer workloads, the connection string is in the data source definition. An example of a data source might look like this:

HTTP

```
{
    "name": "my-blob-ds",
    "type": "azureblob",
    "subtype": null,
    "credentials": {
        "connectionString": "DefaultEndpointsProtocol=https;AccountName=<YOUR-
```

```
STORAGE-ACCOUNT>;AccountKey=..."  
    }
```

4. For indexer workloads, remember to set the execution environment in the indexer definition. An example of an indexer definition might look like this:

HTTP

```
"name": "indexer",  
"dataSourceName": "my-blob-ds",  
"targetIndexName": "my-index",  
"parameters": {  
    "configuration": {  
        "executionEnvironment": "private"  
    }  
},  
"fieldMappings": []  
}
```

5. Run the indexer. If the indexer execution succeeds and the search index is populated, the shared private link is working.

Troubleshooting

- If your indexer creation fails with "Data source credentials are invalid," check the approval status of the shared private link before debugging the connection. If the status is `Approved`, check the `properties.provisioningState` property. If it's `Incomplete`, there might be a problem with underlying dependencies. In this case, reissue the `PUT` request to re-create the shared private link. You might also need to repeat the approval step.
- If indexers fail consistently or intermittently, check the `executionEnvironment` property on the indexer. The value should be set to `private`. If you didn't set this property, and indexer runs succeeded in the past, it's because the search service used a private environment of its own accord. A search service moves processing out of the multitenant environment if the system is under load.
- If you get an error when creating a shared private link, check `service limits` to verify that you're under the quota for your tier.

Create a shared private link for a SQL managed instance from Azure AI Search

Article • 01/28/2025

This article explains how to configure an indexer in Azure AI Search for a private connection to a SQL managed instance that runs within a virtual network. The private connection is through a [shared private link](#) and Azure Private Link.

On a private connection to a managed instance, the fully qualified domain name (FQDN) of the instance must include the [DNS Zone](#). Currently, only the Azure AI Search Management REST API provides a `dnsZonePrefix` parameter for accepting the DNS zone specification.

Although you can call the Management REST API directly, it's easier to use the Azure CLI `az rest` module to send Management REST API calls from a command line. This article uses the Azure CLI with REST to set up the private link.

ⓘ Note

This article refers to Azure portal for obtaining properties and confirming steps.

However, when creating the shared private link for SQL Managed Instance, make

sure you're using the REST API. Although the Networking tab lists

`Microsoft.Sql/managedInstances` as an option, the Azure portal doesn't currently

support the extended URL format used by SQL Managed Instance.

Prerequisites

- [Azure CLI](#)
- Azure AI Search, Basic or higher. If you're using [AI enrichment](#) and skillsets, use Standard 2 (S2) or higher. See [Service limits](#) for details.
- Azure SQL Managed Instance, configured to run in a virtual network.
- You should have a minimum of Contributor permissions on both Azure AI Search and SQL Managed Instance.
- Azure SQL Managed Instance connection string. Managed identity isn't currently supported with shared private link. Your connection string must include a user name and password.

ⓘ Note

Shared private links are billable through [Azure Private Link pricing](#) and charges are invoiced based on usage.

1 - Retrieve connection information

In this section, get the DNS zone from the host name and a connection string.

1. In Azure portal, find the SQL managed instance object.
2. On the **Overview** tab, locate the Host property. Copy the *DNS zone* portion of the FQDN for the next step. The DNS zone is part of the domain name of the SQL Managed Instance. For example, if the FQDN of the SQL Managed Instance is `my-sql-managed-instance.a1b22c333d44.database.windows.net`, the DNS zone is `a1b22c333d44`.
3. On the **Connection strings** tab, copy the ADO.NET connection string for a later step. It's needed for the data source connection when testing the private connection.

For more information about connection properties, see [Create an Azure SQL Managed Instance](#).

2 - Create the body of the request

1. Using a text editor, create the JSON for the shared private link.

JSON

```
{  
  "name": "{{shared-private-link-name}}",  
  "properties": {  
    "privateLinkResourceId": "/subscriptions/{{target-resource-subscription-ID}}/resourceGroups/{{target-resource-rg}}/providers/Microsoft.Sql/managedInstances/{{target-resource-name}}",  
    "dnsZonePrefix": "a1b22c333d44",  
    "groupId": "managedInstance",  
    "requestMessage": "please approve"  
  }  
}
```

Provide a meaningful name for the shared private link. The shared private link appears alongside other private endpoints. A name like "shared-private-link-for-search" can remind you how it's used.

Paste in the DNS zone name in "dnsZonePrefix" that you retrieved in an earlier step.

Edit the "privateLinkResourceId", substitute valid for values for the placeholders. Provide a valid subscription ID, resource group name, and managed instance name.

2. Save the file locally as *create-pe.json* (or use another name, remembering to update the Azure CLI syntax in the next step).
3. In the Azure CLI, type `dir` to note the current location of the file.

3 - Create a shared private link

1. From the command line, sign into Azure using `az login`.
2. If you have multiple subscriptions, make sure you're using the one you intend to use: `az account show`.
To set the subscription, use `az account set --subscription {{subscription ID}}`
3. Call the `az rest` command to use the [Management REST API](#) of Azure AI Search.

Because shared private link support for SQL managed instances is still in preview, you need a preview version of the management REST API. Use `2021-04-01-preview` or a later preview API version for this step. We recommend using the latest preview API version.

Azure CLI

```
az rest --method put --uri
https://management.azure.com/subscriptions/{{search-service-
subscription-ID}}/resourceGroups/{{search service-resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service-
name}}/sharedPrivateLinkResources/{{shared-private-link-name}}?api-
version=2024-06-01-preview --body @create-pe.json
```

Provide the subscription ID, resource group name, and service name of your Azure AI Search resource.

Provide the same shared private link name that you specified in the JSON body.

Provide a path to the `create-pe.json` file if you've navigated away from the file location. You can type `dir` at the command line to confirm the file is in the current directory.

4. Run the command.

When you complete these steps, you should have a shared private link that's provisioned in a pending state. **It takes several minutes to create the link.** Once it's created, the resource owner needs to approve the request before it's operational.

You can check the status of the shared private link in the Azure portal. On your search service page, under **Settings > Properties**, scroll down to find the shared private link resources and view the JSON value. When the provisioning state changes from *pending* to *succeeded*, you can continue on to the next step.

4 - Approve the private endpoint connection

On the SQL Managed Instance side, the resource owner must approve the private connection request you created.

1. In the Azure portal, open the **Security > Private endpoint connections** of the managed instance.
2. Find the section that lists the private endpoint connections.
3. Select the connection, and then select **Approve**. It can take a few minutes for the status to be updated in the Azure portal.

After the private endpoint is approved, Azure AI Search creates the necessary DNS zone mappings in the DNS zone that's created for it.

5 - Check shared private link status

On the Azure AI Search side, you can confirm request approval by revisiting the Shared Private Access tab of the search service **Networking** page. Connection state should be approved.

The screenshot shows the Azure portal interface for a search service named 'contoso'. On the left, there's a navigation sidebar with various options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Settings (which is currently selected), Quick start, Keys, Scale, Search traffic analytics, Identity, Networking (which is also selected), Properties, Locks, Monitoring, Alerts, Metrics, Diagnostic settings, Logs, and Automation. The main content area is titled 'Shared Private Access' under 'Access Control'. It displays a table with four rows of data. The columns are Name, Resource, Sub-Resource, Provisioning state, Connection state, and Message. The 'blob-pe' row is highlighted with a red box around its entire row.

Name	Resource	Sub-Resource	Provisioning state	Connection state	Message
vault-pe	contoso-vault	vault	Succeeded	Pending	please approve
cosmos-pe	contoso-sql	Sql	Succeeded	Pending	please approve
test-pe	contoso-table	blob	Succeeded	Pending	Please approve
blob-pe	contoso-storage	blob	Succeeded	Approved	Please approve

6 - Configure the indexer to run in the private environment

You can now configure an indexer and its data source to use an outbound private connection to your managed instance.

This article assumes a [REST client](#) and uses the REST APIs.

1. [Create the data source definition](#) as you would normally for Azure SQL. By default, a managed instance listens on port 3342, but on a virtual network it listens on 1433.

Provide the connection string that you copied earlier with an Initial Catalog set to your database name.

```
HTTP

POST https://myservice.search.windows.net/datasources?api-version=2024-07-01
Content-Type: application/json
api-key: admin-key
{
    "name" : "my-sql-datasource",
    "description" : "A database for testing Azure AI Search indexes.",
    "type" : "azuresql",
    "credentials" : {
        "connectionString" :
"Server=tcp:contoso.a1b22c333d44.database.windows.net,1433;Persist Security Info=False; User ID=<your user name>; Password=<your password>;MultipleActiveResultsSets=False; Encrypt=True;Connection Timeout=30;Initial Catalog=<your database name>"}
```

```
        },
        "container" : {
            "name" : "Name of table or view to index",
            "query" : null (not supported in the Azure SQL indexer)
        },
        "dataChangeDetectionPolicy": null,
        "dataDeletionDetectionPolicy": null,
        "encryptionKey": null
    }
}
```

2. Create the indexer definition, setting the indexer `executionEnvironment` to "private".

Indexer execution occurs in either a private execution environment that's specific to your search service, or a multitenant environment hosted by Microsoft and used to offload expensive skillset processing for multiple customers. **When connecting over a private endpoint, indexer execution must be private.**

HTTP

```
POST https://myservice.search.windows.net/indexers?api-version=2024-07-01
Content-Type: application/json
api-key: admin-key
{
    "name": "indexer",
    "dataSourceName": "my-sql-datasource",
    "targetIndexName": "my-search-index",
    "parameters": {
        "configuration": {
            "executionEnvironment": "private"
        }
    },
    "fieldMappings": []
}
```

3. Run the indexer. If the indexer execution succeeds and the search index is populated, the shared private link is working.

You can monitor the status of the indexer in Azure portal or by using the [Indexer Status API](#).

You can use [Search explorer](#) in Azure portal to check the contents of the index.

7 - Test the shared private link

If you ran the indexer in the previous step and successfully indexed content from your managed instance, then the test was successful. However, if the indexer fails or there's no content in the index, you can modify your objects and repeat testing by choosing any client that can invoke an outbound request from an indexer.

An easy choice is [running an indexer](#) in Azure portal, but you can also try a [REST client](#) and REST APIs for more precision. Assuming that your search service isn't also configured for a private connection, the REST client connection to Azure AI Search can be over the public internet.

Here are some reminders for testing:

- If you use a REST client, use the [Management REST API](#) and the [2021-04-01-Preview API version](#) to create the shared private link. Use the [Search REST API](#) and a [stable API version](#) to create and invoke indexers and data sources.
- You can use the Import data wizard to create an indexer, data source, and index. However, the generated indexer won't have the correct execution environment setting.
- You can edit data source and indexer JSON in Azure portal to change properties, including the execution environment and the connection string.
- You can reset and rerun the indexer in Azure portal. Reset is important for this scenario because it forces a full reprocessing of all documents.
- You can use Search explorer to check the contents of the index.

Document-level access control in Azure AI Search

Azure AI Search supports document-level access control, enabling organizations to enforce fine-grained permissions at the document level, from data ingestion through query execution. This capability is essential for building secure AI agentic systems grounding data, Retrieval-Augmented Generation (RAG) applications, and enterprise search solutions that require authorization checks at the document level.

Approaches for document-level access control

[] Expand table

Approach	Description
Security filters	<p>String comparison. Your application passes in a user or group identity as a string, which populates a filter on a query, excluding any documents that don't match on the string.</p> <p>Security filters are a technique for achieving document-level access control. This approach isn't bound to an API so you can use any version or package.</p>
POSIX-like ACL / RBAC scopes (preview)	<p>Microsoft Entra security principal behind the query token is compared to the permission metadata of documents returned in search results, excluding any documents that don't match on permissions. Access Control Lists (ACL) permissions apply to Azure Data Lake Storage (ADLS) Gen2 directories and files. Role-based access control (RBAC) scopes apply to ADLS Gen2 content and to Azure blobs.</p> <p>Built-in support for identity-based access at the document level is in preview, available in REST APIs and preview Azure SDK packages that provide the feature. Be sure to check the SDK package change log for evidence of feature support.</p>
Microsoft Purview sensitivity labels (preview)	<p>Indexer extracts sensitivity labels defined in Microsoft Purview from supported data sources (Azure Blob Storage, ADLS Gen2, SharePoint in Microsoft 365, OneLake). These labels are stored as metadata and evaluated at query time to enforce user access based on Microsoft Entra tokens and Purview policy assignments. This approach aligns Azure AI Search authorization with your enterprise's Microsoft Information Protection model.</p>
SharePoint in Microsoft 365 ACLs (preview)	<p>When configured, Azure AI Search indexers extract SharePoint document permissions directly from in Microsoft 365 ACLs during initial ingestion. Access checks use Microsoft Entra user and group memberships. Supported group types include Microsoft Entra security groups, Microsoft 365 groups, and mail-enabled security groups. SharePoint groups are not yet supported in preview.</p>

Pattern for security trimming using filters

For scenarios where native ACL/RBAC scopes integration isn't viable, we recommend security string filters for trimming results based on exclusion criteria. The pattern includes the following components:

- To store user or group identities, create a string field in the index.
- Load the index using source documents that include associated ACLs.
- Include a filter expression in your query logic for matching on the string.
- At query time, get the identity of the caller.
- Pass in the identity of the caller as the filter string.
- Results are trimmed to exclude any matches that fail to include the user or group identity string,

You can use push or pull model APIs. Because this approach is API agnostic, you just need to ensure that the index and query have valid strings (identities) for the filtration step.

This approach is useful for systems with custom access models or non-Microsoft security frameworks. For more information this approach, see [Security filters for trimming results in Azure AI Search](#).

Pattern for native support for POSIX-like ACL and RBAC scope permissions (preview)

Native support is based on Microsoft Entra users and groups affiliated with documents that you want to index and query.

Azure Data Lake Storage (ADLS) Gen2 containers support ACLs on the container and on files. For ADLS Gen2, RBAC scope preservation at document level is natively supported when you use an [ADLS Gen2 indexer](#) or a [Blob knowledge source \(supports ADLS Gen2\)](#) and a preview API to ingest content. For Azure blobs using the [Azure blob indexer](#) or knowledge source, RBAC scope preservation is at the container level.

For ACL-secured content, we recommend group access over individual user access for ease of management. The pattern includes the following components:

- Start with documents or files that have ACL assignments.
- [Enable permission filters](#) in the index.
- [Add a permission filter](#) to a string field in an index.
- Load the index with source documents having associated ACLs.
- Query the index, adding [x-ms-query-source-authorization](#) in the request header.

Your client app receives read permissions to the index through **Search Index Data Reader** or **Search Index Data Contributor** role. Access at query time is determined by user or group permission metadata in the indexed content. Queries that include a permission filter pass a user or group token as `x-ms-query-source-authorization` in the request header. When you use permission filters at query time, Azure AI Search checks for two things:

- First, it checks for **Search Index Data Reader** permission that allows your client application to access the index.
- Second, given the extra token on the request, it checks for user or group permissions on documents that are returned in search results, excluding any that don't match.

To get permission metadata into the index, you can use the push model API, pushing any JSON documents to the search index, where the payload includes a string field providing POSIX-like ACLs for each document. The important difference between this approach and security trimming is that the permission filter metadata in the index and query is recognized as Microsoft Entra ID authentication, whereas the security trimming workaround is simple string comparison. Also, you can use the Graph SDK to retrieve the identities.

You can also use the pull model (indexer) APIs if the data source is [Azure Data Lake Storage \(ADLS\) Gen2](#) and your code calls a preview API for indexing.

Retrieve ACL permissions metadata during data ingestion process (preview)

How you retrieve ACL permissions varies depending on whether you're pushing a documents payload or using the ADLS Gen2 indexer.

Start with a preview API that provides the feature:

- [2025-11-01-preview REST API](#)
- [Azure SDK for Python prerelease package ↗](#)
- [Azure SDK for .NET prerelease package ↗](#)
- [Azure SDK for Java prerelease package ↗](#)

For the [push model approach](#):

1. Ensure your index schema is also created with a preview or prerelease SDK and that the schema has permission filters.
2. Consider using the Microsoft Graph SDK to get group or user identities.
3. Use the [Index Documents](#) or equivalent Azure SDK API to push documents and their associated permission metadata into the search index.

For the [pull model ADLS Gen2 indexer approach](#) or [Blob \(ADLS Gen2\) knowledge source](#):

1. Verify that files in the directory are secured using the [ADLS Gen2 access control model](#).
2. Use the [Create Indexer REST API](#) or [Create Knowledge Source REST API](#) or equivalent Azure SDK API to create the indexer, index, and data source.

Pattern for SharePoint in Microsoft 365 basic ACL permissions ingestion (preview)

For SharePoint in Microsoft 365 content, Azure AI Search can apply document-level permissions based on SharePoint ACLs. This integration promotes that only users or groups with access to the source document in SharePoint can retrieve it in search results, as soon as the permissions are synchronized in the index. Permissions are applied to the index either during initial document ingestion.

SharePoint ACL support is available in preview through the SharePoint indexer using the [2025-11-01-preview REST API](#) or supported SDK. The indexer extracts file and list item permission metadata and preserves it in the search index, where it's used to enforce access control at query time.

The pattern includes the following components:

- Use the SharePoint in Microsoft 365 indexer with application permissions to read SharePoint site content and full permissions to read ACLs. Follow the [SharePoint indexer ACL setup instructions](#) for enablement and limitations.
- During initial indexing, SharePoint ACL entries (users and groups) are stored as permission metadata in the search index.
- For incremental indexing of ACLs, review the [SharePoint ACL resync available mechanisms](#) available during public preview.
- At query time, Azure AI Search checks the Microsoft Entra principal in the query token against SharePoint ACL metadata stored in the index. It excludes any documents the caller isn't authorized to access.

During preview, only the following principal types are supported in SharePoint ACLs:

- Microsoft Entra user accounts
- Microsoft Entra security groups
- Microsoft 365 groups
- Mail-enabled security groups

SharePoint groups aren't supported in the preview release.

For configuration details and full limitations, see [How to index SharePoint in Microsoft 365 document-level permissions \(preview\)](#).

Pattern for Microsoft Purview sensitivity labels (preview)

Azure AI Search can ingest and enforce **Microsoft Purview sensitivity labels** for document-level access control, extending information protection policies from Microsoft Purview into your search and retrieval applications.

When label ingestion is enabled, Azure AI Search extracts sensitivity metadata from supported data sources. These include: Azure Blob Storage, Azure Data Lake Storage Gen2 (ADLS Gen2), SharePoint in Microsoft 365, and Microsoft OneLake. The extracted labels are stored in the index alongside document content.

At query time, Azure AI Search checks each document's sensitivity label, the user's Microsoft Entra token, and the organization's Purview policies to determine access. Documents are returned only if the user's identity and label-based permissions allow access under the configured Purview policies.

The pattern includes the following components:

- Configure your [index](#), [data source](#) and [indexer](#) (for scheduling purposes) using the 2025-11-01-preview REST API or a corresponding SDK that supports Purview label ingestion.
- Enable a [system-assigned managed identity](#) to your search service. Then ask your tenant global administrator or privileged role administrator to [grant the required access](#), so the search service can securely access Microsoft Purview and extract label metadata.
- Apply sensitivity labels to documents before indexing so they can be recognized and preserved during ingestion.
- At query time, attach a valid Microsoft Entra token via the header `x-ms-query-source-authorization` to each query request. Azure AI Search evaluates the token and the associated label metadata to enforce label-based access control.

Purview sensitivity label enforcement is limited to single-tenant scenarios, requires RBAC authentication, and during public preview is supported only through REST API or SDK. Autocomplete and Suggest APIs aren't available for Purview-enabled indexes at this time.

For more information, see [Use Azure AI Search indexers to ingest Microsoft Purview sensitivity labels](#).

Enforce document-level permissions at query time

With native [token-based querying](#), Azure AI Search validates a user's [Microsoft Entra token](#), trimming result sets to include only documents the user is authorized to access.

You can achieve automatic trimming by attaching the user's Microsoft Entra token to your query request. For more information, see [Query-time ACL and RBAC enforcement in Azure AI Search](#).

Benefits of document-level access control

Document-level access control is critical for safeguarding sensitive information in AI-driven applications. It helps organizations build systems that align with their access policies, reducing the risk of exposing unauthorized or confidential data. By integrating access rules directly into the search pipeline, AI systems can provide responses grounded in secure and authorized information.

By offloading permission enforcement to Azure AI Search, developers can focus on building high-quality retrieval and ranking systems. This approach helps reducing the need to handle nested groups, write custom filters, or manually trim search results.

Document-level permissions in Azure AI Search provide a structured framework for enforcing access controls that align with organizational policies. By using Microsoft Entra-based ACLs and RBAC roles, organizations can create systems that support robust compliance and promote trust among users. These built-in capabilities reduce the need for custom coding, offering a standardized approach to document-level security.

Security filters for trimming results in Azure AI Search

07/16/2025

For search solutions that can't use the [built-in access control list \(ACL\) support](#) for document-level authorization, Azure AI Search supports creating a filter that trims search results based on a string containing a group or user identity.

This article describes a pattern for security filtering having the following steps:

- ✓ Assemble source documents with the required content, including a string for storing an identity
- ✓ Create a field in the search index for the principal identifiers
- ✓ Push the documents to the search index for indexing
- ✓ Query the index with the `search.in` filter function

It concludes with links to demos and examples that provide hands-on learning. We recommend reviewing this article first to understand the pattern.

About the security filter pattern

The security filter pattern simulates document-level authorization by using a regular OData filter that includes or excludes a search result based on a string consisting of a security principal. There's no authentication or authorization through the security principal. The principal is just a string, used in a filter expression, to include or exclude a document from the search results.

There are several ways to achieve security filtering. One way is through a complicated disjunction of equality expressions: for example, `Id eq 'id1' or Id eq 'id2'`, and so forth. This approach is error-prone, difficult to maintain, and in cases where the list contains hundreds or thousands of values, slows down query response time by many seconds.

A better solution is using the `search.in` function for security filters, as described in this article. If you use `search.in(Id, 'id1, id2, ...')` instead of an equality expression, you can expect subsecond response times.

Prerequisites

- A string field containing a group or user identity, such as a Microsoft Entra object identifier.

- Other fields in the same document should provide the content that's accessible to that group or user. In the following JSON documents, the "security_id" fields contain identities used in a security filter, and the name, salary, and marital status are included if the identity of the caller matches the "security_id" of the document.

```
JSON

{
    "Employee-1": {
        "employee_id": "100-1000-10-1-10000-1",
        "name": "Abram",
        "salary": 75000,
        "married": true,
        "security_id": "alphanumeric-object-id-for-employee-1"
    },
    "Employee-2": {
        "employee_id": "200-2000-20-2-20000-2",
        "name": "Adams",
        "salary": 75000,
        "married": true,
        "security_id": "alphanumeric-object-id-for-employee-2"
    }
}
```

Create security field

In the search index, within the fields collection, you need one field that contains the group or user identity, similar to the fictitious "security_id" field in the previous example.

1. Add a security field as a `Collection(Edm.String)`.
2. Set the field's `filterable` attribute set to `true`.
3. Set the field's `retrievable` attribute to `false` so that it isn't returned as part of the search request.
4. Indexes require a document key. The "file_id" field satisfies that requirement.
5. Indexes should also contain searchable and retrievable content. The "file_name" and "file_description" fields represent that in this example.

The following index schema satisfies the field requirements. Documents that you index on Azure AI Search should have values for all of these fields, including the "group_ids". For the document with `file_name` "secured_file_b", only users that belong to group IDs "group_id1" or "group_id2" have read access to the file.

```
https
```

```
POST https://[search
service].search.windows.net/indexes/securedfiles/docs/index?api-version=2024-
07-01
{
    "name": "securedfiles",
    "fields": [
        {"name": "file_id", "type": "Edm.String", "key": true, "searchable": false },
        {"name": "file_name", "type": "Edm.String", "searchable": true },
        {"name": "file_description", "type": "Edm.String", "searchable": true },
        {"name": "group_ids", "type": "Collection(Edm.String)" },
        "filterable": true, "retrievable": false }
    ]
}
```

Push data into your index using the REST API

Populate your search index with documents that provide values for each field in the fields collection, including values for the security field. Azure AI Search doesn't provide APIs or features for populating the security field specifically. However, several of the examples listed at the end of this article explain techniques for populating this field.

In Azure AI Search, the approaches for loading data are:

- A single push or pull (indexer) operation that imports documents populated with all fields
- Multiple push or pull operations. As long as secondary import operations target the right document identifier, you can load fields individually through multiple imports.

The following example shows a single HTTP POST request to the docs collection of your index's URL endpoint (see [Documents - Index](#)). The body of the HTTP request is a JSON rendering of the documents to be indexed:

```
HTTP
```

```
POST https://[search service].search.windows.net/indexes/securedfiles/docs/index?
api-version=2024-07-01
{
    "value": [
        {
            "@search.action": "upload",
            "file_id": "1",
            "file_name": "secured_file_a",
            "file_description": "File access is restricted to Human Resources.",
            "group_ids": ["group_id1"]
        },
    ],
}
```

```
{
    "@search.action": "upload",
    "file_id": "2",
    "file_name": "secured_file_b",
    "file_description": "File access is restricted to Human Resources and Recruiting.",
    "group_ids": ["group_id1", "group_id2"]
},
{
    "@search.action": "upload",
    "file_id": "3",
    "file_name": "secured_file_c",
    "file_description": "File access is restricted to Operations and Logistics.",
    "group_ids": ["group_id5", "group_id6"]
}
]
```

If you need to update an existing document with the list of groups, you can use the `merge` or `mergeOrUpload` action:

JSON

```
{
    "value": [
        {
            "@search.action": "mergeOrUpload",
            "file_id": "3",
            "group_ids": ["group_id7", "group_id8", "group_id9"]
        }
    ]
}
```

Apply the security filter in the query

In order to trim documents based on `group_ids` access, you should issue a search query with a `group_ids/any(g:search.in(g, 'group_id1, group_id2,...'))` filter, where 'group_id1, group_id2,...' are the groups to which the search request issuer belongs.

This filter matches all documents for which the `group_ids` field contains one of the given identifiers. For full details on searching documents using Azure AI Search, you can read [Search Documents](#).

This sample shows how to set up query using a POST request.

Issue the HTTP POST request, specifying the filter in the request body:

HTTP

```
POST https://[service name].search.windows.net/indexes/securedfiles/docs/search?  
api-version=2024-07-01  
  
{  
    "filter": "group_ids/any(g:search.in(g, 'group_id1, group_id2'))"  
}
```

You should get the documents back where `group_ids` contains either "group_id1" or "group_id2". In other words, you get the documents to which the request issuer has read access.

JSON

```
{  
    [  
        {  
            "@search.score":1.0,  
            "file_id": "1",  
            "file_name": "secured_file_a",  
        },  
        {  
            "@search.score":1.0,  
            "file_id": "2",  
            "file_name": "secured_file_b"  
        }  
    ]  
}
```

Next steps

This article describes a pattern for filtering results based on user identity and the `search.in()` function. You can use this function to pass in principal identifiers for the requesting user to match against principal identifiers associated with each target document. When a search request is handled, the `search.in` function filters out search results for which none of the user's principals have read access. The principal identifiers can represent things like security groups, roles, or even the user's own identity.

Indexing document Access Control Lists (ACLs) using the push REST APIs

09/18/2025

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Indexing documents, along with their associated [Access Control Lists \(ACLs\)](#) and container [Role-Based Access Control \(RBAC\) roles](#), into an Azure AI Search index via the [push REST APIs](#) preserves document-level permission on indexed content at query time.

Key features include:

- Flexible control over ingestion pipelines.
- Standardized schema for permissions metadata.
- Support for hierarchical permissions, such as folder-level ACLs.

This article explains how to use the push REST API to index document-level permissions' metadata in Azure AI Search. This process prepares your index to query and enforce end-user permissions on search results.

Prerequisites

- Content with ACL metadata from [Microsoft Entra ID](#) or another POSIX-style ACL system.
- The [latest preview REST API](#) or a preview Azure SDK package providing equivalent features.
- An index schema with a `permissionFilterOption` enabled, plus `permissionFilter` field attributes that store the permissions associated with the document.

Limitations

- An ACL field with permission filter type `userIds` or `groupIds` can hold at most 32 values.

- An index can hold at most five unique values among fields of type `rbacScope` on all documents. There's no limit on the number of documents that share the same value of `rbacScope`.
- A preexisting field can be converted into a `permissionFilter` field type for use with built-in ACLs or RBAC metadata filtering. To enable filtering on an existing index, create new fields or modify an existing field to include a `permissionFilter`.
- Only one field of each `permissionFilter` type (one each of `groupIds`, `usersIds`, and `rbacScope`) can exist in an index.
- Each `permissionFilter` field should have `filterable` set to true.
- This functionality is currently not supported in the Azure portal.

Create an index with permission filter fields

Indexing document ACLs and RBAC metadata with the REST API requires setting up an index schema that enables permission filters and has fields with permission filter assignments.

First, add a `permissionFilterOption` option. Valid values are `enabled` or `disabled`, and you should set it to `enabled`. You can switch it to `disabled` if you want to turn off the permission filter functionality at the index level.

Second, create string fields for your permission metadata and include `permissionFilter`. Recall that you can have one of each permission filter type.

Here's a basic example schema that includes all `permissionFilter` types:

```
JSON

{
  "fields": [
    { "name": "UserIds", "type": "Collection(Edm.String)", "permissionFilter": "userIds", "filterable": true },
    { "name": "GroupIds", "type": "Collection(Edm.String)", "permissionFilter": "groupIds", "filterable": true },
    { "name": "RbacScope", "type": "Edm.String", "permissionFilter": "rbacScope", "filterable": true },
    { "name": "DocumentId", "type": "Edm.String", "key": true }
  ],
  "permissionFilterOption": "enabled"
}
```

REST API indexing example

Once you have an index with permission filter fields, you can populate those values using the indexing push API as with any other document fields. Here's an example using the specified index schema, where each document specifies the upload action, the key field (DocumentId), and permission fields. It should also have content, but that field is omitted in this example for brevity.

```
https
```

```
POST  
https://exampleservice.search.windows.net/indexes('indexdocumentsexample')/docs/search.index?api-version=2025-08-01-preview  
{  
    "value": [  
        {  
            "@search.action": "upload",  
            "DocumentId": "1",  
            "UserIds": ["00aa00aa-bb11-cc22-dd33-44ee44ee44ee", "11bb11bb-cc22-dd33-  
ee44-55ff55ff55ff", "22cc22cc-dd33-ee44-ff55-66aa66aa66aa"],  
            "GroupIds": ["none"]  
            "RbacScope": "/subscriptions/00000000-0000-0000-0000-  
000000000000/resourceGroups/Example-Storage-  
rg/providers/Microsoft.Storage/storageAccounts/azurestorage12345/blobServices/defa  
ult/containers/blob-container-01"  
        },  
        {  
            "@search.action": "merge",  
            "DocumentId": "2",  
            "UserIds": ["all"],  
            "GroupIds": ["33dd33dd-ee44-ff55-aa66-77bb77bb77bb", "44ee44ee-ff55-aa66-  
bb77-88cc88cc88cc"]  
        },  
        {  
            "@search.action": "mergeOrUpload",  
            "DocumentId": "3",  
            "UserIds": ["1cdd8521-38cf-49ab-b483-17ddaa48f68f"],  
            "RbacScope": "/subscriptions/00000000-0000-0000-0000-  
000000000000/resourceGroups/Example-Storage-  
rg/providers/Microsoft.Storage/storageAccounts/azurestorage12345/blobServices/defa  
ult/containers/blob-container-03"  
        }  
    ]  
}
```

ACL access resolution rules

This section explains how document access is determined for a user based on the ACL values assigned to each document. The key rule is that *a user only needs to match one ACL type to*

gain access to the document. For example, if a document has fields for `userIds`, `groupIds`, and `rbacScope`, the user can access the document by matching any one of these ACL fields.

Special ACL values "all" and "none"

ACL fields, such as `userIds` and `groupIds`, typically contain lists of GUIDs (Globally Unique Identifiers) that identify the users and groups with access to the document. Two special string values, "all" and "none", are supported for these ACL field types. These values act as broad filters to control access at the global level as showcased in the following table.

[] Expand table

userIds / groupIds value	Meaning
<code>["all"]</code>	Any user can access the document
<code>["none"]</code>	No user can access the document by matching this ACL type
<code>[] (empty array)</code>	No user can access the document by matching this ACL type

Because a user needs to match only one field type, the special value "all" grants public access regardless of the contents of any other ACL field, as all users are matched and granted permission. In contrast, setting `userIds` to "none" or "empty" means no users are granted access to the document *based on their user ID*. It might be possible that they're still granted access by matching their group ID or by RBAC metadata.

Access control example

This example illustrates how the document access rules are resolved based on the specific document ACL field values. For readability, this scenario uses ACL aliases such as "user1," "group1," instead of GUIDs.

[] Expand table

Document #	userIds	groupIds	RBAC Scope	Permitted users list	Note
1	<code>["none"]</code>	<code>[]</code>	Empty	No users have access	The values <code>["none"]</code> and <code>[]</code> behave exactly the same
2	<code>["none"]</code>	<code>[]</code>	<code>scope/to/container1</code>	Users with RBAC permissions to container1	The value of "none" doesn't block access

Document #	userIds	groupIds	RBAC Scope	Permitted users list	Note
					by matching other ACL fields
3	["none"]	["group1", "group2"]	Empty	Members of group1 or group2	
4	["all"]	["none"]	Empty	Any user	Any querying user matches the ACL filter "all", so all users have access
5	["all"]	["group1", "group2"]	scope/to/container1	Any user	Since all users match the "all" filter for userID, the groupID and RBAC filters don't have any impact
6	["user1", "user2"]	["group1"]	Empty	User1, user2, or any member of group1	
7	["user1", "user2"]	[]	Empty	User1, user2, or any user with RBAC permissions to container1

Use an ADLS Gen2 indexer to ingest permission metadata and filter search results based on user access rights

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

The permission model in Azure Data Lake Storage (ADLS) Gen2 allows for per-user access to specific directories or files. Preview APIs in Azure AI Search now support ingestion of user permissions alongside document ingestion so that you can use those permissions to control access to search results. If a user lacks permissions on a specific directory or file in ADLS Gen2, that user doesn't have access to the corresponding documents in Azure AI Search results.

- 2025-05-01-preview and later, ADLS Gen2 permissions can be ingested using the [ADLS Gen2 indexer](#).
- 2025-11-01-preview provides equivalent support for [ADLS Gen2 blob knowledge sources](#) in Azure Storage.

You can use the push APIs to upload and index content and permission metadata manually, or you can use an indexer or knowledge source to automate data ingestion.

This article focuses on the indexing automation approaches, built on this foundation:

- The [ADLS Gen2 access control model](#) that provides [Access control lists \(ACLs\)](#) and [Role-based access control \(Azure RBAC\)](#). There's no support for Attribute-based access control (Azure ABAC).
- An [ADLS Gen2 indexer](#) or [ADLS Gen2 blob knowledge source](#) that retrieves and ingests data and metadata, including permission filters. To get permission filter support, use the latest preview REST API or a preview package of an Azure SDK that supports the feature.
- An [index in Azure AI Search](#) containing the ingested documents and corresponding permissions. Permission metadata is stored as fields in the index. To set up [queries that respect the permission filters](#), use the latest preview REST API or a preview package of an Azure SDK that supports the feature.

This functionality helps align [document-level permissions](#) in the search index with the access controls defined in ADLS Gen2, allowing users to retrieve content in a way that reflects their existing permissions.

This article supplements [Index data from ADLS Gen2](#) and [ADLS Gen2 blob knowledge sources](#) with information that's specific to ingesting permissions alongside document content into an Azure AI Search index.

Prerequisites

- [Microsoft Entra ID authentication and authorization](#). Services and apps must be in the same tenant. Users can be in different tenants as long as all of the tenants are Microsoft Entra ID. Role assignments are used for each authenticated connection.
- Azure AI Search, any region, but you must have a billable tier (basic and higher) for managed identity support. The search service must be [configured for role-based access](#) and it must [have a managed identity \(either system or user\)](#).
- ADLS Gen2 blobs in a hierarchical namespace, with user permissions granted through ACLs or roles.

Limitations

- [Limits on Azure role assignments and ACL entries](#) in ADLS Gen2 impose a maximum number of role assignments and ACL entries.
- The `owning users`, `owning groups`, `Other (all)`, [ACL identities categories](#) aren't supported during public preview. Use `named users` and `named groups` assignments instead.
- The following indexer features don't support permission inheritance in indexed documents originating from ADLS Gen2. If you use any of these features in a skillset or indexer, document-level permissions aren't included in the indexed content.
 - [Custom Web API skill](#)
 - [GenAI Prompt skill](#)
 - [Knowledge store](#)
 - [Indexer enrichment cache](#)
 - [Debug sessions](#)
- This functionality is currently not supported in the Azure portal.

Support for the permission model

This section compares document-level access control features between ADLS Gen2 and Azure AI Search. It explains which Azure Data Lake Storage (ADLS) Gen2 access control mechanisms AI Search supports or maps. This helps you understand how permissions are enforced at the document level.

[+] [Expand table](#)

ADLS Gen2 Feature	Description	Supported	Notes
RBAC	Coarse-grained access at container level	Yes	AI Search honors RBAC for access to all documents in the entire container.
ABAC	Attribute-based conditions on top of RBAC	No	AI Search doesn't evaluate ABAC conditions for document-level access.
ACL	Fine-grained permissions at directory/file (document) level	Yes	AI Search uses document-level ACLs for permission filters .
Security Groups	Group-based permission assignments	Yes	Supported if security groups are mapped inside the document-level ACL.

About ACL hierarchical permissions

Indexers and knowledge sources can retrieve ACL assignments from the specified container and all directories leading to each file by following the ADLS Gen2 [hierarchical access evaluation flow](#). The final effective access lists for each file are computed and the different access categories are indexed into the corresponding index fields.

For example, in [ADLS Gen2 common scenarios related to permissions](#) as the file path /Oregon/Portland/Data.txt.

[+] [Expand table](#)

Operation	/	Oregon/	Portland/	Data.txt
Read Data.txt	--X	--X	--X	R--

The indexer or knowledge source collects ACLs from each container and directory. It then determines effective access at lower levels and continues until it resolves permissions for every file.

txt

```
/ assigned access vs Oregon/ assigned access  
=> Oregon/ effective access vs Portland/ assigned access  
=> Portland/ effective access vs Data.txt assigned access  
=> Data.txt effective access
```

Configure ADLS Gen2

An indexer or knowledge source can retrieve ACLs on a storage account if the following criteria are met. For more information about ACL assignments, see [ADLS Gen2 ACL assignments](#).

Authorization

For indexing, your search service identity must have **Storage Blob Data Reader** permission.

If you're testing locally, you should also have a **Storage Blob Data Reader** role assignment. For more information, see [Connect to Azure Storage using a managed identity](#).

Root container permissions:

1. Assign all `Group` and `User` sets (security principals) at the root container `/` with `Read` and `Execute` permissions.
2. Ensure both `Read` and `Execute` are added as "Default permissions" so they propagate to newly created files and directories automatically.

Propagate permissions down the file hierarchy

Although new directories and files inherit permissions, existing directories and files don't automatically inherit these assignments.

Use the ADLS Gen2 tool to [apply ACLs recursively](#) for assignments propagation on existing content. This tool propagates the root container's ACL assignments to all underlying directories and files.

Remove excess permissions

After applying ACLs recursively, review permissions for each directory and file.

Remove any `Group` or `User` sets that shouldn't have access to specific directories or files. For example, remove `User2` on folder `Portland/`, and for folder `Idaho` remove `Group2` and `User2` from its assignments, and so on.

Sample ACL assignments structure

Here's a diagram of the ACL assignment structure for the [fictitious directory hierarchy](#) in the ADLS Gen2 documentation.

Updating ACL assignments over time

Over time, as any new ACL assignments are added or modified, repeat the above steps to ensure proper propagation and permissions alignment. Updated permissions in ADLS Gen2 are updated in the search index when you re-ingest the content using the indexer or knowledge source.

Configure Azure AI Search

Recall that the search service must have:

- [Role-based access enabled](#)
- [Managed identity configured](#)

Authorization

For indexing, the client issuing the API call must have **Search Service Contributor** permission to create objects, **Search Index Data Contributor** permission to perform data import, and **Search Index Data Reader** to query an index.

If you're testing locally, you should have the same role assignments. For more information, see [Connect to Azure AI Search using roles](#).

Configure a knowledge source

If you're using a knowledge source, definitions in the knowledge source are used to generate a full indexing pipeline (indexer, data source, and index). ACL assignments are detected and automatically included in the generated index. There's no need to modify any of the generated objects if you want permission inheritance in your indexed content.

Key points about the configuration that make it work for this scenario:

- `isADLSGen2` is set to true, meeting the data source requirement for this scenario.
- `ingestionPermissionOptions` specifies user and group IDs.

- `disableImageVerbalization` is set to true because the GenAI Prompt skill that backs this experience isn't currently supported in ADLS Gen2 permission inheritance.

HTTP

```
# Create / Update Azure Blob Knowledge Source
###

    }  

  }  

}  

}###
```

Configure indexer-based indexing

If you're using an indexer, configure it, the data source, and the index to pull permission metadata from ADLS Gen2 blobs.

Create the data source

This section supplements [Index data from ADLS Gen2](#) with information that's specific to ingesting permissions alongside document content into an Azure AI Search index.

- Data Source type must be `adlsgen2`.
- Data source must have `indexerPermissionOptions` with `userIds`, `groupIds` and/or `rbacScope`.
 - For `rbacScope`, configure the [connection string](#) with managed identity format.
 - For connection strings using a [user-assigned managed identity](#), you must also specify the `identity` property.

JSON example with system managed identity:

JSON

```
{  
  "name" : "my-adlsgen2-acl-datasource",  
  "type": "adlsgen2",  
  "indexerPermissionOptions": ["userIds", "groupIds", "rbacScope"],  
  "credentials": {  
    "connectionString": "ResourceId=/subscriptions/<your subscription  
ID>/resourceGroups/<your resource group  
name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;"  
  },  
  "container": {  
    "name": "<your container name>",  
    "query": "<optional-virtual-directory-name>"  
  }  
}
```

JSON schema example with a user-managed identity in the connection string:

JSON

```
{  
  "name" : "my-adlsgen2-acl-datasource",  
  "type": "adlsgen2",  
  "indexerPermissionOptions": ["userIds", "groupIds", "rbacScope"],  
  "credentials": {  
    "connectionString": "ResourceId=/subscriptions/<your subscription  
ID>/resourceGroups/<your resource group  
name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;"  
  },  
  "container": {  
    "name": "<your container name>",  
    "query": "<optional-virtual-directory-name>"  
  }  
}
```

```

},
"identity": {
"@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
"userAssignedIdentity": "/subscriptions/{subscription-ID}/resourceGroups/{resource-group-name}/providers/Microsoft.ManagedIdentity/userAssignedIdentities/{user-assigned-managed-identity-name}"
}
}

```

Create permission fields in the index

In Azure AI Search, make sure your index contains field definitions for the permission metadata. Permission metadata can be indexed when `indexerPermissionOptions` is specified in the data source definition.

Recommended schema attributes for ACL (UserIds, GroupIds) and RBAC Scope:

- User identifier (ID) field with `userIds` permissionFilter value.
- Group IDs filed with `groupIds` permissionFilter value.
- RBAC scope field with `rbacScope` permissionFilter value.
- Property `permissionFilterOption` to enable filtering at querying time.
- Use string fields for permission metadata
- Set `filterable` to true on all fields.

Notice that `retrievable` is false. You can set it true during development to verify permissions are present, but remember to set to back to false before deploying to a production environment.

JSON schema example:

JSON

```
{
...
"fields": [
...
  { "name": "UserIds", "type": "Collection(Edm.String)", "permissionFilter": "userIds", "filterable": true, "retrievable": false },
  { "name": "GroupIds", "type": "Collection(Edm.String)", "permissionFilter": "groupIds", "filterable": true, "retrievable": false },
  { "name": "RbacScope", "type": "Edm.String", "permissionFilter": "rbacScope", "filterable": true, "retrievable": false }
],
"permissionFilterOption": "enabled"
}
```

Configure the indexer

Field mappings within an indexer set the data path to fields in an index. Target and destination fields that vary by name or data type require an explicit field mapping. The following metadata fields in ADLS Gen2 might need field mappings if you vary the field name:

- `metadata_user_ids` (`Collection(Edm.String)`) - the ACL user IDs list.
- `metadata_group_ids` (`Collection(Edm.String)`) - the ACL group IDs list.
- `metadata_rbac_scope` (`Edm.String`) - the container RBAC scope.

Specify `fieldMappings` in the indexer to route the permission metadata to target fields during indexing.

JSON schema example:

JSON

```
{  
  ...  
  "fieldMappings": [  
    { "sourceFieldName": "metadata_user_ids", "targetFieldName": "UserIds" },  
    { "sourceFieldName": "metadata_group_ids", "targetFieldName": "GroupIds" },  
    { "sourceFieldName": "metadata_rbac_scope", "targetFieldName": "RbacScope" }  
  ]  
}
```

Recommendations and best practices

- Plan the ADLS Gen2 folder structure carefully before creating any folders.
- Organize identities into groups and use groups whenever possible, rather than granting access directly to individual users. Continuously adding individual users instead of applying groups increases the number of access control entries that must be tracked and evaluated. Not following this best practice can lead to more frequent security metadata updates required to the index as this metadata changes, causing increased delays and inefficiencies in the refresh process.

Synchronize permissions between indexed and source content

Enabling ACL or RBAC enrichment on an indexer works automatically only in two situations:

- **The very first full indexer run / data crawl:** all permission metadata that exists at that moment for each document is captured.
- **Brand-new documents added after ACL/RBAC support is enabled:** their ACL/RBAC information is ingested along with their content.

If you change document permissions, such as adding a user to an ACL or updating a role assignment, the change doesn't appear in the search index unless you tell the indexer to crawl the document's permission metadata again.

Choose one of the following mechanisms, depending on how many items changed:

 Expand table

Scope of your change	Best trigger	What gets refreshed on the next run
A single blob or just a handful	Update the blob's <code>Last-Modified</code> timestamp in storage (touch the file)	Document content and ACL/RBAC metadata
Dozens to thousands of blobs	Call /resetdocs (preview) and list the affected document keys.	Document content and ACL/RBAC metadata
Entire data source	Call /resync (preview) with the permissions option.	Only ACL/RBAC metadata (content is left untouched)

Resetdocs (preview) API example:

HTTP

```
POST https://{{service}}.search.windows.net/indexers/{{indexer}}/resetdocs?api-version=2025-11-01-preview
{
  "documentKeys": [
    "1001",
    "4452"
  ]
}
```

Resync (preview) API example:

HTTP

```
POST https://{{service}}.search.windows.net/indexers/{{indexer}}/resync?api-version=2025-11-01-preview
{
  "options": [
    "permissions"
  ]
}
```

]
}

ⓘ Important

If you change permissions on indexed documents and don't trigger one of the mechanisms above, the search index continues serving outdated ACL or RBAC data. New documents continue to be indexed automatically; no manual trigger is needed for them.

Deletion tracking

To manage blob deletion effectively, make sure [deletion tracking](#) is enabled before your indexer runs for the first time. This feature lets the system detect deleted blobs in your source and remove them from the index.

Last updated on 11/19/2025

Use a Blob indexer or knowledge source to ingest RBAC scopes metadata

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Azure Storage allows for role-based access on containers in blob storage, where roles like **Storage Blob Data Reader** or **Storage Blob Data Contributor** determine whether someone has access to content. Preview APIs in Azure AI Search now support ingestion of user permissions alongside document ingestion so that you can use those permissions to control access to search results. If a user lacks permissions on a specific directory or file in Azure Storage, that user doesn't have access to the corresponding documents in Azure AI Search results, even if you personally have a **Search Index Data Reader** assignment *on the index*.

- 2025-05-01-preview and later, RBAC scopes metadata can be ingested using the [Blob indexer](#).
- 2025-11-01-preview provides equivalent support for [Blob knowledge sources](#) in Azure Storage.

RBAC scope is set at the container level and flows to all blobs (documents) through permission inheritance. RBAC scope is captured during indexing as permission metadata. You can use the push APIs to upload and index content and permission metadata manually (see [Indexing Permissions using the push REST API](#)), or you can use an indexer or knowledge source to automate data ingestion. This article focuses on indexing automation.

At query time, the identity of the caller is included in the request header via the `x-ms-query-source-authorization` parameter. The identity must match the permission metadata on documents if the user is to see the search results.

This article focuses on the indexing automation approaches, built on this foundation:

- [Azure Storage blobs secured using role-based access control \(Azure RBAC\)](#). There's no support for Attribute-based access control (Azure ABAC).
- [Azure Blob indexer](#) or a [Blob knowledge source](#) that retrieves and ingests data and metadata, including permission filters. To get permission filter support, use the latest preview REST API or a preview package of an Azure SDK that supports the feature.

- An index in Azure AI Search containing the ingested documents and corresponding permissions. Permission metadata is stored as fields in the index.
- A query that uses permission filters. To set up queries that respect the permission filters, use the latest preview REST API or a preview package of an Azure SDK that supports the feature.

Prerequisites

- Microsoft Entra ID authentication and authorization. Services and apps must be in the same tenant. Users can be in different tenants as long as all of the tenants are Microsoft Entra ID. Role assignments are used for each authenticated connection.
- Azure AI Search, any region, but you must have a billable tier (basic and higher) for managed identity support. The search service must be [configured for role-based access](#) and it must [have a managed identity \(either system or user\)](#).
- Azure Storage, Standard performance (general-purpose v2), on hot, cool, and cold access tiers, with RBAC-secured containers or blobs.
- You should understand how indexers and knowledge sources work and how to create an index. This article explains the configuration settings for the data source and indexer, but doesn't provide steps for creating the index. For more information about indexes designed for permission filters, see [Create an index with permission filter fields](#).
- This functionality is currently not supported in the Azure portal, this includes Permission filters created through the [Import wizards](#). Use a programmatic approach to create or modify existing objects for document-level access.

Configure Blob storage

Verify your blob container uses role-based access.

1. Sign in to the Azure portal and find your storage account.
2. Expand **containers** and select the container that has the blobs you want to index.
3. Select **Access Control (IAM)** to check role assignments. Users and groups with **Storage Blob Data Reader** or **Storage Blob Data Contributor** will have access to search documents in the index after the container is indexed.

Authorization

For indexer execution, your search service identity must have **Storage Blob Data Reader** permission. For more information, see [Connect to Azure Storage using a managed identity](#).

Configure Azure AI Search

Recall that the search service must have:

- Role-based access enabled
- Managed identity configured

Authorization

For indexer execution, the client issuing the API call must have **Search Service Contributor** permission to create objects, **Search Index Data Contributor** permission to perform data import, and **Search Index Data Reader** to query an index see [Connect to Azure AI Search using roles](#).

Configure a knowledge source

If you're using a knowledge source, definitions in the knowledge source are used to generate a full indexing pipeline (indexer, data source, and index). RBAC scope is detected and automatically included in the generated index. There's no need to modify any of the generated objects if you want permission inheritance in your indexed content.

Key points about the configuration that make it work for this scenario:

- `isADLSGen2` is set to false, which means the data source is Azure Blob storage.
- `ingestionPermissionOptions` specifies `rbacScope`.

HTTP

```
# Create / Update Azure Blob Knowledge Source
###
PUT {{url}}/knowledgesources/azure-blob-ks?api-version=2025-11-01-preview
api-key: {{key}}
Content-Type: application/json

{
    "name": "azure-blob-ks",
    "kind": "azureBlob",
    "description": "A sample azure blob knowledge source",
    "azureBlobParameters": {
        "connectionString": "{{blob-connection-string}}",
        "containerName": "blobcontainer",
        "FolderPath": null,
```

```
        "isADLSGen2": false,
        "ingestionParameters": {
            "identity": null,
            "embeddingModel": {
                "kind": "azureOpenAI",
                "azureOpenAIParameters": {
                    "deploymentId": "text-embedding-3-large",
                    "modelName": "text-embedding-3-large",
                    "resourceUri": "{{aoai-endpoint}}",
                    "apiKey": "{{aoai-key}}"
                }
            },
            "chatCompletionModel": null,
            "disableImageVerbalization": true,
            "ingestionSchedule": null,
            "ingestionPermissionOptions": ["rbacScope"],
            "contentExtractionMode": "minimal",
            "aiServices": {
                "uri": "{{ai-endpoint}}",
                "apiKey": "{{ai-key}}"
            }
        }
    }
}
```

Configure indexer-based indexing

If you're using an indexer, configure it, the data source, and the index to pull permission metadata from blobs.

Create the data source

- Data Source type must be `azureblob`.
- Data source parsing mode must be the default.
- Data source must have `indexerPermissionOptions` with `rbacScope`.
 - For `rbacScope`, configure the [connection string](#) with managed identity format.
 - For connection strings using a [user-assigned managed identity](#), you must also specify the `identity` property.

JSON example with system managed identity and `indexerPermissionOptions`:

JSON

```
{
  "name" : "my-blob-datasource",
  "type": "azureblob",
  "indexerPermissionOptions": ["rbacScope"],
  "credentials": {
    "connectionString": "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;"
  },
  "container": {
    "name": "<your-container-name>",
    "query": "<optional-query-used-for-selecting-specific-blobs>"
  }
}
```

JSON schema example with a user-managed identity in the connection string:

JSON

```
{
  "name" : "my-blob-datasource",
  "type": "azureblob",
  "indexerPermissionOptions": ["rbacScope"],
  "credentials": {
    "connectionString": "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/";
  },
  "container": {
    "name": "<your-container-name>",
    "query": "<optional-query-used-for-selecting-specific-blobs>"
  },
  "identity": {
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
    "userAssignedIdentity": "/subscriptions/{subscription-ID}/resourceGroups/{resource-group-name}/providers/Microsoft.ManagedIdentity/userAssignedIdentities/{user-assigned-managed-identity-name}"
  }
}
```

Create permission fields in the index

In Azure AI Search, make sure your index contains field definitions for the permission metadata. Permission metadata can be indexed when `indexerPermissionOptions` is specified in the data source definition.

Recommended schema attributes RBAC Scope:

- RBAC scope field with `rbacScope` permissionFilter value.

- Property `permissionFilterOption` to enable filtering at querying time.
- Use string fields for permission metadata
- Set `filterable` to true on all fields.

Notice that `retrievable` is false. You can set it true during development to verify permissions are present, but remember to set it back to false before deploying to a production environment so that security principal identities aren't visible in results.

JSON schema example:

```
JSON
{
  ...
  "fields": [
    ...
    {
      "name": "RbacScope",
      "type": "Edm.String",
      "permissionFilter": "rbacScope",
      "filterable": true,
      "retrievable": false
    }
  ],
  "permissionFilterOption": "enabled"
}
```

Configure the indexer

Field mappings within an indexer set the data path to fields in an index. Target and destination fields that vary by name or data type require an explicit field mapping. The following metadata fields in Azure Blob Storage might need field mappings if you vary the field name:

- `metadata_rbac_scope` (`Edm.String`) - the container RBAC scope.

Specify `fieldMappings` in the indexer to route the permission metadata to target fields during indexing.

JSON schema example:

```
JSON
{
  ...
  "fieldMappings": [
    { "sourceFieldName": "metadata_rbac_scope", "targetFieldName": "RbacScope" }
  ]
}
```

```
]  
}
```

Run the indexer

Once your indexer, data source, and index are configured, run the indexer to set the process in motion. If there's a problem with configuration or permissions, those problems will surface in this step.

By default, an indexer runs as soon as you post it to a search service, but if the indexer configuration includes `disabled` set to true, the indexer is posted in a disabled state so that you can run the indexer manually.

We recommend [running the indexer from the Azure portal](#) so that you can monitor status and messages.

Assuming no errors, the index is now populated and you can move forward with [queries and testing](#).

Deletion tracking

To effectively manage blob deletion, ensure that you have enabled [deletion tracking](#) before your indexer runs for the first time. This feature allows the system to detect deleted blobs from your source and delete the corresponding content from the index.

See also

- [Connect to Azure AI Search using roles](#)

- [Configure a blob indexer](#)

Use a SharePoint indexer to ingest permission metadata and filter search results based on user access rights

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

This article explains how to ingest an Access Control List (ACL) alongside other content from SharePoint in Microsoft 365 using an Azure AI Search indexer. Permissions from SharePoint are preserved as permission metadata for each indexed document. When users query an index containing content from SharePoint, their search results consist of only those documents for which they have permission to access.

i Important

For scenarios that require the full SharePoint permissions model, sensitivity labels, and out-of-the-box security trimming, use a [remote SharePoint knowledge source](#). This approach calls SharePoint directly via the [Copilot retrieval API](#) so governance remains fully in SharePoint and query results automatically respect all applicable permissions and labels.

Prerequisites

- [Azure AI Search](#) (Basic or higher).
- SharePoint in Microsoft 365 sites, libraries, folders, and files with configured permissions.
- Follow all configuration steps mentioned in the [SharePoint indexer documentation](#). Make sure that you apply the specific requirements in this document for ACL ingestion configuration.
- Configure [Application permissions](#) with `Files.Read.All` and `Sites.FullControl.All` (or `Sites.Selected` instead of `Sites.FullControl.All`), to index only the content and permissions of specific sites. Then, grant the application full control permissions for just those selected sites.

Limitations

- During public preview, this functionality applies to initial ingestion only: ACLs are captured on the first ingestion of each file. If permissions change in the source, you must [explicitly reindex those documents or their respective ACLs](#).
- Not supported in this preview:
 - [SharePoint Information Management policies](#) applicable to user access.
 - Document [shareable](#) "Anyone links" or "People in your organization links". Only "specific people links" sync are supported.
 - [SharePoint groups](#) that can't be resolved to Microsoft Entra groups (such as Owners, Members, Visitors groups).
 - Azure portal is out of support during preview; use REST API version 2025-11-01-preview or SDK preview packages.
 - This feature must not be tested in combination with [sensitivity labels preservation and honoring](#) feature at this time. Both features must be tested on different indexers and indexes accordingly, since their coexistence is not supported currently.

Support for the SharePoint permission model

This preview supports only basic ACLs for documents, as shown in the following table. The SharePoint indexer doesn't support lists ingestion, so it excludes lists permissions.

[] Expand table

SharePoint Feature	Description	Supported	Notes
Site & library inheritance	Site → library → folder → file.	✓	Evaluated at ingestion; effective ACLs computed per file.
Folder & file unique ACLs	Item-level access.	✓	Included when present at first ingestion.
Microsoft Entra (M365/Security) Groups	Group-based access.	✓	Group IDs included when resolvable to Entra identifier (ID).
SharePoint site groups	Owners/Members/Visitors.	⚠ Partial	Included only when resolvable to Entra group ID.
Shareable "Anyone links" or "People in your organization links"	Org-wide or public access.	✗	Not supported in preview.

SharePoint Feature	Description	Supported	Notes
External/guest users	Access for guests.	✗	Not supported.
Information Management policies	Policies to define specific permissions requirements.	✗	Not supported in preview.
Purview sensitivity labels	Document-level security for privacy, categorization, permissions, and encryption	✗	Supported via a separate feature: preserving and honoring sensitivity labels and not to be tested in the same indexer/index as this ACL feature at this time.

How hierarchical permissions are evaluated

SharePoint permissions inherit the hierarchy of Site → Library → Folder → File, unless inheritance is broken.

During ingestion, the indexer gathers user and group identifiers (ID) at each level and computes the effective ACL for each file.

Configure your search service for ACL ingestion and honoring at query time

These steps configure your search service for ACL ingestion and enable ACL honoring at query time.

1. Data source configuration

Set `indexerPermissionOptions` in the [data source definition](#) to allow indexing of `userIds` and `groupIds` from SharePoint documents.

```
{
  "name": "my-sharepoint-acl-datasource",
  "type": "sharepoint",
  "indexerPermissionOptions": ["userIds", "groupIds"],
  "credentials": {
    "connectionString": "<connection-string>;"
  },
  "container": {
    "name": "<library-name>",
    "query": "<optional-folder-path>"}
```

```
}
```

2. Add permission fields to the index definition

Add fields to your [index schema definition](#) to store ACLs and support query-time filtering.

```
{
  "fields": [
    { "name": "UserIds", "type": "Collection(Edm.String)", "permissionFilter": "userIds", "filterable": true, "retrievable": false },
    { "name": "GroupIds", "type": "Collection(Edm.String)", "permissionFilter": "groupIds", "filterable": true, "retrievable": false }
  ],
  "permissionFilterOption": "enabled"
}
```

Set `retrievable` attribute to `true` only during development to verify values. You can change `retrievable` from `true` to `false` with no index rebuild requirement.

3. Configure index projections in your skillset (if applicable)

If your indexer uses a [skillset](#) with data chunking, such as a [split skill](#) when enabling [integrated vectorization](#), make sure to map ACL properties to each chunk using [index projections](#).

```
PUT https://{{service}}.search.windows.net/skillsets/{{skillset}}?api-version=2025-11-01-preview
{
  "name": "my-skillset",
  "skills": [
    {
      "@odata.type": "#Microsoft.Skills.Text.SplitSkill",
      "name": "#split",
      "context": "/document",
      "inputs": [{ "name": "text", "source": "/document/content" }],
      "outputs": [{ "name": "textItems", "targetName": "chunks" }]
    }
    // ... (other skills such as embeddings, entity recognition, etc.)
  ],
  "indexProjections": {
    "selectors": [
      {
        "targetIndexName": "chunks-index",
        "parentKeyFieldName": "parentId",           // must exist in target index
        "sourceContext": "/document/chunks/*",       // match your split output path
      }
    ]
  }
}
```

```

    "mappings": [
        { "name": "chunkId",           "source": "/document/chunks/*/id" },      // if you create an id per chunk
        { "name": "content",          "source": "/document/chunks/*/text" },      // chunk text
        { "name": "parentId",         "source": "/document/id" },                // parent doc id
        { "name": "UserIds",          "source": "/document/metadata_user_ids" } // <-- parent → child
        { "name": "GroupIds",         "source": "/document/metadata_group_ids" } // <-- parent → child
    ],
    "parameters": {
        "projectionMode": "skipIndexingParentDocuments"
    }
}
}

```

4. Configure the indexer field mappings for ACLs

Besides your required [indexer configuration](#), map raw metadata ACL fields from SharePoint to your index fields.

```
{
  "fieldMappings": [
    { "sourceFieldName": "metadata_user_ids", "targetFieldName": "UserIds" },
    { "sourceFieldName": "metadata_group_ids", "targetFieldName": "GroupIds" }
  ]
}
```

Synchronize permissions between indexed and source content

During public preview when the configuration is completed, and ACLs are captured during the first indexer run and for new files only. To pick up later changes:

 Expand table

Change Scope	Recommended	Trigger	What refreshes
Single/few files	Update	LastModified	Content and ACLs

Change Scope	Recommended	Trigger	What refreshes
Many items	Update	/resetdocs (preview) with document keys	Content and ACLs
Entire site/library (as defined in the data source configuration)	Update	/resync (preview) with permissions	Only ACLs (no content refresh)

Reset specific documents

You can [reset specific documents](#) to fully ingest again content and ACLs.

```
POST https://{{service}}.search.windows.net/indexers/{{indexer}}/resetdocs?api-version=2025-11-01-preview
{
  "documentKeys": ["doc123", "doc456"]
}
```

Resync ACLs across the full data source

You can [resync the full data set ACL content](#) after initial ingestion.

```
POST https://{{service}}.search.windows.net/indexers/{{indexer}}/resync?api-version=2025-11-01-preview
{
  "options": ["permissions"]
}
```

i Important

If you change SharePoint permissions without triggering an update mechanism, the index serves stale ACL data for previously ingested files.

After indexing your data and ACLs, you can [query the index](#).

[Query-Time ACL enforcement](#)

Last updated on 11/18/2025

Query-time ACL and RBAC enforcement in Azure AI Search

Query-time access control ensures that users only retrieve search results they're authorized to access, based on their identity, group memberships, roles, or attributes. This functionality is essential for secure enterprise search and compliance-driven workflows.

Authorized access depends on permission metadata that's ingested during indexing. For indexer data sources that have built-in access models, such as Azure Data Lake Storage (ADLS) Gen2 and SharePoint in Microsoft 365, an indexer can pull in the permission metadata for each document automatically. For other data sources, you must assemble the document payload yourself, and the payload must include both content and the associated permission metadata. You then use the [push APIs](#) to load the index.

This article explains how to set up queries that use permission metadata to filter results.

Prerequisites

- Permission metadata must be in `filterable` string fields. You won't use the filter in your queries, but the search engine builds a filter internally to exclude unauthorized content.
- Permission metadata must consist of either POSIX-style permissions that identify the level of access and the group or user ID, or the resource ID of the container in ADLS Gen2 if you're using RBAC scope.
- Depending on the data source:
 - For ADLS Gen2 data sources, you must have configured Access Control Lists (ACLs) and/or Azure role-based access control (RBAC) roles at the container level.
 - For Azure Blob data sources, you must have role assignments on the container. You can use a [built-in indexer](#), a [knowledge source](#), or [Push APIs](#) to index permission metadata in your index.
 - For SharePoint data sources, you must have configured Access Control Lists (ACLs). You can use a [built-in SharePoint indexer](#) and configure it with [ACL ingestion capabilities](#).
- Use the [latest preview REST API](#) or a preview package of an Azure SDK to query the index or knowledge source. This API version supports internal queries that filter out unauthorized results.

Limitations

- If ACL evaluation fails (for example, the Graph API is unavailable), the service returns **5xx** and does **not** return a partially filtered result set.
- Document visibility requires both:
 - the calling application's RBAC role (Authorization header)
 - the user identity carried by **x-ms-query-source-authorization**
- Initial ACL-based queries may experience higher latency compared to subsequent requests, due to caching and permission resolution overhead.

ACL entry limits per data source

Access Control List (ACL) entry limits define how many distinct permission records can be associated with a file, folder, or item within a connected data source. Each entry represents a single user or group identity and the access rights granted to that identity (for example, Read, Write, or Execute).

The maximum number of ACL entries supported by Azure AI Search functionality varies depending on the data source type:

Azure Data Lake Storage Gen2 (ADLS Gen2): Each file or directory can have up to [32 ACL entries permissions](#). In this context, an entry means a single principal (user or group) with a specific permission set. Example: assigning "Everyone" read access and "Azure users" execute access would count as two ACL entries.

SharePoint in Microsoft 365: SharePoint data source in search supports up to 1,000 permission entries per file. Each entry represents a unique user or group assignment in the item's permission list. This is distinct from the overall [unique permission scopes limits](#) per list or library, which governs how many items can have unique permissions.

These limits determine how granularly Azure AI Search can honor item-level permissions when indexing or filtering search results. If an item exceeds these ACL entry limits, permissions beyond the limit may not be enforced at query time.

How query-time enforcement works

This section lists the order of operations for ACL enforcement at query time. Operations vary depending on whether you use Azure RBAC scope or Microsoft Entra ID group or user IDs.

1. User permissions input

The end-user application includes a query access token as part of the search query request, and that access token is typically the identity of the user. The following table lists the source of the user permissions supported by Azure AI Search for ACL enforcement:

 Expand table

Permission type	Source
userIds	oid from <code>x-ms-query-source-authorization</code> token
groupIds	Group membership fetched using the Microsoft Graph API
rbacScope	Permissions the user from <code>x-ms-query-source-authorization</code> has on a storage container

2. Security filter construction

Internally, Azure AI Search dynamically constructs security filters based on the user permissions provided. These security filters are automatically appended to any filters that might come in with the query if the index has the permission filter option enabled.

For Azure RBAC, permissions are lists of resource ID strings. There must be an Azure role assignment (Storage Blob Data Reader) on the data source that grants access to the security principal token in the authorization header. The filter excludes documents if there's no role assignment for the principal behind the access token on the request.

3. Results filtering

The security filter efficiently matches the userIds, groupIds, and rbacScope from the request against each list of ACLs in every document in the search index to limit the results returned to ones the user has access to. It's important to note that each filter is applied independently and a document is considered authorized if any filter succeeds. For example, if a user has access to a document through userIds but not through groupIds, the document is still considered valid and returned to the user.

Query example

Here's an example of a query request from [sample code](#). The query token is passed in the request header. The query token is the personal access token of a user or a group identity behind the request.

HTTP

```
POST {{endpoint}}/indexes/stateparks/docs/search?api-version=2025-11-01-preview
Authorization: Bearer {{query-token}}
x-ms-query-source-authorization: {{query-token}}
Content-Type: application/json

{
    "search": "*",
    "select": "name,description,location,GroupIds",
    "orderby": "name asc"
}
```

! Note

If the query token is omitted, only public documents accessible to everyone are returned in the query request.

Elevated permissions for investigating incorrect results

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Debugging queries that include permission metadata can be problematic because search results are specific to each user. As a developer or administrator, you might need elevated permissions to return results regardless of the permission metadata so that you can investigate problems with queries returning unauthorized content.

To investigate, you must be able to:

- View the set of documents that the end user is able to view based on that user's permissions.
- View all documents in the index to investigate why some might not be visible to the end user.

You can accomplish these tasks by adding a custom header, `x-ms-enable-elevated-read: true`, to a query.

Permissions for elevated-read requests

Currently, you must [create a custom role](#) to run queries with elevated permissions. Add the `Microsoft.Search/searchServices/indexes/contentSecurity/elevatedOperations/read` permission to run the queries.

Add an elevated-read header to a query

The following example is a query request against a search index.

HTTP

```
POST {endpoint}/indexes('{indexName}')/search.post.search?api-version=2025-11-01-preview
Authorization: Bearer {AUTH_TOKEN}
x-ms-query-source-authorization: Bearer {TOKEN}
x-ms-enable-elevated-read: true

{
    "search": "prototype tests",
    "select": "filename, author, date",
    "count": true
}
```

Important

The `x-ms-enable-elevated-read` header only works on Search POST actions. You can't perform an elevated read query on a [knowledge base retrieve](#) action.

Important ACL functionality behavior change in specific preview API versions

Before REST API version `2025-11-01-preview`, earlier preview versions `2025-05-01-preview` and `2025-08-01-preview` returned all documents when using a service API key or authorized Entra roles, even if no user token was provided. Applications that didn't validate the presence of a user token could inadvertently expose results to end users if not implemented correctly or following best practices.

Starting in November 2025, this behavior changed:

- ACL permission filters now apply even when using only service API keys or Entra authentication across all versions that support ACL.
- If the user token is omitted, ACL-protected content isn't returned.

- To view all documents for troubleshooting, you must explicitly include the elevated-read header when using REST API version `2025-11-01-preview`.

This update helps keep content protected when applications don't enforce best practices for token validation.

Last updated on 12/01/2025

Use Azure AI Search indexers to ingest Microsoft Purview sensitivity labels and enforce document-level security

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see

[Supplemental Terms of Use for Microsoft Azure Previews](#).

Azure AI Search now supports automatic extraction of [Microsoft Purview sensitivity labels](#) at document-level during indexing, with label-based access control enforced at query time. Available in public preview, this feature enables organizations to align search experiences with existing [information protection policies](#) defined in Microsoft Purview.

With sensitivity label indexing, Azure AI Search extracts and stores metadata that describes each document's sensitivity level. It also enforces label-based access control, ensuring that only authorized users can view or retrieve labeled content in search results.

This functionality is available for the following data sources:

- [Azure Blob Storage](#)
- [Azure Data Lake Storage Gen2](#)
- [SharePoint in Microsoft 365 \(Preview\)](#)
- [Microsoft OneLake](#)

ⓘ Important

The feature is available in all regions except West US2. Use the [REST API version 2025-11-01-preview](#) or a preview SDK to evaluate the feature.

Portal configuration and debug mode for administrators aren't supported at this time.

Policy enforcement

At query time, Azure AI Search evaluates sensitivity labels and enforces [document-level access control](#) in accordance with the user's Microsoft Entra ID token and Purview label policies.

Only users authorized to access content with [READ usage right](#) under a given label can retrieve corresponding documents in search results. There's a delay in how often the labels are pulled from a document after changed.

When configured [on a schedule](#), the indexer pulls new documents and updates from the data source. It captures:

- Newly added documents and their associated sensitivity labels
- Changes in document content
- Updates to sensitivity labels on existing documents

These updates are detected if they occurred since the last indexer run.

Prerequisites

- [Microsoft Purview sensitivity label policies](#) must be configured and [applied to documents](#) before indexing.
- [Global Administrator](#) or [Privileged Role Administrator](#) roles in your Microsoft Entra tenant are required to grant the search service access to Purview APIs and sensitivity labels.
- Both the Azure AI Search service and end users querying the content must belong to the same Microsoft Entra tenant. Guest users and multitenant scenarios aren't supported.
- File types must be included in the [Purview sensitivity labels supported formats list](#) and also be recognized as [Office supported file types](#) by Azure AI Search indexers.

Limitations

- There's a known issue with document deletion and sensitivity labels. When sensitivity labels are enabled for an index, the indexer fails to enumerate the index's documents. As a result, soft delete operations don't run because the indexer can't list the documents that need to be removed. This applies to indexers that support soft delete, including Azure Blob, ADLS Gen2, OneLake, SharePoint.
- Initial release supports REST API version 2025-11-01-preview and associated beta SDK only. There's no portal experience for configuration or management.
- This feature isn't supported when used simultaneously with [ACL-based security filters](#) (currently also in preview). Test each feature independently until Microsoft announces official coexistence support.

- [Autocomplete](#) and [Suggest](#) APIs are disabled for Purview-enabled indexes, as they can't yet enforce label-based access control.
- Guest accounts and cross-tenant queries aren't supported.
- In the initial release, sensitivity label-enabled indexes don't support unlabeled documents and don't return them in query results. This capability will be documented when available.
- The following indexer features don't support documents with sensitivity labels. If you use any of these features in a skillset or indexer, they don't process those documents.
 - Custom Web API skill
 - GenAI Prompt skill
 - Knowledge store
 - Indexer enrichment cache
 - Debug sessions

The following steps must be followed in order to configure sensitivity label synchronization in Azure AI Search.

1. Enable AI Search managed identity

Enable a [system-assigned managed identity](#) for your Azure AI Search service. This identity is required for the indexer to securely access Microsoft Purview and extract label metadata.

2. Enable RBAC on your AI Search service

Enable a [role-based access control \(RBAC\)](#) on your Azure AI Search service. This step is required so content-related operations such as indexing content and query the index succeed. Keep both RBAC and API keys to avoid disrupting operations that rely on API keys.

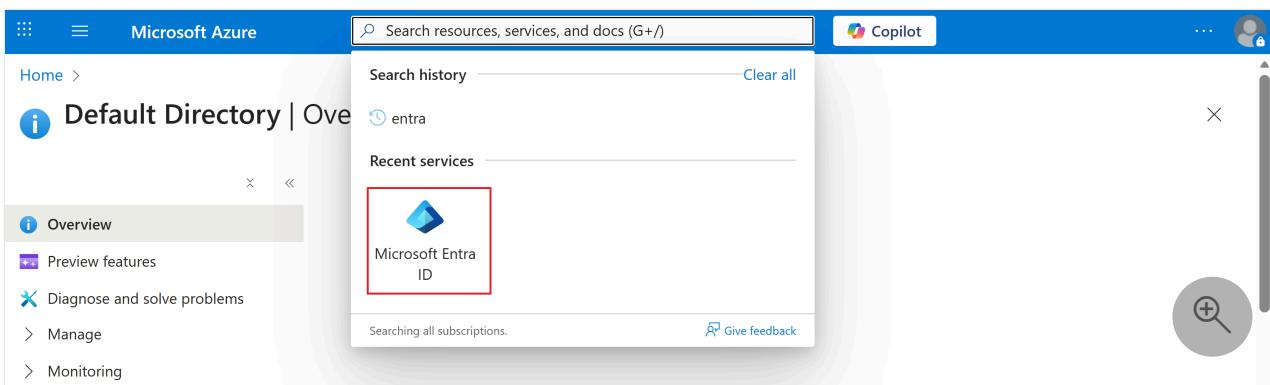

3. Granting access to extract sensitivity labels

Accessing Microsoft Purview sensitivity label metadata involves highly privileged operations, including reading encrypted content and security classifications. To enable this capability in Azure AI Search, you must grant specific roles to the service's managed identity—following your organization's internal governance and approval processes.

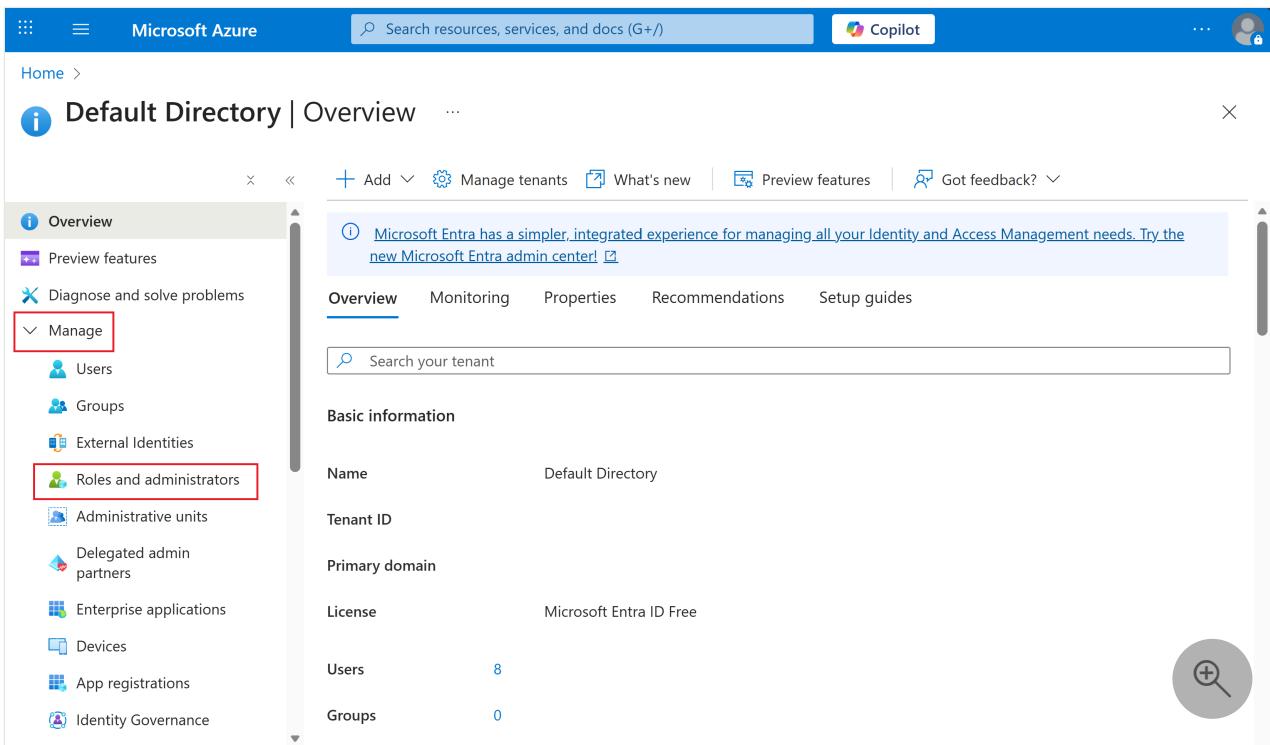

Identify your Global or Privileged Role Administrators

If you need to determine who can authorize permissions for the search service, you can locate active or eligible Global Administrators in your Microsoft Entra tenant.

1. In the [Azure portal](#), search for Microsoft Entra ID.

2. In the left navigation pane, select Manage > Roles and administrators.

3. Search for the Global Administrator or Privileged Role Administrator role and select it.

The screenshot shows the 'Roles and administrators | All roles' page in Microsoft Azure. On the left, a sidebar lists categories like 'All roles', 'Admin units', 'Protected actions', 'Diagnose and solve problems', 'Activity', and 'Troubleshooting + Support'. The main area displays two roles: 'Global Administrator' (selected) and 'Global Reader'. The 'Global Administrator' role is described as 'Can manage all aspects of Microsoft Entra ID and Microsoft services that use Microsoft Entra identities.' It is marked as 'PRIVILEGED' and has 4 assignments. The 'Global Reader' role is described as 'Can read everything that a Global Administrator can, but not update anything.' It is also marked as 'PRIVILEGED' and has 0 assignments. A search bar at the top right is set to 'Global'.

- Under **Eligible assignments** and **Active assignments**, review the list of administrators authorized to run the permissions setup process.

The screenshot shows the 'Global Administrator | Assignments' page. The sidebar includes 'Diagnose and solve problems' and 'Manage' sections, with 'Assignments' selected. The main area shows 'Eligible assignments' tab selected, displaying a table of users assigned to the Global Administrator role. The table columns are Name, UserName, Type, and Scope. Two users are listed: 'azureadmin' and 'demouser', both assigned to 'User' type with 'Directory' scope.

Name	UserName	Type	Scope
<input type="checkbox"/> azureadmin	azureadmin	User	Directory
<input type="checkbox"/> demouser	demouser	User	Directory

Secure Governance Approval

Engage your internal security or compliance teams to review the request. Microsoft recommends following your company's standard governance and security review process before proceeding with any role assignments.

Once approved, a Global Administrator or Privileged Role Administrator must assign the following roles to the Azure AI Search system-assigned managed identity:

- ContentSuperUser – for label and content extraction

- `UnifiedPolicy.Tenant.Read` – for Purview policy and label metadata access

Assign Roles via PowerShell

Your Global Administrator or Privileged Role Administrator should use the following PowerShell script to grant the required permissions. Replace the placeholder values with your actual subscription, resource group, and search service names.

PowerShell

```
Install-Module -Name Az -Scope CurrentUser
Install-Module -Name Microsoft.Entra -AllowClobber
Import-Module Az.Resources
Connect-Entra -Scopes 'Application.ReadWrite.All'

$resourceIdWithManagedIdentity =
"subscriptions/<subscriptionId>/resourceGroups/<resourceGroup>/providers/Microsoft.Search/searchServices/<searchServiceName>"
$managedIdentityObjectId = (Get-AzResource -ResourceId
$resourceIdWithManagedIdentity).Identity.PrincipalId

# Microsoft Information Protection (MIP)
$MIPResourceSP = Get-EntraServicePrincipal -Filter "appId eq '870c4f2e-85b6-4d43-bdda-6ed9a579b725'"
New-EntraServicePrincipalAppRoleAssignment -ServicePrincipalId
$managedIdentityObjectId -Principal $managedIdentityObjectId -ResourceId
$MIPResourceSP.Id -Id "8b2071cd-015a-4025-8052-1c0dba2d3f64"

# ARM Service Principal for policy read
$ARMSResourceSP = Get-EntraServicePrincipal -Filter "appId eq '00000012-0000-0000-c000-000000000000'"
New-EntraServicePrincipalAppRoleAssignment -ServicePrincipalId
$managedIdentityObjectId -Principal $managedIdentityObjectId -ResourceId
$ARMSResourceSP.Id -Id "7347eb49-7a1a-43c5-8eac-a5cd1d1c7cf0"
```

The appId roles in the provided PowerShell script are associated to the following Azure roles:

[] Expand table

AppID	Service Principal
870c4f2e-85b6-4d43-bdda-6ed9a579b725	Microsoft Info Protection Sync Service
00000012-0000-0000-c000-000000000000	Azure Resource Manager

4. Configure the index to enable Purview sensitivity label

When sensitivity label support is required, set the `purviewEnabled` property to true in your [index definition](#).

Important

The `purviewEnabled` property must be set to true when the index is created. This setting is permanent and can't be modified later. When `purviewEnabled` is set to true, only RBAC authentication is supported for all document operations APIs. API key access is limited to index schema retrieval (list and get).

```
PUT https://{{service}}.search.windows.net/indexes('{{indexName}}')?api-version=2025-11-01-preview
{
  "purviewEnabled": true,
  "fields": [
    {
      "name": "sensitivityLabel",
      "type": "Edm.String",
      "filterable": true,
      "sensitivityLabel": true,
      "retrievable": true
    }
  ]
}
```

5. Configure the data source

To enable sensitivity label ingestion, configure the [data source](#) with the `indexerPermissionOptions` property set to `["sensitivityLabel"]`.

```
{
  "name": "purview-sensitivity-datasource",
  "type": "azureblob", // < adjust type value according to the data source you are enabling this for: sharepoint, onelake, adlsgen2.
  "indexerPermissionOptions": [ "sensitivityLabel" ],
  "credentials": {
    "connectionString": <your-connection-string>
  },
}
```

```
"container": {  
    "name": "<container-name>"  
}  
}
```

The `indexerPermissionOptions` property instructs the indexer to extract sensitivity label metadata during ingestion and attach it to the indexed document.

6. Configure index projections in your skillset (if applicable)

If your indexer has a [skillset](#) and you're implementing data chunking through [split skill](#), for example, if you have integrated vectorization, you must ensure you also map the sensitivity label to each chunk via [index projections in the skillset](#).

```
PUT https://<service>.search.windows.net/skillsets/<skillset>?api-version=2025-11-01-preview  
{  
    "name": "my-skillset",  
    "skills": [  
        {  
            "@odata.type": "#Microsoft.Skills.Text.SplitSkill",  
            "name": "#split",  
            "context": "/document",  
            "inputs": [{ "name": "text", "source": "/document/content" }],  
            "outputs": [{ "name": "textItems", "targetName": "chunks" }]  
        }  
        // ... (other skills such as embeddings, entity recognition, etc.)  
    ],  
    "indexProjections": {  
        "selectors": [  
            {  
                "targetIndexName": "chunks-index",  
                "parentKeyFieldName": "parentId",           // must exist in target index  
                "sourceContext": "/document/chunks/*",      // match your split output path  
                "mappings": [  
                    { "name": "chunkId",           "source": "/document/chunks/*/id" },     //  
                    if you create an id per chunk  
                    { "name": "content",          "source": "/document/chunks/*/text" },   //  
                    chunk text  
                    { "name": "parentId",         "source": "/document/id" },           //  
                    parent doc id  
                    { "name": "sensitivityLabel", "source":  
                        "/document/metadata_sensitivity_label" } // <-- parent → child  
                ]  
            }  
        ],  
        "parameters": {
```

```
        "projectionMode": "skipIndexingParentDocuments"
    }
}
```

7. Configure the indexer

- Define field mappings in your [indexer definition](#) to route extracted label metadata to the index fields. If your data source emits label metadata under a different field name (for example, `metadata_sensitivity_label`), map it explicitly.

```
{
  "fieldMappings": [
    {
      "sourceFieldName": "metadata_sensitivity_label",
      "targetFieldName": "sensitivityLabel"
    }
  ]
}
```

- Sensitivity label updates are indexed automatically when changes to a document's label, content, or metadata are detected during a scheduled indexer run. [Configure the indexer on a recurring schedule](#). The minimum supported interval is every 5 minutes.

Query-Time Microsoft Purview Sensitivity Label Enforcement in Azure AI Search

!Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

At query time, Azure AI Search enforces sensitivity label policies defined in [Microsoft Purview](#). These policies include evaluation of [READ usage rights](#) tied to each document. As a result, users can only retrieve documents they are allowed to view.

This capability extends [document-level access control](#) to align with your organization's [information protection and compliance requirements](#) managed in Microsoft Purview.

When Purview sensitivity label indexing is enabled, Azure AI Search checks each document's label metadata during query time. It applies access filters based on Purview policies to return only results the requesting user is allowed to access.

This article explains how query-time sensitivity label enforcement works and how to issue secure search queries.

Prerequisites

Before you can query a sensitivity-label-enabled index, the following conditions must be met:

- You must follow all steps for [Azure AI Search indexers to ingest Microsoft Purview sensitivity labels](#).
- Both the Azure AI Search service and the user issuing the query must belong to the same Microsoft Entra tenant.
- The latest [preview API version 2025-11-01-preview](#) or a compatible beta SDK must be used to query the index.
- Queries must be authenticated using [Azure role-based access control \(RBAC\)](#), not API keys. API key access is restricted to index schema retrieval only when Purview sensitivity labels functionality is enabled.

Limitations

- [Microsoft Entra Guest users](#) and cross-tenant queries aren't supported.
- [Autocomplete](#) and [Suggest](#) APIs are unsupported for Purview-enabled indexes.
- If label evaluation fails (for example, Purview APIs are temporarily unavailable), the service returns 5xx and does **not** return a partial or unfiltered result set.
- [ACL-based security filters](#) aren't supported alongside sensitivity label functionality at this time. Don't enable both at the same time. Once combined usage is supported, it will be documented accordingly.
- The system evaluates labels only as they existed at the time of the last indexer run; recent label changes may not be reflected until the next scheduled reindex.

How query-time sensitivity label enforcement works

When you query an index that includes Microsoft Purview sensitivity labels, Azure AI Search checks the associated Purview policies before returning results. In this way, the query returns only documents that the user token is allowed to access.

1. User identity and application role input

At query time, Azure AI Search validates both:

- The calling application's RBAC role, provided in the `Authorization` header.
- The user identity via token, provided in the `x-ms-query-source-authorization` header.

Both are required to authorize label-based visibility.

 Expand table

Input type	Description	Example source
Application role	Determines whether the calling app has permission to execute queries on the index.	<code>Authorization: Bearer <app-token></code>
User identity	Determines which sensitivity labels the end user is allowed to access.	<code>x-ms-query-source-authorization: Bearer <user-token></code>

2. Sensitivity label evaluation

When a query request is received, Azure AI Search evaluates:

1. The sensitivityLabel field in each indexed document (extracted from Microsoft Purview during ingestion).
2. The user's effective Purview permissions, as defined by Microsoft Entra ID and Purview label policy.

If the user isn't authorized for a document's sensitivity label with extract permissions, that document is excluded from the query results.

 **Note**

Internally, the service builds dynamic access filters similar to RBAC enforcement. These filters aren't user-visible and can't be modified in the query payload.

3. Secure result filtering

Azure AI Search applies the security filter after all user-defined filters and scoring steps. A document is included in the final result set only if:

- The calling application has a valid role assignment (via RBAC), and
- The user identity token represented by `x-ms-query-source-authorization` is valid and permitted to view content with the document's sensitivity label.

If either condition fails, the document is omitted from the results.

Query example

Here's an example of a query request using Microsoft Purview sensitivity label enforcement. The query token is passed in the request headers. Both headers must include valid bearer tokens representing the application and the end user.

HTTP

```
POST {{endpoint}}/indexes/sensitivity-docs/docs/search?api-version=2025-11-01-preview
Authorization: Bearer {{app-query-token}}
x-ms-query-source-authorization: Bearer {{user-query-token}}
Content-Type: application/json

{
  "search": "*",
  "select": "title,summary,sensitivityLabel",
  "orderby": "title asc"
}
```

Sensitivity label handling in Azure AI Search

When Azure AI Search indexes document content with sensitivity labels from sources like SharePoint, Azure Blob, and others, it stores both the content and the label metadata. The search query returns indexed content along with the GUID that identifies the sensitivity label applied to the document, only if the user has data READ access for that document. This GUID uniquely identifies the label but doesn't include human-readable properties such as the label name or associated permissions.

Note that the GUID alone is insufficient for scenarios that include user interface because sensitivity labels often carry other policy controls enforced by [Microsoft Purview Information Protection](#), such as: print permissions or screenshot and screen capture restrictions. Azure AI Search doesn't surface these capabilities.

To display label names and/or enforce UI-specific restrictions, your application must call the Microsoft Purview Information Protection endpoint to retrieve full label metadata and associated permissions.

You can use the GUID returned by Azure AI Search to resolve the label properties and call the [Purview Labels APIs](#) to fetch the label name, description, and policy settings. This [end-to-end demo sample](#) includes code that shows how to call the endpoint from a user interface. It also demonstrates how to extract the label name and expose it as part of the citations used in your RAG applications or agents.

Configure customer-managed keys for data encryption in Azure AI Search

09/18/2025

Azure AI Search automatically encrypts data at rest with [Microsoft-managed keys](#). If you need another layer of encryption or the ability to revoke keys and shut down access to content, you can use keys that you create and manage in Azure Key Vault. This article explains how to set up customer-managed key (CMK) encryption.

You can store keys using either:

- Azure Key Vault
- Azure Key Vault Managed HSM (Hardware Security Module). An Azure Key Vault Managed HSM is an FIPS 140-2 Level 3 validated HSM. HSM support is new in Azure AI Search. To migrate from Azure Key Vault to HSM, [rotate your keys](#) and choose Managed HSM for storage.

Important

- CMK provides encryption for data at rest. If you need to protect data in use, consider using [confidential computing](#).
- CMK encryption is irreversible. You can rotate keys and change CMK configuration, but index encryption lasts for the lifetime of the index. Post-CMK encryption, an index is only accessible if the search service has access to the key. If you revoke access to the key by deleting or changing role assignment, the index is unusable and the service can't be scaled until the index is deleted or access to the key is restored. If you delete or rotate keys, the most recent key is cached for up to 60 minutes.

CMK encrypted objects

CMK encryption applies to individual objects when they're created. This means you can't encrypt objects that already exist. CMK encryption occurs each time an object is saved to disk, for both data at rest (long-term storage) or temporary cached data (short-term storage). With CMK, the disk never sees unencrypted data.

Objects that can be encrypted include indexes, synonym lists, indexers, data sources, and skillsets. Encryption is computationally expensive to decrypt so only sensitive content is

encrypted.

Encryption is performed over the following content:

- All content within indexes and synonym lists.
- Sensitive content in indexers, data sources, skillsets, and vectorizers. Sensitive content refers to connection strings, descriptions, identities, keys, and user inputs. For example, skillsets have Azure AI services keys, and some skills accept user inputs, such as custom entities. In both cases, keys and user inputs are encrypted. Any references to external resources (such as Azure data sources or Azure OpenAI models) are also encrypted.

If you require CMK across your search service, [set an enforcement policy](#).

Although you can't add encryption to an existing object, once an object is configured for encryption, you can change all parts of its encryption definition, including switching to a different key vault or HMS storage as long as the resource is in the same tenant.

Prerequisites

- [Azure AI Search](#) on a [billable tier](#) (Basic or higher, in any region).
- [Azure Key Vault](#) and a key vault with [soft-delete](#) and [purge protection](#) enabled. Or, [Azure Key Vault Managed HSM](#). This resource can be in any subscription, but it must be in the same tenant as Azure AI Search.
- Ability to set up permissions for key access and to assign roles. To create keys, you must be [Key Vault Crypto Officer](#) in Azure Key Vault or [Managed HSM Crypto Officer](#) in Azure Key Vault Managed HSM.

To assign roles, you must be subscription [Owner](#), [User Access Administrator](#), [Role-based Access Control Administrator](#), or be assigned to a custom role with [Microsoft.Authorization/roleAssignments/write](#) permissions.

Step 1: Create an encryption key

Use either Azure Key Vault or Azure Key Vault Managed HSM to create a key. Azure AI Search encryption supports RSA keys of sizes 2048, 3072 and 4096. For more information about supported key types, see [About keys](#).

We recommend reviewing [these tips](#) before you start.

Required operations are [Wrap](#), [Unwrap](#), [Encrypt](#), and [Decrypt](#).

You can [create a key vault using the Azure portal](#), [Azure CLI](#), or [Azure PowerShell](#).

1. Sign in to the [Azure portal](#) and open your key vault overview page.
2. Select **Objects > Keys** on the left, and then select **Generate/Import**.
3. In the **Create a key** pane, from the list of **Options**, choose **Generate** to create a new key.
4. Enter a **Name** for your key, and accept the defaults for other key properties.
5. Optionally, set a key rotation policy to [enable auto rotation](#).
6. Select **Create** to start the deployment.
7. After the key is created, get its key identifier. Select the key, select the current version, and then copy the key identifier. It's composed of the **key value Uri**, the **key name**, and the **key version**. You need the identifier to define an encrypted index in Azure AI Search. Recall that required operations are **Wrap**, **Unwrap**, **Encrypt**, and **Decrypt**.

 Encrypt Decrypt Sign Verify Wrap Key Unwrap Key

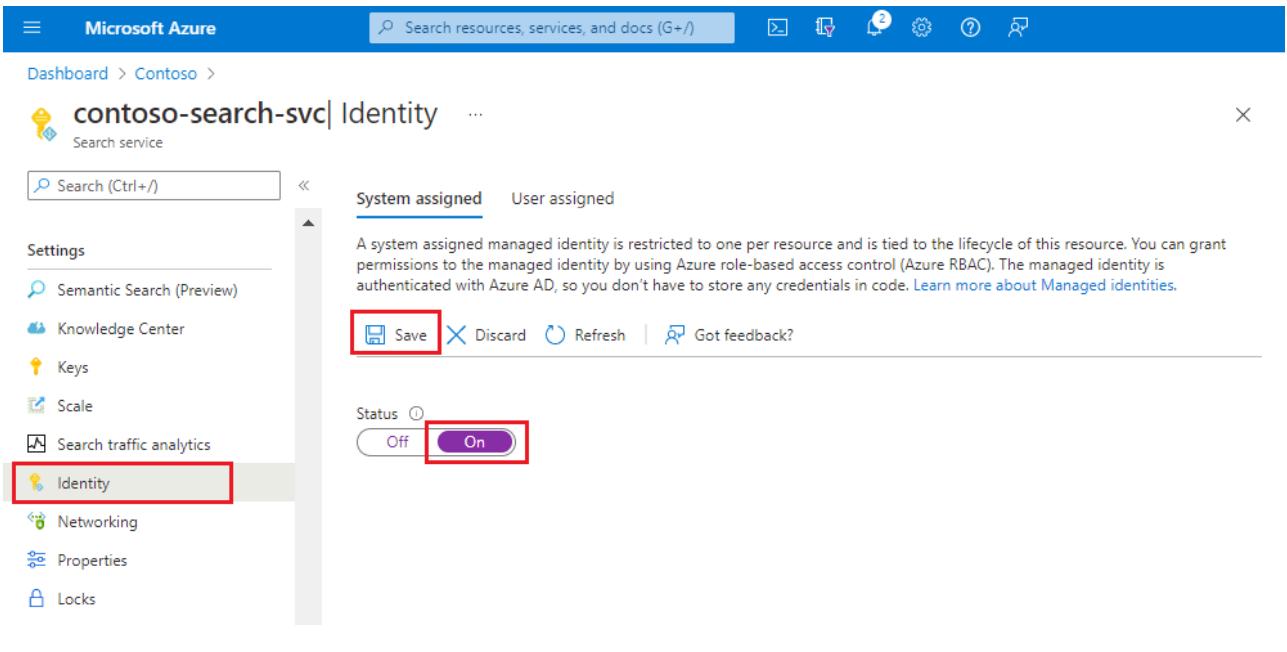

Step 2: Create a security principal

Create a security principal that your search service uses to access to the encryption key. You can use a managed identity and role assignment, or you can register an application and have the search service provide the application ID on requests.

We recommend using a managed identity and roles. You can use either a system-managed identity or user-managed identity. A managed identity enables your search service to authenticate through Microsoft Entra ID, without storing credentials (ApplicationID or ApplicationSecret) in code. The lifecycle of this type of managed identity is tied to the lifecycle of your search service, which can only have one system assigned managed identity. For more information about how managed identities work, see [What are managed identities for Azure resources](#).

System-managed identity

Enable the system-assigned managed identity for your search service. It's a two-click operation: enable and save.

The screenshot shows the Azure portal interface for managing a search service. The top navigation bar includes 'Microsoft Azure', a search bar, and various icons. Below the navigation is a breadcrumb trail: 'Dashboard > Contoso > contoso-search-svc Identity'. The main content area has a title 'contoso-search-svc| Identity' and tabs for 'System assigned' and 'User assigned'. A note explains that a system assigned managed identity is restricted to one per resource and is tied to the lifecycle of the resource. It mentions Azure RBAC and Azure AD authentication. At the bottom are buttons for 'Save' (highlighted), 'Discard', 'Refresh', and 'Got feedback?'. On the left, a sidebar lists 'Settings' (Semantic Search, Knowledge Center, Keys, Scale, Search traffic analytics), 'Networking', 'Properties', and 'Locks'. The 'Identity' option is specifically highlighted with a red box. The 'Status' section shows a toggle switch between 'Off' (gray) and 'On' (purple, highlighted with a red box). The overall theme is light blue and white.

Step 3: Grant permissions

If you configured your search service to use a managed identity, assign roles that give it access to the encryption key.

Role-based access control is recommended over the Access Policy permission model. For more information or migration steps, start with [Azure role-based access control \(Azure RBAC\) vs. access policies \(legacy\)](#).

1. Sign in to the [Azure portal](#) and find your key vault.
2. Select **Access control (IAM)** and select **Add role assignment**.
3. Select a role:
 - On Azure Key Vault, select **Key Vault Crypto Service Encryption User**.

- On Managed HSM, select **Managed HSM Crypto Service Encryption User**.
4. Select managed identities, select members, and then select the managed identity of your search service. If you're testing locally, assign this role to yourself as well.
5. Select **Review + Assign**.

Wait a few minutes for the role assignment to become operational.

Step 4: Encrypt content

Encryption occurs when you create or update an object. You can use the Azure portal for selected objects. For any object, use the [Search REST API](#) or an Azure SDK. Review the [Python example](#) in this article to see how content is encrypted programmatically.

Azure portal

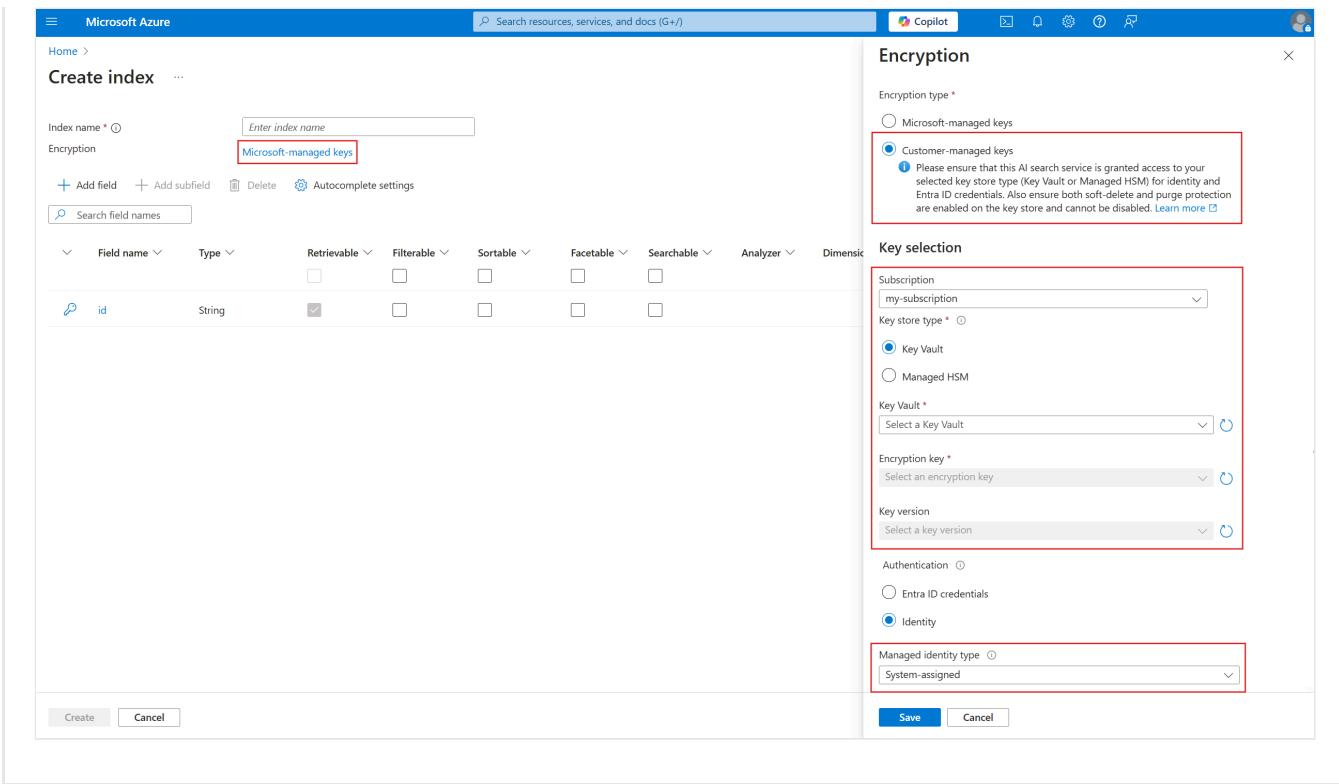

When you create a new object in the Azure portal, you can specify a predefined customer-managed key in a key vault. The Azure portal lets you enable CMK encryption for:

- Indexes
- Data sources
- Indexers

Requirements for using the Azure portal are that the key vault and key must exist, and you completed the previous steps for authorized access to the key.

In the Azure portal, skillsets are defined in JSON view. Use the JSON shown in the REST API examples to provide a customer-managed key on a skillset.

1. Sign in to the [Azure portal](#) and open your search service page.
2. Under **Search management**, select **Indexes**, **Indexers**, or **Data Sources**.
3. Add a new object. In the object definition, select **Microsoft-managed encryption**.
4. Select **Customer-managed keys** and choose your subscription, vault, key, and version.

Step 5: Test encryption

To verify encryption is working, revoke the encryption key, query the index (it should be unusable), and then reinstate the encryption key.

Use the Azure portal for this task. Make sure you have a role assignment that grants read access to the key.

1. On the Azure Key Vault page, select **Objects > Keys**.
2. Select the key you created, and then select **Delete**.
3. On the Azure AI Search page, select **Search management > Indexes**.
4. Select your index and use Search Explorer to run a query. You should get an error.
5. Return to the Azure Key Vault **Objects > Keys** page.
6. Select **Manage deleted keys**.
7. Select your key, and then select **Recover**.
8. Return to your index in Azure AI Search and rerun the query. You should see search results. If you don't see immediate results, wait a minute and try again.

Set up a policy to enforce CMK compliance

Azure policies help to enforce organizational standards and to assess compliance at-scale. Azure AI Search has two optional built-in policies related to CMK. These policies apply to new and existing search services.

[] Expand table

Effect	Effect if enabled
AuditIfNotExists	Checks for policy compliance: do objects have a customer-managed key defined, and is the content encrypted. This effect applies to existing services with content. It's evaluated each time an object is created or updated, or per the evaluation schedule . Learn more... ↗
Deny	Checks for policy enforcement: does the search service have SearchEncryptionWithCmk set to <code>Enabled</code> . This effect applies to new services only, which must be created with encryption enabled. Existing services remain operational but you can't update them unless you patch the service. None of the tools used for provisioning services expose this property, so be aware that setting the policy limits you to programmatic set up .

Assign a policy

1. In the Azure portal, navigate to a built-in policy and then select **Assign**.

- [AuditIfExists](#) ↗
- [Deny](#) ↗

Here's an example of the **AuditIfExists** policy in the Azure portal:

2. Set **policy scope** by selecting the subscription and resource group. Exclude any search services for which the policy shouldn't apply.
3. Accept or modify the defaults. Select **Review +create**, followed by **Create**.

Enable CMK policy enforcement

A policy that's assigned to a resource group in your subscription is effective immediately. Audit policies flag non-compliant resources, but Deny policies prevent the creation and update of non-compliant search services. This section explains how to create a compliant search service

or update a service to make it compliant. To bring objects into compliance, start at [step one](#) of this article.

Create a compliant search service

For new search services, create them with [SearchEncryptionWithCmk](#) set to `Enabled`.

Neither the Azure portal nor the command line tools (the Azure CLI and Azure PowerShell) provide this property natively, but you can use [Management REST API](#) to provision a search service with a CMK policy definition.

Management REST API

This example is from [Manage your Azure AI Search service with REST APIs](#), modified to include the [SearchEncryptionWithCmk](#) property.

```
rest

### Create a search service (provide an existing resource group)
@Resource-group = my-rg
@search-service-name = my-search
PUT
https://management.azure.com/subscriptions/{{subscriptionId}}/resourceGroups/{{resource-group}}/providers/Microsoft.Search/searchServices/{{search-service-name}}?api-version=2025-05-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}

{
    "location": "North Central US",
    "sku": {
        "name": "basic"
    },
    "properties": {
        "replicaCount": 1,
        "partitionCount": 1,
        "hostingMode": "default",
        "encryptionWithCmk": {
            "enforcement": "Enabled"
        }
    }
}
```

Update an existing search service

For existing search services that are now non-compliant, patch them using [Services - Update API](#) or the Azure CLI `az resource update` command. Patching the services restores the ability to update search service properties.

Management REST API

HTTP

```
PATCH https://management.azure.com/subscriptions/<your-subscription-Id>/resourceGroups/<your-resource-group-name>/providers/Microsoft.Search/searchServices/<your-search-service-name>?api-version=2025-05-01

{
  "properties": {
    "encryptionWithCmk": {
      "enforcement": "Enabled"
    }
  }
}
```

Rotate or update encryption keys

Use the following instructions to rotate keys or to migrate from Azure Key Vault to the Hardware Security Model (HSM).

For key rotation, we recommend using the [autorotation capabilities of Azure Key Vault](#). If you use autorotation, omit the key version in object definitions. The latest key is used, rather than a specific version.

When you change a key or its version, any object that uses the key must first be updated to use the new values **before** you delete the old values. Otherwise, the object becomes unusable because it can't be decrypted.

Recall that keys are cached for 60 minutes. Remember this when testing and rotating keys.

1. [Determine the key used by an index or synonym map.](#)
2. [Create a new key in key vault](#), but leave the original key available. In this step, you can switch from key vault to HSM.
3. [Update the encryptionKey properties](#) on an index or synonym map to use the new values. Only objects that were originally created with this property can be updated to use a different value.

4. Disable or delete the previous key in the key vault. Monitor key access to verify the new key is being used.

For performance reasons, the search service caches the key for up to several hours. If you disable or delete the key without providing a new one, queries continue to work on a temporary basis until the cache expires. However, once the search service can no longer decrypt content, you get this message: "Access forbidden. The query key used might have been revoked - please retry."

Key Vault tips

- If you're new to Azure Key Vault, review this quickstart to learn about basic tasks: [Set and retrieve a secret from Azure Key Vault using PowerShell](#).
- Use as many key vaults as you need. Managed keys can be in different key vaults. A search service can have multiple encrypted objects, each one encrypted with a different customer-managed encryption key, stored in different key vaults.
- Use the same [Azure tenant](#) so that you can retrieve your managed key through role assignments and by connecting through a system or user-managed identity. For more information about creating a tenant, see [Set up a new tenant](#).
- [Enable purge protection](#) and [soft-delete](#) on a key vault. Due to the nature of encryption with customer-managed keys, no one can retrieve your data if your Azure Key Vault key is deleted. To prevent data loss caused by accidental Key Vault key deletions, soft-delete and purge protection must be enabled on the key vault. Soft-delete is enabled by default, so you'll only encounter issues if you purposely disable it. Purge protection isn't enabled by default, but it's required for CMK encryption in Azure AI Search.
- [Enable logging](#) on the key vault so that you can monitor key usage.
- [Enable autorotation of keys](#) or follow strict procedures during routine rotation of key vault keys and application secrets and registration. Always update all [encrypted content](#) to use new secrets and keys before deleting the old ones. If you miss this step, your content can't be decrypted.

Work with encrypted content

With CMK encryption, you might notice latency for both indexing and queries due to the extra encrypt/decrypt work. Azure AI Search doesn't log encryption activity, but you can monitor key access through key vault logging.

We recommend that you [enable logging](#) as part of key vault configuration.

1. [Create a log analytics workspace](#).
2. [Add a diagnostic setting in key vault](#) that uses the workspace for data retention.
3. Select **audit** or **allLogs** for the category, give the diagnostic setting a name, and then save it.

Python example of an encryption key configuration

This section shows the Python representation of an `encryptionKey` in an object definition. The same definition applies to indexes, data sources, skillets, indexers, and synonym maps. To try this example on your search service and key vault, download the notebook from [azure-search-python-samples](#) ↗.

Install some packages.

Python

```
! pip install python-dotenv
! pip install azure-core
! pip install azure-search-documents==11.5.1
! pip install azure-identity
```

Create an index that has an encryption key.

Python

```
from azure.search.documents.indexes import SearchIndexClient
from azure.search.documents.indexes.models import (
    SimpleField,
    SearchFieldDataType,
    SearchableField,
    SearchIndex,
    SearchResourceEncryptionKey
)
from azure.identity import DefaultAzureCredential

endpoint=<PUT YOUR AZURE SEARCH SERVICE ENDPOINT HERE>
credential = DefaultAzureCredential()

index_name = "test-cmk-index"
index_client = SearchIndexClient(endpoint=endpoint, credential=credential)
fields = [
    SimpleField(name="Id", type=SearchFieldDataType.String, key=True),
```

```

        SearchableField(name="Description", type=SearchFieldDataType.String)
    ]

scoring_profiles = []
suggester = []
encryption_key = SearchResourceEncryptionKey(
    key_name=<PUT YOUR KEY VAULT NAME HERE>,
    key_version=<PUT YOUR ALPHANUMERIC KEY VERSION HERE>,
    vault_uri=<PUT YOUR KEY VAULT ENDPOINT HERE>
)

index = SearchIndex(name=index_name, fields=fields, encryption_key=encryption_key)
result = index_client.create_or_update_index(index)
print(f' {result.name} created')

```

Get the index definition to verify encryption key configuration exists.

Python

```

index_name = "test-cmk-index-qs"
index_client = SearchIndexClient(endpoint=AZURE_SEARCH_SERVICE,
credential=credential)

result = index_client.get_index(index_name)
print(f"{result}")

```

Load the index with a few documents. All field content is considered sensitive and is encrypted on disk using your customer managed key.

Python

```

from azure.search.documents import SearchClient

# Create a documents payload
documents = [
    {
        "@search.action": "upload",
        "Id": "1",
        "Description": "The hotel is ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Time's Square and the historic centre of the city, as well as other places of interest that make New York one of America's most attractive and cosmopolitan cities."
    },
    {
        "@search.action": "upload",
        "Id": "2",
        "Description": "The hotel is situated in a nineteenth century plaza, which has been expanded and renovated to the highest architectural standards to create a modern, functional and first-class hotel in which art and unique historical elements coexist with the most modern comforts."
    },
]

```

```

    },
    "@search.action": "upload",
    "Id": "3",
    "Description": "The hotel stands out for its gastronomic excellence under the
management of William Dough, who advises on and oversees all of the Hotel's
restaurant services."
},
{
    "@search.action": "upload",
    "Id": "4",
    "Description": "The hotel is located in the heart of the historic center of
Sublime in an extremely vibrant and lively area within short walking distance to
the sites and landmarks of the city and is surrounded by the extraordinary beauty
of churches, buildings, shops and monuments. Sublime Palace is part of a lovingly
restored 1800 palace."
}
]

search_client = SearchClient(endpoint=AZURE_SEARCH_SERVICE, index_name=index_name,
credential=credential)
try:
    result = search_client.upload_documents(documents=documents)
    print("Upload of new document succeeded: {}".format(result[0].succeeded))
except Exception as ex:
    print(ex.message)

index_client = SearchClient(endpoint=AZURE_SEARCH_SERVICE,
credential=credential)

```

Run a query to confirm the index is operational.

Python

```

from azure.search.documents import SearchClient

query = "historic"

search_client = SearchClient(endpoint=AZURE_SEARCH_SERVICE, credential=credential,
index_name=index_name)

results = search_client.search(
    query_type='simple',
    search_text=query,
    select=["Id", "Description"],
    include_total_count=True
)

for result in results:
    print(f"Score: {result['@search.score']}")
    print(f"Id: {result['Id']}")
    print(f"Description: {result['Description']}")

```

Output from the query should produce results similar to the following example.

```
Score: 0.6130029
```

```
Id: 4
```

```
Description: The hotel is located in the heart of the historic center of Sublime in an extremely vibrant and lively area within short walking distance to the sites and landmarks of the city and is surrounded by the extraordinary beauty of churches, buildings, shops and monuments. Sublime Palace is part of a lovingly restored 1800 palace.
```

```
Score: 0.26286605
```

```
Id: 1
```

```
Description: The hotel is ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Time's Square and the historic centre of the city, as well as other places of interest that make New York one of America's most attractive and cosmopolitan cities.
```

Since encrypted content is decrypted prior to data refresh or queries, you won't see visual evidence of encryption. To verify encryption is working, check the resource logs.

Next steps

If you're unfamiliar with Azure security architecture, review the [Azure Security documentation](#), and in particular, this article:

[Data encryption-at-rest](#)

Configure customer-managed keys across different tenants

10/14/2025

When Azure Key Vault and Azure AI Search are in different Azure tenants, use a Microsoft Entra multitenant app to enable [customer-managed key \(CMK\) encryption](#) using a key from another tenant.

Prerequisites

- A tenant containing the search service that has content you want to encrypt. Azure AI Search must be [configured for role-based access](#). Support for CMK requires Basic pricing tier or higher.
- A separate tenant having the Azure Key Vault and the encryption keys you want to use. Azure Key Vault must be [configured for role-based access](#).
- Azure CLI for sending requests.

Create a multitenant Microsoft Entra application in tenant A

Use the Azure CLI to send requests. We refer to the tenant containing Azure AI Search as *tenant A*.

1. Get the tenant ID:

```
az account show --query tenantId --output tsv
```

2. Make sure you're signed in to tenant A:

```
az login --tenant <tenant-A-id>
```

3. Create the application registration:

```
az ad app create --display-name cross-tenant-auth --sign-in-audience
AzureADMultipleOrgs
```

4. Save the app ID output from this step.

Add a client secret to the multitenant application

1. To add the client secret to the multitenant application in tenant A, run the following command:

```
az ad app credential reset --id <multitenant-app-id>
```

2. Save the password output from this step. The password output is a required input for [setting up CMK](#) in Azure AI Search.

3. To specify when the client secret expires, you can specify an end-date parameter to this command.

```
az ad app credential reset --id <multitenant-app-id> --end-date <end-date>
```

The end-date parameter accepts a date in ISO 8601 format. For example: `az ad app credential reset --id <multitenant-app-id> --end-date 2026-12-31`.

Create a service principal in tenant B for the multitenant application

We refer to the tenant containing Azure Key Vault as *tenant B*. In tenant B, create a service principal for the multitenant application in tenant A.

1. Sign in to tenant B:

```
az login --tenant <tenant-B-id>
```

2. Create the service principal using the multitenant app ID output from the first step:

```
az ad sp create --id <multitenant-app-id>
```

This service principal is an instance of the multitenant application in tenant A. Roles assigned to this service principal in tenant B are also assigned to the multitenant application in tenant A.

3. Verify the link between tenant A and B by reviewing the "appOwnerOrganizationId" in the following command:

```
az ad sp show --id <multitenant-app-id>
```

This command displays the service principal details in JSON. Look for the "appOwnerOrganizationId" field in the output to confirm it matches tenant A's ID.

4. Save the object ID of the service principal (from the "id" field) from this step. The object ID is a required input for setting up CMK in Azure AI Search.

5. Get the resource ID for Azure Key Vault:

```
az keyvault show --name <key-vault-name> --query id --output tsv
```

6. Assign the **Key Vault Crypto Service Encryption User** role on the key vault in tenant B to the new service principal.

```
az role assignment create --assignee <service-principal-object-id> --role "Key Vault  
Crypto Service Encryption User" --scope <key-vault-resource-id>
```

An example of this assignment might look like this:

```
az role assignment create --assignee 12345678-1234-1234-1234-123456789012 --role  
"Key Vault Crypto Service Encryption User" --scope /subscriptions/87654321-4321-  
4321-4321-  
210987654321/resourceGroups/myKeyVaultRG/providers/Microsoft.KeyVault/vaults/myCompa  
nyKeyVault
```

Test encryption

Create a test index in the search service (tenant A) to validate the setup. Use the multitenant app ID and the credentials you added in the "access credentials" object to authenticate to the key vault in the other tenant.

You can use this sample index schema for testing. You can use the Azure portal to add an index and provide this JSON, or use a [REST client](#) to send a Create Index request.

JSON

```
{  
  "name": "cross-tenant-cmk-test",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true  
    }  
  ],  
  "encryptionKey": {  
    "keyVaultUri": "https://myCompanyKeyVault.vault.azure.net/",  
    "keyVaultKeyName": "search-encryption-key",  
    "keyVaultKeyVersion": "abc123def456ghi789",  
    "accessCredentials": {  
      "tenantId": "87654321-4321-4321-4321-210987654321",  
      "clientSecret": "MyClientSecret",  
      "objectType": "ServicePrincipal"  
    }  
  }  
}
```

```
        "applicationId": "12345678-1234-1234-1234-123456789012",
        "applicationSecret": "secretValueFromStep2"
    }
}
```

Verify the index was created successfully:

HTTP

```
GET https://<search-service>.search.windows.net/indexes/cross-tenant-cmk-test?api-version=2025-09-01
```

For more information about how to rotate or manage keys, see [Configure customer-managed keys for data encryption](#).

Find encrypted objects and information

Article • 04/14/2025

In Azure AI Search, customer-managed encryption keys are created, stored, and managed in Azure Key Vault. If you need to determine whether an object is encrypted, or what key name or version is used in Azure Key Vault, use the REST API or an Azure SDK to retrieve the **encryptionKey** property from the object definition in your search service.

Objects that aren't encrypted with a customer-managed key have an empty **encryptionKey** property. Otherwise, you might see a definition similar to the following example.

JSON

```
"encryptionKey":{  
    "keyVaultUri":"https://demokeyvault.vault.azure.net",  
    "keyVaultKeyName":"myEncryptionKey",  
    "keyVaultKeyVersion":"eaab6a663d59439ebb95ce2fe7d5f660",  
    "accessCredentials":{  
        "applicationId":"00001111-aaaa-2222-bbbb-3333cccc4444",  
        "applicationSecret":"myApplicationSecret"  
    }  
}
```

The **encryptionKey** construct is the same for all encrypted objects. It's a first-level property, on the same level as the object name and description.

Permissions for retrieving object definitions

You must have [Search Service Contributor](#) or equivalent permissions. To use [key-based authentication](#) instead, provide an admin API key. Admin permissions are required on requests that return object definitions and metadata. The easiest way to get the admin API key is through the Azure portal.

1. Sign in to the [Azure portal](#) and open the search service overview page.
2. On the left side, select **Keys** and copy an admin API.

For the remaining steps, switch to PowerShell and the REST API. The Azure portal doesn't show encryption key information for any object.

Retrieve object properties

Use PowerShell and REST to run the following commands to set up the variables and get object definitions.

Alternatively, you can also use the Azure SDK for [.NET](#), [Python](#), [JavaScript](#), and [Java](#).

First, connect to your Azure account.

```
PowerShell
```

```
Connect-AzAccount
```

If you have more than one active subscription in your tenant, specify the subscription containing your search service:

```
PowerShell
```

```
Set-AzContext -Subscription <your-subscription-ID>
```

Set up the headers used on each request in the current session. Provide the admin API key used for search service authentication.

```
PowerShell
```

```
$headers = @{
    'api-key' = '<YOUR-ADMIN-API-KEY>'
    'Content-Type' = 'application/json'
    'Accept' = 'application/json' }
```

To return a list of all search indexes, set the endpoint to the indexes collection.

```
PowerShell
```

```
$uri= 'https://<YOUR-SEARCH-SERVICE>.search.windows.net/indexes?api-version=2024-07-01&$select=name'
Invoke-RestMethod -Uri $uri -Headers $headers | ConvertTo-Json
```

To return a specific index definition, provide its name in the path. The encryptionKey property is at the end.

```
PowerShell
```

```
$uri= 'https://<YOUR-SEARCH-SERVICE>.search.windows.net/indexes/<YOUR-INDEX-NAME>?api-version=2024-07-01'
Invoke-RestMethod -Uri $uri -Headers $headers | ConvertTo-Json
```

To return synonym maps, set the endpoint to the synonyms collection and then send the request.

```
PowerShell
```

```
$uri= 'https://<YOUR-SEARCH-SERVICE>.search.windows.net/synonyms?api-version=2024-07-01&$select=name'  
Invoke-RestMethod -Uri $uri -Headers $headers | ConvertTo-Json
```

The following example returns a specific synonym map definition, including the encryptionKey property is towards the end of the definition.

```
PowerShell
```

```
$uri= 'https://<YOUR-SEARCH-SERVICE>.search.windows.net/synonyms/<YOUR-SYNONYM-MAP-NAME>?api-version=2024-07-01'  
Invoke-RestMethod -Uri $uri -Headers $headers | ConvertTo-Json
```

Use the same pattern to return the encryptionKey property for other top-level objects such as indexers, skillsets, data sources, and index aliases.

Next steps

We recommend that you [enable logging](#) on Azure Key Vault so that you can monitor key usage.

For more information about using Azure Key or configuring customer managed encryption:

- [Quickstart: Set and retrieve a secret from Azure Key Vault using PowerShell](#)
- [Configure customer-managed keys for data encryption in Azure AI Search](#)

API versions in Azure AI Search

Azure AI Search rolls out feature updates regularly. Sometimes, but not always, these updates require a new version of the API to preserve backward compatibility. Publishing a new version allows you to control when and how you integrate search service updates in your code.

As a rule, the REST APIs and libraries are versioned only when necessary, since it can involve some effort to upgrade your code to use a new API version. A new version is needed only if some aspect of the API has changed in a way that breaks backward compatibility. Such changes can happen because of fixes to existing features, or because of new features that change existing API surface area.

For more information about the deprecation path, see the [Azure SDK lifecycle and support policy](#).

Deprecated versions

2023-07-01-preview was deprecated on April 8, 2024 and won't be supported after July 8, 2024.

This was the first REST API that offered vector search support. Newer API versions have a different vector configuration. You should [migrate to a newer version](#) as soon as possible.

Discontinued versions

Some API versions are discontinued and are no longer documented or supported:

- 2015-02-28
- 2015-02-28-Preview
- 2014-07-31-Preview
- 2014-10-20-Preview

All SDKs are based on REST API versions. If a REST version is discontinued, SDK packages based on that version are also discontinued. All Azure AI Search .NET SDKs older than [3.0.0-rc](#) are now obsolete.

Support for the above-listed versions ended on October 15, 2020. If you have code that uses a discontinued version, you can [migrate existing code](#) to a newer [REST API version](#) or to a newer Azure SDK.

REST APIs

Preview features in Azure AI Search

This article identifies all data plane and control plane features in public preview. This list is helpful for checking feature status. It also explains how to call a preview REST API.

Preview API versions are cumulative and roll up to the next preview. We recommend always using the latest preview APIs for full access to all preview features.

Preview features are removed from this list if they're retired or transition to general availability. For announcements regarding general availability and retirement, see [Service Updates](#) or [What's New](#).

Data plane preview features

[+] [Expand table](#)

Feature	Description	Availability
Agentic retrieval	<p>Create a conversational search experience powered by large language models (LLMs). Agentic retrieval breaks down complex user queries into subqueries, runs the subqueries simultaneously, reranks the results for relevance, and either extracts grounding data or synthesizes answers into natural language. To get started, see Quickstart: Agentic retrieval.</p> <p>The pipeline involves one or more knowledge sources within a knowledge base, whose response payload provides full transparency into the query plan and reference data.</p> <p>Knowledge sources and knowledge bases created in the Azure portal use the 2025-08-01-preview schema and aren't compatible with the latest 2025-11-01-preview. To get started, see Quickstart: Agentic retrieval in the Azure portal.</p>	Knowledge Sources (preview) , Knowledge bases (preview) , Knowledge Retrieval (preview) , and the Azure portal
Purview index configuration	Apply Microsoft Purview classifications and sensitivity labels to indexed content based on source metadata for enhanced data governance.	Create or Update Index (preview)
Scoring function aggregation	Combine and aggregate multiple scoring functions, enabling more sophisticated	Create or Update Index (preview)

Feature	Description	Availability
	relevance customization and weighted signal combination.	
Facet aggregations	Use sum, count, minimum, maximum, and other aggregate functions to provide enhanced analytics in faceted search experiences.	Search Documents (preview)
Improved indexer runtime tracking information	Cumulative indexer processing information for the search service and for specific indexers.	Get Service Statistics (preview) and Get Status - Indexers (preview)
Strict postfiltering for vector queries	Adds the <code>strictPostFilter</code> mode to the <code>vectorFilterMode</code> parameter. When specified, filters are applied after the global top- k vector results are identified, ensuring that returned documents are a subset of the unfiltered results.	Search Documents (preview)
Multivector support	Index multiple child vectors within a single document field. You can now use vector types in nested fields of complex collections, effectively allowing multiple vectors to be associated with a single document.	Create or Update Index (preview)
Document-level access control	Flow document-level permissions from blobs in Azure Data Lake Storage (ADLS) Gen2 to searchable documents in an index. Queries can now filter results based on user identity for selected data sources.	Create or Update Index (preview)
GenAI Prompt skill	Skill that connects to a large language model (LLM) for information using a prompt you provide. With this skill, you can populate a searchable field using content from an LLM. A primary use case for this skill is <i>image verbalization</i> , using an LLM to describe images and send the description to a searchable field in your index.	Create or Update Skillset (preview)
flightingOptIn parameter in a semantic configuration	Opt in to use prerelease semantic ranking models if one is available in a search service region.	Create or Update Index (preview)
Facet hierarchies, aggregations, and facet filters	New facet query parameters support nested facets. For numeric facetable fields, you can sum the values of each field. You can also	Search Documents (preview)

Feature	Description	Availability
	specify filters on a facet to add inclusion or exclusion criteria.	
Query rewrite in the semantic reranker	Set options on a semantic query to rewrite the query input into a revised or expanded query that generates more relevant results from the L2 ranker.	Search Documents (preview)
Keyless billing for Azure AI skills processing.	Use a managed identity and roles for a keyless connection to Foundry Tools for built-in skills processing. This capability removes restrictions for having both search and Foundry Tools in the same region.	Create or Update Skillset (preview)
Markdown parsing mode	With this parsing mode, indexers can generate one-to-one or one-to-many search documents from Markdown files in Azure Storage.	Create or Update Indexer (preview)
Target filters in a hybrid search to just the vector queries	A filter on a hybrid query involves all subqueries on the request, regardless of type. You can override the global filter to scope the filter to a specific subquery. A new <code>filterOverride</code> parameter provides the behaviors.	Search Documents (preview)
Text Split skill (token chunking)	This skill has new parameters that improve data chunking for embedding models. A new <code>unit</code> parameter lets you specify token chunking. You can now chunk by token length, setting the length to a value that makes sense for your embedding model. You can also specify the tokenizer and any tokens that shouldn't be split during data chunking.	Create or Update Skillset (preview)
Azure Vision multimodal embedding skill	Skill that calls the Azure Vision multimodal API to generate embeddings for text or images during indexing.	Create or Update Skillset (preview)
Azure Machine Learning (AML) skill	AML skill integrates an inferencing endpoint from Azure Machine Learning. In previous preview APIs, it supports connections to deployed custom models in an AML workspace. Starting in the 2025-11-01-preview, you can use this skill in workflows that connect to embedding models in the Microsoft Foundry model catalog. It's also available in the Azure portal, in skillset design, assuming Azure AI Search and Azure Machine Learning services are deployed in the same subscription.	Create or Update Skillset (preview)

Feature	Description	Availability
Incremental enrichment cache	Adds caching to an enrichment pipeline, allowing you to reuse existing output if a targeted modification, such as an update to a skillset or another object, doesn't change the content. Caching applies only to enriched documents produced by a skillset.	Create or Update Indexer (preview)
Azure Files indexer	Data source for indexer-based indexing from Azure Files .	Create or Update Data Source (preview)
SharePoint indexer	Data source for indexer-based indexing of SharePoint content.	Sign up to enable the feature. Create or Update Data Source (preview) or the Azure portal.
MySQL indexer	Data source for indexer-based indexing of Azure MySQL data sources.	Sign up to enable the feature. Create or Update Data Source (preview) , .NET SDK 11.2.1, and Azure portal
Azure Cosmos DB for MongoDB indexer	Data source for indexer-based indexing through the MongoDB APIs in Azure Cosmos DB.	Sign up to enable the feature. Create or Update Data Source (preview) or the Azure portal.
Azure Cosmos DB for Apache Gremlin indexer	Data source for indexer-based indexing through the Apache Gremlin APIs in Azure Cosmos DB.	Sign up to enable the feature. Create or Update Data Source (preview) .
Native blob soft delete	Applies to the Azure Blob Storage indexer. Recognizes blobs that are in a soft-deleted state, and removes the corresponding search document during indexing.	Create or Update Data Source (preview) .
Reset Documents	Reprocesses individually selected search documents in indexer workloads.	Reset Documents (preview) .

Feature	Description	Availability
speller	Optional spelling correction on query term inputs for simple, full, and semantic queries.	Search Documents (preview)
featuresMode parameter	BM25 relevance score expansion to include details: per field similarity score, per field term frequency, and per field number of unique tokens matched. You can consume these data points in custom scoring solutions .	Search Documents (preview)
vectorQueries.threshold parameter	Exclude low-scoring search result based on a minimum score.	Search Documents (preview)
hybridSearch.maxTextRecallSize and countAndFacetMode parameters	Adjust the inputs to a hybrid query by controlling the amount BM25-ranked results that flow to the hybrid ranking model.	Search Documents (preview)
moreLikeThis	Finds documents that are relevant to a specific document. This feature has been in earlier previews.	Search Documents (preview)

Control plane preview features

Currently, there are no control plane features in preview.

Preview features in Azure SDKs

Each Azure SDK team releases beta packages on their own timeline. Check the change log for mentions of new features in beta packages:

- [Change log for Azure SDK for .NET](#)
- [Change log for Azure SDK for Java](#)
- [Change log for Azure SDK for JavaScript](#)
- [Change log for Azure SDK for Python](#).

Using preview features

Experimental features are available through the preview REST API first, followed by Azure portal, and then the Azure SDKs.

The following statements apply to preview features:

- Preview features are available under [Supplemental Terms of Use](#), without a service level agreement.
- Preview features might undergo breaking changes if a redesign is required.
- Sometimes preview features don't make it into a GA release.

If you write code against a preview API, you should prepare to upgrade that code to newer API versions when they roll out. We maintain an [Upgrade REST APIs](#) document to make that step easier.

How to call a preview REST API

Preview REST APIs are accessed through the api-version parameter on the URI. Older previews are still operational but become stale over time and aren't updated with new features or bug fixes.

For data plane operations on content, [2025-11-01-preview](#) is the most recent preview version. The following example shows the syntax for [Indexes GET \(preview\)](#):

```
rest
GET {endpoint}/indexes('{indexName}')?api-version=2025-11-01-Preview
```

For management operations on the search service, [2025-05-01-preview](#) is the most recent preview version. The following example shows the syntax for Update Service 2025-05-01-preview version.

```
rest
PATCH
https://management.azure.com/subscriptions/subid/resourceGroups/rg1/providers/Microsoft.Search/searchServices/mysearchservice?api-version=2025-05-01-preview

{
  "tags": {
    "app-name": "My e-commerce app",
    "new-tag": "Adding a new tag"
  },
  "properties": {
    "replicaCount": 2
  }
}
```

Last updated on 11/18/2025

Upgrade to the latest REST API in Azure AI Search

Use this article to migrate to newer versions of the [Search Service REST APIs](#) and the [Search Management REST APIs](#) for [data plane and control plane](#) operations.

Here are the most recent versions of the REST APIs:

[+] [Expand table](#)

Targeted operations	REST API	Status
Data plane	2025-09-01	Stable
Data plane	2025-11-01-preview	Preview
Control plane	2025-05-01	Stable
Control plane	2025-02-01-preview	Preview

Upgrade instructions focus on code changes that get you through breaking changes from previous versions so that existing code runs the same as before, but on the newer API version. Once your code is in working order, you can decide whether to adopt newer features. To learn more about new features, see [What's New](#).

We recommend upgrading API versions in succession, working through each version until you get to the newest one.

[2023-07-01-preview](#) was the first REST API for vector support. **Do not use this API version.** It's now deprecated and you should migrate to either stable or newer preview REST APIs immediately.

(!) Note

REST API reference docs are now versioned. For version-specific content, open a reference page and then use the selector located above the table of contents, to pick your version.

When to upgrade

Azure AI Search breaks backward compatibility as a last resort. Upgrade is necessary when:

- Your code references a retired or unsupported API version and is subject to one or more breaking changes. You must address breaking changes if your code targets [2025-11-01-](#)

[preview](#) for agentic retrieval, [2025-05-01-preview](#) for knowledge agents, [2023-07-10-preview](#) for vectors, [2020-06-01-preview](#) for semantic ranker, and [2019-05-06](#) for obsolete skills and workarounds.

- Your code fails when unrecognized properties are returned in an API response. As a best practice, your application should ignore properties that it doesn't understand.
- Your code persists API requests and tries to resend them to the new API version. For example, this might happen if your application persists continuation tokens returned from the Search API (for more information, look for `@search.nextPageParameters` in the [Search API Reference](#)).

How to upgrade

1. If you're upgrading a data plane version, review the [release notes](#) for the new API version.
2. Update the `api-version` parameter, specified in the request header, to a newer version.

In your application code that makes direct calls to the REST APIs, search for all instances of the existing version and then replace it with the new version. For more information about structuring a REST call, see [Quickstart: Full-text search using REST](#).

If you're using an Azure SDK, those packages target specific versions of the REST API. Package updates might coincide with a REST API update, but each SDK is on its own release schedule that ships independently of Azure AI Search REST API versions. Check the change log of your SDK package to determine whether a package release targets the latest REST API version.

3. If you're upgrading a data plane version, review the breaking changes documented in this article and implement the workarounds. Start with the version used by your code and resolve any breaking change for each newer API version until you get to the newest stable or preview release.

Breaking changes

The following breaking changes apply to data operations.

Breaking changes for agentic retrieval

The latest `2025-11-01-preview` refactors the APIs for knowledge agents (bases), knowledge sources, and the retrieve action. The latest `2025-11-01-preview` renames knowledge agents to

knowledge bases and relocates several properties. Several properties are replaced or relocated to other objects.

For help with breaking changes, see [Migrate your agentic retrieval code](#).

Breaking changes for knowledge agents

[Knowledge agents](#) were introduced in `2025-05-01-preview`. In `2025-08-01-preview`, `targetIndexes` was replaced with a new knowledge source object and `defaultMaxDocsForReranker` was replaced with other APIs. More breaking changes are introduced in `2025-11-01-preview`.

For help with breaking changes, see [Migrate your agentic retrieval code](#).

Breaking changes for client code that reads connection information

Effective March 29, 2024 and applicable to all [supported REST APIs](#):

- [GET Skillset](#), [GET Index](#), and [GET Indexer](#) no longer return keys or connection properties in a response. This is a breaking change if you have downstream code that reads keys or connections (sensitive data) from a GET response.
- If you need to retrieve admin or query API keys for your search service, use the [Search Management REST APIs](#).
- If you need to retrieve connection strings of another Azure resource such as Azure Storage or Azure Cosmos DB, use the APIs of that resource and published guidance to obtain the information.

Breaking changes for semantic ranker

[Semantic ranker](#) became generally available in `2023-11-01`. These are the breaking changes from earlier releases:

- In all versions after `2020-06-01-preview`: `semanticConfiguration` replaces `searchFields` as the mechanism for specifying which fields to use for L2 ranking.
- For all API versions, updates on July 14, 2023 to the Microsoft-hosted semantic models made semantic ranker language-agnostic, effectively decommissioning the `queryLanguage` property. There's no "breaking change" in code, but the property is ignored.

See [Migrate from preview version](#) to transition your code to use `semanticConfiguration`.

Data plane upgrades

Upgrade guidance assumes upgrade from the most recent previous version. If your code is based on an old API version, we recommend upgrading through each successive version to get to the newest version.

Upgrade to 2025-11-01-preview

[2025-11-01-preview](#) introduces the following breaking changes to agentic retrieval as implemented in the [2025-08-01-preview](#):

- Replaces `agents` with `knowledgebases`. Several properties related to knowledge sources moved out of the knowledge base definition and to the retrieve action.
- Knowledge source properties are refactored, implementing a new `ingestionParameters` object for knowledge sources that generate an indexer pipeline.

For more information on changes and code migration, see [breaking changes in 2025-11-01-preview](#) and [How to migrate](#).

For all other existing APIs, there are no behavior changes. You can swap in the new API version and your code runs the same as before.

Upgrade to 2025-09-01

[2025-09-01](#) is the latest stable REST API version and it adds general availability for the OneLake indexer, Document Layout skill, and other APIs.

There are no breaking changes if you're upgrading from [2024-07-01](#) and not using any preview features. To use the new stable release, change the API version and test your code.

Upgrade to 2025-08-01-preview

[2025-08-01-preview](#) introduces the following breaking changes to knowledge agents created using [2025-05-01-preview](#):

- Replaces `targetIndexes` with `knowledgeSources`.
- Removes `defaultMaxDocsForReranker` without replacement.

Otherwise, there are no behavior changes on existing APIs. You can swap in the new API version and your code runs the same as before.

Upgrade to 2025-05-01-preview

[2025-05-01-preview](#) provides new features, but there are no behavior changes on existing APIs. You can swap in the new API version and your code runs the same as before.

Upgrade to 2025-03-01-preview

[2025-03-01-preview](#) provides new features, but there are no behavior changes on existing APIs. You can swap in the new API version and your code runs the same as before.

Upgrade to 2024-11-01-preview

[2024-11-01-preview](#) query rewrite, Document Layout skill, keyless billing for skills processing, Markdown parsing mode, and rescore options for compressed vectors.

If you're upgrading from [2024-09-01-preview](#), you can swap in the new API version and your code runs the same as before.

However, the new version introduces syntax changes to `vectorSearch.compressions`:

- Replaces `rerankWithOriginalVectors` with `enableRescoring`
- Moves `defaultOversampling` to a new `rescoringOptions` property object

Backwards compatibility is preserved due to an internal API mapping, but we recommend changing the syntax if you adopt the new preview version. For a comparison of the syntax, see [Compress vectors using scalar or binary quantization](#).

Upgrade to 2024-09-01-preview

[2024-09-01-preview](#) adds Matryoshka Representation Learning (MRL) compression for text-embedding-3 models, targeted vector filtering for hybrid queries, vector subscore details for debugging, and token chunking for [Text Split skill](#).

If you're upgrading from [2024-05-01-preview](#), you can swap in the new API version and your code runs the same as before.

Upgrade to 2024-07-01

[2024-07-01](#) is a general release. The former preview features are now generally available: integrated chunking and vectorization (Text Split skill, AzureOpenAIEmbedding skill), query vectorizer based on AzureOpenAIEmbedding, vector compression (scalar quantization, binary quantization, stored property, narrow data types).

There are no breaking changes if you upgrade from `2024-05-01-preview` to stable. To use the new stable release, change the API version and test your code.

There are breaking changes if you upgrade directly from `2023-11-01`. Follow the steps outlined for each newer preview to migrate from `2023-11-01` to `2024-07-01`.

Upgrade to 2024-05-01-preview

[2024-05-01-preview](#) adds an indexer for Microsoft OneLake, binary vectors, and more embedding models.

If you're upgrading from `2024-03-01-preview`, the AzureOpenAIEmbedding skill now requires a model name and dimensions property.

1. Search your codebase for [AzureOpenAIEmbedding](#) references.
2. Set `modelName` to "text-embedding-ada-002" and set `dimensions` to "1536".

Upgrade to 2024-03-01-preview

[2024-03-01-preview](#) adds narrow data types, scalar quantization, and vector storage options.

If you're upgrading from `2023-10-01-preview`, there are no breaking changes. However, there's one behavior difference: for `2023-11-01` and newer previews, the `vectorFilterMode` default changed from postfilter to prefilter for [filter expressions](#).

1. Search your codebase for `vectorFilterMode` references.
2. If the property is explicitly set, no action is required. If you relied on the default value, the new default behavior is to filter *before* query execution. If you want post-query filtering, explicitly set `vectorFilterMode` to postfilter to retain the old behavior.

Upgrade to 2023-11-01

[2023-11-01](#) is a general release. The former preview features are now generally available: semantic ranker and vector support.

There are no breaking changes from `2023-10-01-preview`, but there are multiple breaking changes from `2023-07-01-preview` to `2023-11-01`. For more information, see [Upgrade from 2023-07-01-preview](#).

To use the new stable release, change the API version and test your code.

Upgrade to 2023-10-01-preview

[2023-10-01-preview](#) was the first preview version to add [built-in data chunking and vectorization during indexing](#) and [built-in query vectorization](#). It also supports vector indexing and queries from the previous version.

If you're upgrading from the previous version, the next section has the steps.

Upgrade from 2023-07-01-preview

Don't use this API version. It implements a vector query syntax that's incompatible with any newer API version.

[2023-07-01-preview](#) is now deprecated, so you shouldn't base new code on this version, nor should you upgrade to this version under any circumstances. This section explains the migration path from [2023-07-01-preview](#) to any newer API version.

Portal upgrade for vector indexes

Azure portal supports a one-click upgrade path for [2023-07-01-preview](#) indexes. It detects vector fields and provides a **Migrate** button.

- Migration path is from [2023-07-01-preview](#) to [2024-05-01-preview](#).
- Updates are limited to vector field definitions and vector search algorithm configurations.
- Updates are one-way. You can't reverse the upgrade. Once the index is upgraded, you must use [2024-05-01-preview](#) or later to query the index.

There's no portal migration for upgrading vector query syntax. See [code upgrades](#) for query syntax changes.

Before selecting **Migrate**, select **Edit JSON** to review the updated schema first. You should find a schema that conforms to the changes described in the [code upgrade](#) section. Portal migration only handles indexes with one vector search algorithm configuration. It creates a default profile that maps to the [2023-07-01-preview](#) vector search algorithm. Indexes with multiple vector search configurations require manual migration.

Code upgrade for vector indexes and queries

[Vector search](#) support was introduced in [Create or Update Index \(2023-07-01-preview\)](#).

Upgrading from [2023-07-01-preview](#) to any newer stable or preview version requires:

- Renaming and restructuring the vector configuration in the index
- Rewriting your vector queries

Use the instructions in this section to migrate vector fields, configuration, and queries from `2023-07-01-preview`.

1. Call [Get Index](#) to retrieve the existing definition.
2. Modify the vector search configuration. `2023-11-01` and later versions introduce the concept of *vector profiles* that bundle vector-related configurations under one name. Newer versions also rename `algorithmConfigurations` to `algorithms`.
 - Rename `algorithmConfigurations` to `algorithms`. This is only a renaming of the array. The contents are backwards compatible. This means your existing HNSW configuration parameters can be used.
 - Add `profiles`, giving a name and an algorithm configuration for each one.

Before migration (2023-07-01-preview):

HTTP

```
"vectorSearch": {
  "algorithmConfigurations": [
    {
      "name": "myHnswConfig",
      "kind": "hnsw",
      "hnswParameters": {
        "m": 4,
        "efConstruction": 400,
        "efSearch": 500,
        "metric": "cosine"
      }
    }
  ]
}
```

After migration (2023-11-01):

HTTP

```
"vectorSearch": {
  "algorithms": [
    {
      "name": "myHnswConfig",
      "kind": "hnsw",
      "hnswParameters": {
        "m": 4,
        "efConstruction": 400,
        "efSearch": 500,
        "metric": "cosine"
      }
    }
  ]
}
```

```

        "metric": "cosine"
    }
}
],
"profiles": [
{
    "name": "myHnswProfile",
    "algorithm": "myHnswConfig"
}
]
}

```

3. Modify vector field definitions, replacing `vectorSearchConfiguration` with `vectorSearchProfile`. Make sure the profile name resolves to a new vector profile definition, and not the algorithm configuration name. Other vector field properties remain unchanged. For example, they can't be filterable, sortable, or facetable, nor use analyzers or normalizers or synonym maps.

Before (2023-07-01-preview):

HTTP

```
{
    "name": "contentVector",
    "type": "Collection(Edm.Single)",
    "key": false,
    "searchable": true,
    "retrievable": true,
    "filterable": false,
    "sortable": false,
    "facetable": false,
    "analyzer": "",
    "searchAnalyzer": "",
    "indexAnalyzer": "",
    "normalizer": "",
    "synonymMaps": "",
    "dimensions": 1536,
    "vectorSearchConfiguration": "myHnswConfig"
}
```

After (2023-11-01):

HTTP

```
{
    "name": "contentVector",
    "type": "Collection(Edm.Single)",
    "searchable": true,
    "retrievable": true,
    "filterable": false,
    "sortable": false,
```

```

    "facetable": false,
    "analyzer": "",
    "searchAnalyzer": "",
    "indexAnalyzer": "",
    "normalizer": "",
    "synonymMaps": "",
    "dimensions": 1536,
    "vectorSearchProfile": "myHnswProfile"
}

```

4. Call [Create or Update Index](#) to post the changes.

5. Modify [Search POST](#) to change the query syntax. This API change enables support for polymorphic vector query types.

- Rename `vectors` to `vectorQueries`.
- For each vector query, add `kind`, setting it to `vector`.
- For each vector query, rename `value` to `vector`.
- Optionally, add `vectorFilterMode` if you're using [filter expressions](#). The default is prefilter for indexes created after `2023-10-01`. Indexes created before that date only support postfilter, regardless of how you set the filter mode.

Before (2023-07-01-preview):

HTTP

```
{
  "search": (this parameter is ignored in vector search),
  "vectors": [
    {
      "value": [
        0.103,
        0.0712,
        0.0852,
        0.1547,
        0.1183
      ],
      "fields": "contentVector",
      "k": 5
    }
  ],
  "select": "title, content, category"
}
```

After (2023-11-01):

HTTP

```
{  
  "search": "(this parameter is ignored in vector search)",  
  "vectorQueries": [  
    {  
      "kind": "vector",  
      "vector": [  
        0.103,  
        0.0712,  
        0.0852,  
        0.1547,  
        0.1183  
      ],  
      "fields": "contentVector",  
      "k": 5  
    }  
  ],  
  "vectorFilterMode": "preFilter",  
  "select": "title, content, category"  
}
```

These steps complete the migration to `2023-11-01` stable API version or newer preview API versions.

Upgrade to 2020-06-30

In this version, there's one breaking change and several behavioral differences. Generally available features include:

- [Knowledge store](#), persistent storage of enriched content created through skillsets, created for downstream analysis and processing through other applications. A knowledge store is created through Azure AI Search REST APIs but it resides in Azure Storage.

Breaking change

Code written against earlier API versions breaks on `2020-06-30` and later if code contains the following functionality:

- Any `Edm.Date` literals (a date composed of year-month-day, such as `2020-12-12`) in filter expressions must follow the `Edm.DateTimeOffset` format: `2020-12-12T00:00:00Z`. This change was necessary to handle erroneous or unexpected query results due to timezone differences.

Behavior changes

- [BM25 ranking algorithm](#) replaces the previous ranking algorithm with newer technology. Services created after 2019 use this algorithm automatically. For older services, you must set parameters to use the new algorithm.
- Ordered results for null values have changed in this version, with null values appearing first if the sort is `asc` and last if the sort is `desc`. If you wrote code to handle how null values are sorted, be aware of this change.

Upgrade to 2019-05-06

Features that became generally available in this API version include:

- [Autocomplete](#) is a typeahead feature that completes a partially specified term input.
- [Complex types](#) provides native support for structured object data in search index.
- [JsonLines parsing modes](#), part of Azure Blob indexing, creates one search document per JSON entity that is separated by a newline.
- [AI enrichment](#) provides indexing that uses the AI enrichment engines of Foundry Tools.

Breaking changes

Code written against an earlier API version breaks on `2019-05-06` and later if it contains the following functionality:

1. Type property for Azure Cosmos DB. For indexers targeting an [Azure Cosmos DB for NoSQL API](#) data source, change `"type": "documentdb"` to `"type": "cosmosdb"`.
2. If your indexer error handling includes references to the `status` property, you should remove it. We removed status from the error response because it wasn't providing useful information.
3. Data source connection strings are no longer returned in the response. From API versions `2019-05-06` and `2019-05-06-Preview` onwards, the data source API no longer returns connection strings in the response of any REST operation. In previous API versions, for data sources created using POST, Azure AI Search returned `201` followed by the OData response, which contained the connection string in plain text.
4. Named Entity Recognition cognitive skill is retired. If you called the [Name Entity Recognition](#) skill in your code, the call fails. Replacement functionality is [Entity Recognition Skill \(V3\)](#). Follow the recommendations in [Deprecated skills](#) to migrate to a supported skill.

Upgrading complex types

API version `2019-05-06` added formal support for complex types. If your code implemented previous recommendations for complex type equivalency in 2017-11-11-Preview or 2016-09-01-Preview, there are some new and changed limits starting in version `2019-05-06` of which you need to be aware:

- The limits on the depth of subfields and the number of complex collections per index have been lowered. If you created indexes that exceed these limits using the preview api-versions, any attempt to update or recreate them using API version `2019-05-06` fails. If you find yourself in this situation, you need to redesign your schema to fit within the new limits and then rebuild your index.
- There's a new limit starting in api-version `2019-05-06` on the number of elements of complex collections per document. If you created indexes with documents that exceed these limits using the preview api-versions, any attempt to reindex that data using api-version `2019-05-06` fails. If you find yourself in this situation, you need to reduce the number of complex collection elements per document before reindexing your data.

For more information, see [Service limits for Azure AI Search](#).

How to upgrade an old complex type structure

If your code is using complex types with one of the older preview API versions, you might be using an index definition format that looks like this:

JSON

```
{  
  "name": "hotels",  
  "fields": [  
    { "name": "HotelId", "type": "Edm.String", "key": true, "filterable": true },  
    { "name": "HotelName", "type": "Edm.String", "searchable": true, "filterable": false, "sortable": true, "facetable": false },  
    { "name": "Description", "type": "Edm.String", "searchable": true, "filterable": false, "sortable": false, "facetable": false, "analyzer": "en.microsoft" },  
    { "name": "Description_fr", "type": "Edm.String", "searchable": true, "filterable": false, "sortable": false, "facetable": false, "analyzer": "fr.microsoft" },  
    { "name": "Category", "type": "Edm.String", "searchable": true, "filterable": true, "sortable": true, "facetable": true },  
    { "name": "Tags", "type": "Collection(Edm.String)", "searchable": true, "filterable": true, "sortable": false, "facetable": true, "analyzer": "tagsAnalyzer" },  
    { "name": "ParkingIncluded", "type": "Edm.Boolean", "filterable": true, "sortable": true, "facetable": true },  
    { "name": "LastRenovationDate", "type": "Edm.DateTimeOffset", "filterable": true, "sortable": true, "facetable": true },  
    { "name": "Rating", "type": "Edm.Double", "filterable": true, "sortable": true, "facetable": true }]
```

```

"facetable": true },
  { "name": "Address", "type": "Edm.ComplexType" },
    { "name": "Address/StreetAddress", "type": "Edm.String", "filterable": false,
"sortable": false, "facetable": false, "searchable": true },
      { "name": "Address/City", "type": "Edm.String", "searchable": true,
"filterable": true, "sortable": true, "facetable": true },
        { "name": "Address/StateProvince", "type": "Edm.String", "searchable": true,
"filterable": true, "sortable": true, "facetable": true },
          { "name": "Address/PostalCode", "type": "Edm.String", "searchable": true,
"filterable": true, "sortable": true, "facetable": true },
            { "name": "Address/Country", "type": "Edm.String", "searchable": true,
"filterable": true, "sortable": true, "facetable": true },
              { "name": "Location", "type": "Edm.GeographyPoint", "filterable": true,
"sortable": true },
                { "name": "Rooms", "type": "Collection(Edm.ComplexType)" },
                  { "name": "Rooms/Description", "type": "Edm.String", "searchable": true,
"filterable": false, "sortable": false, "facetable": false, "analyzer": "en.lucene"
},
                    { "name": "Rooms/Description_fr", "type": "Edm.String", "searchable": true,
"filterable": false, "sortable": false, "facetable": false, "analyzer": "fr.lucene"
},
                      { "name": "Rooms/Type", "type": "Edm.String", "searchable": true },
                        { "name": "Rooms/BaseRate", "type": "Edm.Double", "filterable": true,
"facetable": true },
                          { "name": "Rooms/BedOptions", "type": "Edm.String", "searchable": true },
                            { "name": "Rooms/SleepsCount", "type": "Edm.Int32", "filterable": true,
"facetable": true },
                              { "name": "Rooms/SmokingAllowed", "type": "Edm.Boolean", "filterable": true,
"facetable": true },
                                { "name": "Rooms/Tags", "type": "Collection(Edm.String)", "searchable": true,
"filterable": true, "facetable": true, "analyzer": "tagsAnalyzer" }
      ]
}

```

A newer tree-like format for defining index fields was introduced in API version [2017-11-11-Preview](#). In the new format, each complex field has a `fields` collection where its subfields are defined. In API version 2019-05-06, this new format is used exclusively and attempting to create or update an index using the old format will fail. If you have indexes created using the old format, you'll need to use API version [2017-11-11-Preview](#) to update them to the new format before they can be managed using API version 2019-05-06.

You can update flat indexes to the new format with the following steps using API version [2017-11-11-Preview](#):

1. Perform a GET request to retrieve your index. If it's already in the new format, you're done.
2. Translate the index from the flat format to the new format. You have to write code for this task since there's no sample code available at the time of this writing.

3. Perform a PUT request to update the index to the new format. Avoid changing any other details of the index, such as the searchability/filterability of fields, because changes that affect the physical expression of existing index isn't allowed by the Update Index API.

 Note

It isn't possible to manage indexes created with the old "flat" format from the Azure portal. Upgrade your indexes from the "flat" representation to the "tree" representation at your earliest convenience.

Control plane upgrades

Applies to: 2014-07-31-Preview, 2015-02-28, and 2015-08-19

The `listQueryKeys` GET request on older Search Management API versions is now deprecated. We recommend migrating to the most recent stable control plane API version to use the [listQueryKeys POST request](#).

1. In existing code, change the `api-version` parameter to the most recent version (`2025-05-01`).
2. Reframe the request from `GET` to `POST`:

HTTP

POST

```
https://management.azure.com/subscriptions/{subscriptionId}/resourceGroups/{resourceGroupName}/providers/Microsoft.Search/searchServices/{searchServiceName}/listQueryKeys?api-version=2025-05-01
Authorization: Bearer {{token}}
```

3. If you're using an Azure SDK, it's recommended that you upgrade to the latest version.

Next steps

Review the Search REST API reference documentation. If you encounter problems, ask us for help on [Stack Overflow](#) or [contact support](#).

[Search service REST API Reference](#)

Upgrade to Azure AI Search .NET SDK version 11

05/29/2025

If your search solution is built on the [Azure SDK for .NET](#), this article helps you migrate your code from earlier versions of [Microsoft.Azure.Search](#) to version 11, the new [Azure.Search.Documents](#) client library. Version 11 is a fully redesigned client library, released by the Azure SDK development team (previous versions were produced by the Azure AI Search development team).

All features from version 10 are implemented in version 11. Key differences include:

- One package ([Azure.Search.Documents](#)) instead of four
- Three clients instead of two: `SearchClient`, `SearchIndexClient`, `SearchIndexerClient`
- Naming differences across a range of APIs and small structural differences that simplify some tasks

The client library's [Change Log](#) has an itemized list of updates. You can review a [summarized version](#) in this article.

All C# code samples and snippets in the Azure AI Search product documentation have been revised to use the new [Azure.Search.Documents](#) client library.

Why upgrade?

The benefits of upgrading are summarized as follows:

- New features are added to [Azure.Search.Documents](#) only. The previous version, [Microsoft.Azure.Search](#), is now retired. Updates to deprecated libraries are limited to high priority bug fixes only.
- Consistency with other Azure client libraries. [Azure.Search.Documents](#) takes a dependency on [Azure.Core](#) and [System.Text.Json](#), and follows conventional approaches for common tasks such as client connections and authorization.

[Microsoft.Azure.Search](#) is officially retired. If you're using an old version, we recommend upgrading to the next higher version, repeating the process in succession until you reach version 11 and [Azure.Search.Documents](#). An incremental upgrade strategy makes it easier to find and fix blocking issues. See [Previous version docs](#) for guidance.

Package comparison

Version 11 consolidates and simplifies package management so that there are fewer to manage.

[] [Expand table](#)

Version 10 and earlier	Version 11
Microsoft.Azure.Search	Azure.Search.Documents package
Microsoft.Azure.Search.Service	
Microsoft.Azure.Search.Data	
Microsoft.Azure.Search.Common	

Client comparison

Where applicable, the following table maps the client libraries between the two versions.

[] [Expand table](#)

Client operations	Microsoft.Azure.Search (v10)	Azure.Search.Documents (v11)
Targets the documents collection of an index (queries and data import)	SearchIndexClient	SearchClient
Targets index-related objects (indexes, analyzers, synonym maps)	SearchServiceClient	SearchIndexClient
Targets indexer-related objects (indexers, data sources, skillsets)	SearchServiceClient	SearchIndexerClient (new)

✖ Caution

Notice that SearchIndexClient exists in both versions, but targets different operations. In version 10, SearchIndexClient creates indexes and other objects. In version 11, SearchIndexClient works with existing indexes, targeting the documents collection with query and data ingestion APIs. To avoid confusion when updating code, be mindful of the order in which client references are updated. Following the sequence in [Steps to upgrade](#) should help mitigate any string replacement issues.

Naming and other API differences

Besides the client differences (noted previously and thus omitted here), multiple other APIs have been renamed and in some cases redesigned. Class name differences are summarized in

the following sections. This list isn't exhaustive but it does group API changes by task, which can be helpful for revisions on specific code blocks. For an itemized list of API updates, see the [change log](#) for `Azure.Search.Documents` on GitHub.

Authentication and encryption

 [Expand table](#)

Version 10	Version 11 equivalent
SearchCredentials	AzureKeyCredential
EncryptionKey (Undocumented in API reference. Support for this API transitioned to generally available in v10, but was only available in the preview SDK)	SearchResourceEncryptionKey

Indexes, analyzers, synonym maps

 [Expand table](#)

Version 10	Version 11 equivalent
Index	SearchIndex
Field	SearchField
DataType	SearchFieldDataType
ItemError	SearchIndexerError
Analyzer	LexicalAnalyzer (also, <code>AnalyzerName</code> to <code>LexicalAnalyzerName</code>)
AnalyzeRequest	AnalyzeTextOptions
StandardAnalyzer	LuceneStandardAnalyzer
StandardTokenizer	LuceneStandardTokenizer (also, <code>StandardTokenizerV2</code> to <code>LuceneStandardTokenizerV2</code>)
TokenInfo	AnalyzedTokenInfo
Tokenizer	LexicalTokenizer (also, <code>TokenizerName</code> to <code>LexicalTokenizerName</code>)
SynonymMap.Format	None. Remove references to <code>Format</code> .

Field definitions are streamlined: `SearchableField`, `SimpleField`, `ComplexField` are new APIs for creating field definitions.

Indexers, datasources, skillsets

[+] [Expand table](#)

Version 10	Version 11 equivalent
Indexer	SearchIndexer
DataSource	SearchIndexerDataSourceConnection
Skill	SearchIndexerSkill
Skillset	SearchIndexerSkillset
DataSourceType	SearchIndexerDataSourceType

Data import

[+] [Expand table](#)

Version 10	Version 11 equivalent
IndexAction	IndexDocumentsAction
IndexBatch	IndexDocumentsBatch
IndexBatchException.FindFailedActionsToRetry()	SearchIndexingBufferedSender

Query requests and responses

[+] [Expand table](#)

Version 10	Version 11 equivalent
DocumentsOperationsExtensions.SearchAsync	SearchClient.SearchAsync
DocumentSearchResult	SearchResult or SearchResults, depending on whether the result is a single document or multiple.
DocumentSuggestResult	SuggestResults
SearchParameters	SearchOptions
SuggestParameters	SuggestOptions
SearchParameters.Filter	SearchFilter (a new class for constructing OData filter expressions)

JSON serialization

By default, the Azure SDK uses [System.Text.Json](#) for JSON serialization, relying on the capabilities of those APIs to handle text transformations previously implemented through a native [SerializePropertyNamesAsCamelCaseAttribute](#) class, which has no counterpart in the new library.

To serialize property names into camelCase, you can use the [JsonPropertyNameAttribute](#) (similar to [this example](#)).

Alternatively, you can set a [JsonNamingPolicy](#) provided in [JsonSerializerOptions](#). The following System.Text.Json code example, taken from the [Microsoft.Azure.Core.Spatial](#) readme demonstrates the use of camelCase without having to attribute every property:

C#

```
// Get the Azure AI Search service endpoint and read-only API key.
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
AzureKeyCredential credential = new
AzureKeyCredential(Environment.GetEnvironmentVariable("SEARCH_API_KEY"));

// Create serializer options with our converter to deserialize geographic points.
JsonSerializerOptions serializerOptions = new JsonSerializerOptions
{
    Converters =
    {
        new MicrosoftSpatialGeoJsonConverter()
    },
    PropertyNamingPolicy = JsonNamingPolicy.CamelCase
};

SearchClientOptions clientOptions = new SearchClientOptions
{
    Serializer = new JsonObjectSerializer(serializerOptions)
};

SearchClient client = new SearchClient(endpoint, "mountains", credential,
clientOptions);
Response<SearchResults<Mountain>> results = client.Search<Mountain>("Rainier");
```

If you're using [Newtonsoft.Json](#) for JSON serialization, you can pass in global naming policies using similar attributes, or by using properties on [JsonSerializerSettings](#). For an example equivalent to the previous one, see the [Deserializing documents example](#) in the [Newtonsoft.Json](#) readme.

Inside v11

Each version of an Azure AI Search client library targets a corresponding version of the REST API. The REST API is considered foundational to the service, with individual SDKs wrapping a version of the REST API. As a .NET developer, it can be helpful to review the more verbose [REST API documentation](#) for more in depth coverage of specific objects or operations. Version 11 targets the [2020-06-30 search service specification](#).

Version 11.0 fully supports the following objects and operations:

- Index creation and management
- Synonym map creation and management
- Indexer creation and management
- Indexer data source creation and management
- Skillset creation and management
- All query types and syntax

Version 11.1 additions ([change log](#) details):

- [FieldBuilder](#) (added in 11.1)
- [Serializer property](#) (added in 11.1) to support custom serialization

Version 11.2 additions ([change log](#) details):

- [EncryptionKey](#) property added indexers, data sources, and skillsets
- [IndexingParameters.IndexingParametersConfiguration](#) property support
- [Geospatial types](#) are natively supported in [FieldBuilder](#). [SearchFilter](#) can encode geometric types from Microsoft.Spatial without an explicit assembly dependency.

You can also continue to explicitly declare a dependency on [Microsoft.Spatial](#). Examples of this technique are available for [System.Text.Json](#) and [Newtonsoft.Json](#).

Version 11.3 additions ([change log](#) details):

- [KnowledgeStore](#)
- Added support for Azure.Core.GeoJson types in [SearchDocument](#), [SearchFilter](#) and [FieldBuilder](#).
- Added EventSource based logging. Event source name is Azure-Search-Documents. Current set of events are focused on tuning batch sizes for [SearchIndexingBufferedSender](#).
- Added [CustomEntityLookupSkill](#) and [DocumentExtractionSkill](#). Added DefaultCountryHint in [LanguageDetectionSkill](#).

Before upgrading

- Quickstarts, tutorials, and [C# samples](#) have been updated to use the `Azure.Search.Documents` package. We recommend reviewing the samples and walkthroughs to learn about the new APIs before embarking on a migration exercise.
- [How to use Azure.Search.Documents](#) introduces the most commonly used APIs. Even knowledgeable users of Azure AI Search might want to review this introduction to the new library as a precursor to migration.

Steps to upgrade

The following steps get you started on a code migration by walking through the first set of required tasks, especially regarding client references.

1. Install the [Azure.Search.Documents package](#) by right-clicking on your project references and selecting "Manage NuGet Packages..." in Visual Studio.
2. Replace using directives for `Microsoft.Azure.Search` with the following using statements:

```
C#
using Azure;
using Azure.Search.Documents;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;
using Azure.Search.Documents.Models;
```

3. For classes that require JSON serialization, replace `using Newtonsoft.Json` with `using System.Text.Json.Serialization`.
4. Revise client authentication code. In previous versions, you would use properties on the client object to set the API key (for example, the `SearchServiceClient.Credentials` property). In the current version, use the `AzureKeyCredential` class to pass the key as a credential, so that if needed, you can update the API key without creating new client objects.

Client properties have been streamlined to just `Endpoint`, `ServiceName`, and `IndexName` (where appropriate). The following example uses the system `Uri` class to provide the endpoint and the `Environment` class to read in the key value:

```
C#
Uri endpoint = new
Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
AzureKeyCredential credential = new AzureKeyCredential(
```

```
Environment.GetEnvironmentVariable("SEARCH_API_KEY"));
SearchIndexClient indexClient = new SearchIndexClient(endpoint, credential);
```

5. Add new client references for indexer-related objects. If you're using indexers, datasources, or skillsets, change the client references to [SearchIndexClient](#). This client is new in version 11 and has no antecedent.
6. Revise collections and lists. In the new SDK, all lists are read-only to avoid downstream issues if the list happens to contain null values. The code change is to add items to a list. For example, instead of assigning strings to a Select property, you would add them as follows:

```
C#  
  
var options = new SearchOptions
{
    SearchMode = SearchMode.All,
    IncludeTotalCount = true
};

// Select fields to return in results.
options.Select.Add("HotelName");
options.Select.Add("Description");
options.Select.Add("Tags");
options.Select.Add("Rooms");
options.Select.Add("Rating");
options.Select.Add("LastRenovationDate");
```

Select, Facets, SearchFields, SourceFields, ScoringParameters, and OrderBy are all lists that now need to be reconstructed.

7. Update client references for queries and data import. Instances of [SearchIndexClient](#) should be changed to [SearchClient](#). To avoid name confusion, make sure you catch all instances before proceeding to the next step.
8. Update client references for index, synonym map, and analyzer objects. Instances of [SearchServiceClient](#) should be changed to [SearchIndexClient](#).
9. For the remainder of your code, update classes, methods, and properties to use the APIs of the new library. The [naming differences](#) section is a place to start but you can also review the [change log ↴](#).

If you have trouble finding equivalent APIs, we suggest logging an issue on <https://github.com/MicrosoftDocs/azure-docs/issues> so that we can improve the documentation or investigate the problem.

10. Rebuild the solution. After fixing any build errors or warnings, you can make additional changes to your application to take advantage of [new functionality](#).

Breaking changes

Given the sweeping changes to libraries and APIs, an upgrade to version 11 is non-trivial and constitutes a breaking change in the sense that your code will no longer be backward compatible with version 10 and earlier. For a thorough review of the differences, see the [change log ↗](#) for `Azure.Search.Documents`.

In terms of service version updates, where code changes in version 11 relate to existing functionality (and not just a refactoring of the APIs), you'll find the following behavior changes:

- [BM25 ranking algorithm](#) replaces the previous ranking algorithm with newer technology. New services use this algorithm automatically. For existing services, you must set parameters to use the new algorithm.
- [Ordered results](#) for null values have changed in this version, with null values appearing first if the sort is `asc` and last if the sort is `desc`. If you wrote code to handle how null values are sorted, you should review and potentially remove that code if it's no longer necessary.

Due to these behavior changes, it's likely that there are slight variations in ranked results.

How to use Azure.Search.Documents in a .NET application

Article • 04/15/2025

This article explains how to create and manage search objects using C# and the [Azure.Search.Documents](#) client library in the Azure SDK for .NET.

You can use this library for data plane operations, including:

- Create and manage search indexes, data sources, indexers, skillsets, and synonym maps
- Load and manage search documents in an index
- Execute queries, all without having to deal with the details of HTTP and JSON
- Invoke and manage AI enrichment (skillsets) and outputs

The library is distributed as a single [NuGet package](#) that includes all APIs used for programmatic access to a search service.

The client library defines classes like `SearchIndex`, `SearchField`, and `SearchDocument`, as well as operations like `SearchIndexClient.CreateIndex` and `SearchClient.Search` on the `SearchIndexClient` and `SearchClient` classes. These classes are organized into the following namespaces:

- [Azure.Search.Documents](#)
- [Azure.Search.Documents.Indexes](#)
- [Azure.Search.Documents.Indexes.Models](#)
- [Azure.Search.Documents.Models](#)

The [Azure.Search.Documents](#) client library doesn't provide [service management operations](#), such as creating and scaling search services and managing API keys. If you need to manage your search resources from a .NET application, use the [Azure.ResourceManager.Search](#) library in the Azure SDK for .NET.

SDK requirements

- Visual Studio 2019 or later.
- [Azure AI Search](#)
- Download the [NuGet package](#) using **Tools > NuGet Package Manager > Manage NuGet Packages for Solution** in Visual Studio. Search for the package name `Azure.Search.Documents`.

The Azure SDK for .NET conforms to [.NET Standard 2.0](#).

Example application

This article *teaches by example*, relying on the [DotNetHowTo](#) code example on GitHub to illustrate fundamental concepts in Azure AI Search, and how to create, load, and query a search index.

For the rest of this article, assume a new index named *hotels*, populated with a few documents, with several queries that match on results.

The following example shows the main program, with the overall flow:

C#

```
// This sample shows how to delete, create, upload documents and query an index
static void Main(string[] args)
{
    IConfigurationBuilder builder = new
    ConfigurationBuilder().AddJsonFile("appsettings.json");
    IConfigurationRoot configuration = builder.Build();

    SearchIndexClient indexClient = CreateSearchIndexClient(configuration);

    string indexName = configuration["SearchIndexName"];

    Console.WriteLine("{0}", "Deleting index...\\n");
    DeleteIndexIfExists(indexName, indexClient);

    Console.WriteLine("{0}", "Creating index...\\n");
    CreateIndex(indexName, indexClient);

    SearchClient searchClient = indexClient.GetSearchClient(indexName);

    Console.WriteLine("{0}", "Uploading documents...\\n");
    UploadDocuments(searchClient);

    SearchClient indexClientForQueries = CreateSearchClientForQueries(indexName,
configuration);

    Console.WriteLine("{0}", "Run queries...\\n");
    RunQueries(indexClientForQueries);

    Console.WriteLine("{0}", "Complete. Press any key to end application...\\n");
    Console.ReadKey();
}
```

Next is a partial screenshot of the output, assuming you run this application with a valid service name and API keys:

```
C:\Program Files\dotnet\dotnet.exe
Deleting index...
Creating index...
Uploading documents...
Waiting for documents to be indexed...
Query 1: Search for 'motel'. Return only the HotelName in results:
Name: Twin Dome Motel
Name: Secret Point Motel

Query 2: Apply a filter to find hotels with rooms cheaper than $100 per night, areturning the HotelId and Description:
HotelId: 2
Description: The hotel is situated in a nineteenth century plaza, which has been expanded and renovated to the highest architectural standards to create a modern, functional and first-class hotel in which art and unique historical elements coexist with the most modern comforts.

HotelId: 1
Description: The hotel is ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Time's Square and the historic centre of the city, as well as other places of interest that make New York one of America's most attractive and cosmopolitan cities.
```

Client types

The client library uses three client types for various operations: [SearchIndexClient](#) to create, update, or delete indexes, [SearchClient](#) to load or query an index, and [SearchIndexerClient](#) to work with indexers and skillsets. This article focuses on the first two.

At a minimum, all of the clients require the service name or endpoint, and an API key. It's common to provide this information in a configuration file, similar to what you find in the `appsettings.json` file of the [DotNetHowTo sample application](#). To read from the configuration file, add `using Microsoft.Extensions.Configuration;` to your program.

The following statement creates the index client used to create, update, or delete indexes. It takes a service endpoint and admin API key.

```
C#
private static SearchIndexClient CreateSearchIndexClient(IConfigurationRoot configuration)
{
    string searchServiceEndPoint = configuration["YourSearchServiceEndPoint"];
    string adminApiKey = configuration["YourSearchServiceAdminApiKey"];

    SearchIndexClient indexClient = new SearchIndexClient(new
        Uri(searchServiceEndPoint), new AzureKeyCredential(adminApiKey));
    return indexClient;
}
```

The next statement creates the search client used to load documents or run queries.

`SearchClient` requires an index. You need an admin API key to load documents, but you can

use a query API key to run queries.

C#

```
string indexName = configuration["SearchIndexName"];  
  
private static SearchClient CreateSearchClientForQueries(string indexName,  
IConfigurationRoot configuration)  
{  
    string searchServiceEndPoint = configuration["YourSearchServiceEndPoint"];  
    string queryApiKey = configuration["YourSearchServiceQueryApiKey"];  
  
    SearchClient searchClient = new SearchClient(new Uri(searchServiceEndPoint),  
indexName, new AzureKeyCredential(queryApiKey));  
    return searchClient;  
}
```

(!) Note

If you provide an invalid key for the import operation (for example, a query key where an admin key was required), the `SearchClient` throws a `CloudException` with the error message *Forbidden* the first time you call an operation method on it. If this happens to you, double-check the API key.

Delete the index

In the early stages of development, you might want to include a `DeleteIndex` statement to delete a work-in-progress index so that you can recreate it with an updated definition. Sample code for Azure AI Search often includes a deletion step so that you can rerun the sample.

The following line calls `DeleteIndexIfExists`:

C#

```
Console.WriteLine("{0}", "Deleting index...\\n");  
DeleteIndexIfExists(indexName, indexClient);
```

This method uses the given `SearchIndexClient` to check if the index exists, and if so, deletes it:

C#

```
private static void DeleteIndexIfExists(string indexName, SearchIndexClient  
indexClient)  
{  
    try
```

```
{  
    if (indexClient.GetIndex(indexName) != null)  
    {  
        indexClient.DeleteIndex(indexName);  
    }  
}  
catch (RequestFailedException e) when (e.Status == 404)  
{  
    // Throw an exception if the index name isn't found  
    Console.WriteLine("The index doesn't exist. No deletion occurred.");
```

ⓘ Note

The example code in this article uses the synchronous methods for simplicity, but you should use the asynchronous methods in your own applications to keep them scalable and responsive. For example, in the previous method, you could use [DeleteIndexAsync](#) instead of [DeleteIndex](#).

Create an index

You can use [SearchIndexClient](#) to create an index.

The following method creates a new [SearchIndex](#) object with a list of [SearchField](#) objects that define the schema of the new index. Each field has a name, data type, and several attributes that define its search behavior.

Fields can be defined from a model class using [FieldBuilder](#). The [FieldBuilder](#) class uses reflection to create a list of [SearchField](#) objects for the index by examining the public properties and attributes of the given [Hotel](#) model class. We'll take a closer look at the [Hotel](#) class later on.

C#

```
private static void CreateIndex(string indexName, SearchIndexClient indexClient)  
{  
    FieldBuilder fieldBuilder = new FieldBuilder();  
    var searchFields = fieldBuilder.Build(typeof(Hotel));  
  
    var definition = new SearchIndex(indexName, searchFields);  
  
    indexClient.CreateOrUpdateIndex(definition);  
}
```

Besides fields, you could also add scoring profiles, suggesters, or CORS options to the index (these parameters are omitted from the sample for brevity). You can find more information about the `SearchIndex` object and its constituent parts in the [SearchIndex properties list](#), as well as in the [REST API reference](#).

! Note

You can always create the list of `Field` objects directly instead of using `FieldBuilder` if needed. For example, you might not want to use a model class or you might need to use an existing model class that you don't want to modify by adding attributes.

Call CreateIndex in Main()

`Main` creates a new *hotels* index by calling the preceding method:

C#

```
Console.WriteLine("{0}", "Creating index...\n");
CreateIndex(indexName, indexClient);
```

Use a model class for data representation

The DotNetHowTo sample uses model classes for the [Hotel](#), [Address](#), and [Room](#) data structures. `Hotel` references `Address`, a single level complex type (a multi-part field), and `Room` (a collection of multi-part fields).

You can use these types to create and load the index, and to structure the response from a query:

C#

```
// Use-case: <Hotel> in a field definition
FieldBuilder fieldBuilder = new FieldBuilder();
var searchFields = fieldBuilder.Build(typeof(Hotel));

// Use-case: <Hotel> in a response
private static void WriteDocuments(SearchResults<Hotel> searchResults)
{
    foreach ( SearchResult<Hotel> result in searchResults.GetResults())
    {
        Console.WriteLine(result.Document);
    }
}
```

```
        Console.WriteLine();
    }
```

An alternative approach is to add fields to an index directly. The following example shows just a few fields.

C#

```
SearchIndex index = new SearchIndex(indexName)
{
    Fields =
    {
        new SimpleField("hotelId", SearchFieldDataType.String) { IsKey = true, IsFilterable = true, IsSortable = true },
        new SearchableField("hotelName") { IsFilterable = true, IsSortable = true },
        new SearchableField("hotelCategory") { IsFilterable = true, IsSortable = true },
        new SimpleField("baseRate", SearchFieldDataType.Int32) { IsFilterable = true, IsSortable = true },
        new SimpleField("lastRenovationDate",
SearchFieldDataType.DateTimeOffset) { IsFilterable = true, IsSortable = true }
    }
};
```

Field definitions

Your data model in .NET and its corresponding index schema should support the search experience you'd like to give to your end user. Each top level object in .NET, such as a search document in a search index, corresponds to a search result you would present in your user interface. For example, in a hotel search application, your end users might want to search by hotel name, features of the hotel, or the characteristics of a particular room.

Within each class, a field is defined with a data type and attributes that determine how it's used. The name of each public property in each class maps to a field with the same name in the index definition.

Take a look at the following snippet that pulls several field definitions from the Hotel class. Notice that `Address` and `Rooms` are C# types with their own class definitions (refer to the sample code if you want to view them). Both are complex types. For more information, see [How to model complex types](#).

C#

```
public partial class Hotel
{
```

```

[SimpleField(IsKey = true, IsFilterable = true)]
public string HotelId { get; set; }

[SearchableField(IsSortable = true)]
public string HotelName { get; set; }

[SearchableField(AnalyzerName = LexicalAnalyzerName.Values.EnLucene)]
public string Description { get; set; }

[SearchableField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
public string Category { get; set; }

[JsonIgnore]
public bool? SmokingAllowed => (Rooms != null) ? Array.Exists(Rooms, element => element.SmokingAllowed == true) : (bool?)null;

[SearchableField]
public Address Address { get; set; }

public Room[] Rooms { get; set; }

```

Choose a field class

When defining fields, you can use the base `SearchField` class, or you can use derivative helper models that serve as *templates*, with pre-configured properties.

Exactly one field in your index must serve as the document key (`IsKey = true`). It must be a string, and it must uniquely identify each document. It's also required to have `IsHidden = true`, which means it can't be visible in search results.

[] [Expand table](#)

Field type	Description and usage
<code>SearchField</code>	Base class, with most properties set to null, except <code>Name</code> which is required, and <code>AnalyzerName</code> which defaults to standard Lucene.
<code>SimpleField</code>	Helper model. Can be any data type, is always non-searchable (it's ignored for full text search queries), and is retrievable (it's not hidden). Other attributes are off by default, but can be enabled. You might use a <code>SimpleField</code> for document IDs or fields used only in filters, facets, or scoring profiles. If so, be sure to apply any attributes that are necessary for the scenario, such as <code>IsKey = true</code> for a document ID. For more information, see SimpleFieldAttribute.cs in source code.
<code>SearchableField</code>	Helper model. Must be a string, and is always searchable and retrievable. Other attributes are off by default, but can be enabled. Because this field type is searchable, it supports synonyms and the full complement of analyzer properties. For more information, see the SearchableFieldAttribute.cs in source code.

Whether you use the basic `SearchField` API or either one of the helper models, you must explicitly enable filter, facet, and sort attributes. For example, `IsFilterable`, `IsSortable`, and `IsFacetable` must be explicitly attributed, as shown in the previous sample.

Add field attributes

Notice how each field is decorated with attributes such as `IsFilterable`, `IsSortable`, `IsKey`, and `AnalyzerName`. These attributes map directly to the [corresponding field attributes in an Azure AI Search index](#). The `FieldBuilder` class uses these properties to construct field definitions for the index.

Field type mapping

The .NET types of the properties map to their equivalent field types in the index definition. For example, the `Category` string property maps to the `category` field, which is of type `Edm.String`. There are similar type mappings between `bool?`, `Edm.Boolean`, `DateTimeOffset?`, and `Edm.DateTimeOffset` and so on.

Did you happen to notice the `SmokingAllowed` property?

C#

```
[JsonIgnore]
public bool? SmokingAllowed => (Rooms != null) ? Array.Exists(Rooms, element =>
element.SmokingAllowed == true) : (bool?)null;
```

The `JsonIgnore` attribute on this property tells the `FieldBuilder` to not serialize it to the index as a field. This is a great way to create client-side calculated properties that you can use as helpers in your application. In this case, the `SmokingAllowed` property reflects whether any `Room` in the `Rooms` collection allows smoking. If all are false, it indicates that the entire hotel doesn't allow smoking.

Load an index

The next step in `Main` populates the newly created `hotels` index. This index population is done in the following method: (Some code replaced with `...` for illustration purposes. See the full sample solution for the full data population code.)

C#

```
private static void UploadDocuments(SearchClient searchClient)
{
    IndexDocumentsBatch<Hotel> batch = IndexDocumentsBatch.Create(
        IndexDocumentsAction.Upload(
            new Hotel()
            {
                HotelId = "1",
                HotelName = "Stay-Kay City Hotel",
                ...
                Address = new Address()
                {
                    StreetAddress = "677 5th Ave",
                    ...
                },
                Rooms = new Room[]
                {
                    new Room()
                    {
                        Description = "Budget Room, 1 Queen Bed (Cityside)",
                        ...
                    },
                    new Room()
                    {
                        Description = "Budget Room, 1 King Bed (Mountain View)",
                        ...
                    },
                    new Room()
                    {
                        Description = "Deluxe Room, 2 Double Beds (City View)",
                        ...
                    }
                }
            },
            IndexDocumentsAction.Upload(
                new Hotel()
                {
                    HotelId = "2",
                    HotelName = "Old Century Hotel",
                    ...
                },
                Rooms = new Room[]
                {
                    new Room()
                    {
                        Description = "Suite, 2 Double Beds (Mountain View)",
                        ...
                    },
                    new Room()
                    {
                        Description = "Standard Room, 1 Queen Bed (City View)",
                        ...
                    }
                }
            )
        )
    );
}
```

```
        },
        new Room()
    {
        Description = "Budget Room, 1 King Bed (Waterfront View)",
        ...
    }
},
IndexDocumentsAction.Upload(
    new Hotel()
{
    HotelId = "3",
    HotelName = "Gastronomic Landscape Hotel",
    ...
    Address = new Address()
    {
        StreetAddress = "3393 Peachtree Rd",
        ...
    },
    Rooms = new Room[]
    {
        new Room()
        {
            Description = "Standard Room, 2 Queen Beds (Amenities)",
            ...
        },
        new Room()
        {
            Description = "Standard Room, 2 Double Beds (Waterfront
View)",
            ...
        },
        new Room()
        {
            Description = "Deluxe Room, 2 Double Beds (Cityside)",
            ...
        }
    }
}
);

try
{
    IndexDocumentsResult result = searchClient.IndexDocuments(batch);
}
catch (Exception)
{
    // Sometimes when your Search service is under load, indexing will fail
    // for some of the documents in
    // the batch. Depending on your application, you can take compensating
    // actions like delaying and
    // retrying. For this simple demo, we just log the failed document keys
    // and continue.
    Console.WriteLine("Failed to index some of the documents: {0}");
}
```

```
Console.WriteLine("Waiting for documents to be indexed... \n");
Thread.Sleep(2000);
```

This method has four parts. The first creates an array of three `Hotel` objects each with three `Room` objects that serve as our input data to upload to the index. This data is hard-coded for simplicity. In an actual application, data likely comes from an external data source such as a SQL database.

The second part creates an `IndexDocumentsBatch` containing the documents. You specify the operation you want to apply to the batch at the time you create it, in this case by calling `IndexDocumentsAction.Upload`. The batch is then uploaded to the Azure AI Search index by the `IndexDocuments` method.

Note

In this example, you're just uploading documents. If you wanted to merge changes into existing documents or delete documents, you could create batches by calling `IndexDocumentsAction.Merge`, `IndexDocumentsAction.MergeOrUpload`, or `IndexDocumentsAction.Delete` instead. You can also mix different operations in a single batch by calling `IndexBatch.New`, which takes a collection of `IndexDocumentsAction` objects, each of which tells Azure AI Search to perform a particular operation on a document. You can create each `IndexDocumentsAction` with its own operation by calling the corresponding method such as `IndexDocumentsAction.Merge`, `IndexAction.Upload`, and so on.

The third part of this method is a catch block that handles an important error case for indexing. If your search service fails to index some of the documents in the batch, a `RequestFailedException` is thrown. An exception can happen if you're indexing documents while your service is under heavy load. **We strongly recommend explicitly handling this case in your code.** You can delay and then retry indexing the documents that failed, or you can log and continue like the sample does, or you can do something else depending on your application's data consistency requirements. An alternative is to use `SearchIndexingBufferedSender` for intelligent batching, automatic flushing, and retries for failed indexing actions. For more context, see the [SearchIndexingBufferedSender example ↗](#).

Finally, the `UploadDocuments` method delays for two seconds. Indexing happens asynchronously in your search service, so the sample application needs to wait a short time to ensure that the documents are available for searching. Delays like this are typically only necessary in demos, tests, and sample applications.

Call UploadDocuments in Main()

The following code snippet sets up an instance of `SearchClient` using the `GetSearchClient` method of `indexClient`. The `indexClient` uses an admin API key on its requests, which is required for loading or refreshing documents.

An alternate approach is to call `SearchClient` directly, passing in an admin API key on `AzureKeyCredential`.

C#

```
SearchClient searchClient = indexClient.GetSearchClient(indexName);

Console.WriteLine("{0}", "Uploading documents...\n");
UploadDocuments(searchClient);
```

Run queries

First, set up a `SearchClient` that reads the service endpoint and query API key from `appsettings.json`:

C#

```
private static SearchClient CreateSearchClientForQueries(string indexName,
IConfigurationRoot configuration)
{
    string searchServiceEndPoint = configuration["YourSearchServiceEndPoint"];
    string queryApiKey = configuration["YourSearchServiceQueryApiKey"];

    SearchClient searchClient = new SearchClient(new Uri(searchServiceEndPoint),
indexName, new AzureKeyCredential(queryApiKey));
    return searchClient;
}
```

Second, define a method that sends a query request.

Each time the method executes a query, it creates a new `SearchOptions` object. This object is used to specify additional options for the query such as sorting, filtering, paging, and faceting. In this method, we're setting the `Filter`, `Select`, and `OrderBy` property for different queries. For more information about the search query expression syntax, [Simple query syntax](#).

The next step is query execution. Running the search is done using the `SearchClient.Search` method. For each query, pass the search text to use as a string (or `"*"` if there's no search text), plus the search options created earlier. We also specify `Hotel` as the type parameter for

`SearchClient.Search`, which tells the SDK to deserialize documents in the search results into objects of type `Hotel`.

C#

```
private static void RunQueries(SearchClient searchClient)
{
    SearchOptions options;
    SearchResults<Hotel> results;

    Console.WriteLine("Query 1: Search for 'motel'. Return only the HotelName in results:\n");

    options = new SearchOptions();
    options.Select.Add("HotelName");

    results = searchClient.Search<Hotel>("motel", options);

    WriteDocuments(results);

    Console.Write("Query 2: Apply a filter to find hotels with rooms cheaper than $100 per night, ");
    Console.WriteLine("returning the HotelId and Description:\n");

    options = new SearchOptions()
    {
        Filter = "Rooms/any(r: r/BaseRate lt 100)"
    };
    options.Select.Add("HotelId");
    options.Select.Add("Description");

    results = searchClient.Search<Hotel>("*", options);

    WriteDocuments(results);

    Console.Write("Query 3: Search the entire index, order by a specific field (lastRenovationDate) ");
    Console.Write("in descending order, take the top two results, and show only hotelName and ");
    Console.WriteLine("lastRenovationDate:\n");

    options =
        new SearchOptions()
    {
        Size = 2
    };
    options.OrderBy.Add("LastRenovationDate desc");
    options.Select.Add("HotelName");
    options.Select.Add("LastRenovationDate");

    results = searchClient.Search<Hotel>("*", options);

    WriteDocuments(results);
```

```

Console.WriteLine("Query 4: Search the HotelName field for the term
'hotel':\n");

options = new SearchOptions();
options.SearchFields.Add("HotelName");

//Adding details to select, because "Location" isn't supported yet when
deserializing search result to "Hotel"
options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Description");
options.Select.Add("Category");
options.Select.Add("Tags");
options.Select.Add("ParkingIncluded");
options.Select.Add("LastRenovationDate");
options.Select.Add("Rating");
options.Select.Add("Address");
options.Select.Add("Rooms");

results = searchClient.Search<Hotel>("hotel", options);

WriteDocuments(results);
}

```

Third, define a method that writes the response, printing each document to the console:

```

C#

private static void WriteDocuments(SearchResults<Hotel> searchResults)
{
    foreach (SearchResult<Hotel> result in searchResults.GetResults())
    {
        Console.WriteLine(result.Document);
    }

    Console.WriteLine();
}

```

Call RunQueries in Main()

```

C#

SearchClient indexClientForQueries = CreateSearchClientForQueries(indexName,
configuration);

Console.WriteLine("{0}", "Running queries...\n");
RunQueries(indexClientForQueries);

```

Explore query constructs

Let's take a closer look at each of the queries in turn. Here's the code to execute the first query:

```
C#  
  
options = new SearchOptions();  
options.Select.Add("HotelName");  
  
results = searchClient.Search<Hotel>("motel", options);  
  
WriteDocuments(results);
```

In this case, we're searching the entire index for the word *motel* in any searchable field and we only want to retrieve the hotel names, as specified by the `Select` option. Here are the results:

```
Output  
  
Name: Stay-Kay City Hotel  
  
Name: Old Century Hotel
```

In the second query, use a filter to select rooms with a nightly rate of less than \$100. Return only the hotel ID and description in the results:

```
C#  
  
options = new SearchOptions()  
{  
    Filter = "Rooms/any(r: r/BaseRate lt 100)"  
};  
options.Select.Add("HotelId");  
options.Select.Add("Description");  
  
results = searchClient.Search<Hotel>("*", options);
```

This query uses an OData `$filter` expression, `Rooms/any(r: r/BaseRate lt 100)`, to filter the documents in the index. It uses the [any operator](#) to apply the 'BaseRate lt 100' to every item in the Rooms collection. For more information, see [OData filter syntax](#).

In the third query, find the top two hotels that have been most recently renovated, and show the hotel name and last renovation date. Here's the code:

```
C#  
  
options =  
    new SearchOptions()
```

```

    {
        Size = 2
    };
options.OrderBy.Add("LastRenovationDate desc");
options.Select.Add("HotelName");
options.Select.Add("LastRenovationDate");

results = searchClient.Search<Hotel>("*", options);

WriteDocuments(results);

```

In the last query, find all hotels names that match the word *hotel*:

C#

```

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Description");
options.Select.Add("Category");
options.Select.Add("Tags");
options.Select.Add("ParkingIncluded");
options.Select.Add("LastRenovationDate");
options.Select.Add("Rating");
options.Select.Add("Address");
options.Select.Add("Rooms");

results = searchClient.Search<Hotel>("hotel", options);

WriteDocuments(results);

```

This section concludes this introduction to the .NET SDK, but don't stop here. The next section suggests other resources for learning more about programming with Azure AI Search.

Upgrade versions of the Azure Search .NET Management SDK

Article • 02/24/2025

This article points you to libraries in the Azure SDK for .NET for managing a search service. These libraries provide the APIs used to create, configure, and delete search services. They also provide APIs used to adjust capacity, manage API keys, and configure network security.

Management SDKs target a specific version of the Management REST API. Release notes for each library indicate which REST API version is the target for each package. For more information about concepts and operations, see [Search Management \(REST\)](#).

Versions

The following table lists the client libraries used to provision a search service.

[+] Expand table

Namespace	Version	Status	Change log
Azure.ResourceManager.Search	Package versions ↗	Current	Change Log ↗
Microsoft.Azure.Management.Search	Package versions ↗	Deprecated	Release notes ↗

Checklist for upgrade

1. Review the [change log ↗](#) for updates to the library.
2. In your application code, delete the reference to `Microsoft.Azure.Management.Search` and its dependencies.
3. Add a reference for `Azure.ResourceManager.Search` using either the NuGet Package Manager Console or by right-clicking on your project references and selecting "Manage NuGet Packages..." in Visual Studio.
4. Once NuGet has downloaded the new packages and their dependencies, replace the API calls.

Next steps

If you encounter problems, the best forum for posting questions is [Stack Overflow](#). If you find a bug, you can file an issue in the [Azure .NET SDK GitHub repository](#). Make sure to label your issue title with *search*.

Manage concurrency in Azure AI Search

08/22/2025

When managing Azure AI Search resources such as indexes and data sources, it's important to update resources safely, especially if resources are accessed concurrently by different components of your application.

- Resource update operations may not complete immediately. For example, [updating an index](#) or an [indexer](#) may take several seconds to complete. Resource updates are *serialized*, which means multiple update operations may not run simultaneously on the same resource.
- When two clients concurrently update a resource without coordination, a *race condition* is possible. One client could start an update operation while the other client receives a conflict error. To prevent this, Azure AI Search supports an *optimistic concurrency model*. There are no locks on a resource. Instead, there's an ETag for every resource that identifies the resource version so that you can formulate requests that avoid accidental overwrites.

How it works

Optimistic concurrency is implemented through access condition checks in API calls writing to indexes, indexers, data sources, skillsets, knowledge agents, and synonymMap resources.

All resources have an [entity tag \(ETag\)](#) that provides object version information. By checking the ETag first, you can avoid concurrent updates in a typical workflow (get, modify locally, update) by ensuring the resource's ETag matches your local copy.

- The REST API uses an [ETag](#) on the request header.
- The Azure SDK for .NET sets the ETag through an `accessCondition` class, setting the [If-Match | If-Match-None header](#) on the resource. Objects that use ETags, such as [SynonymMap.ETag](#) and [SearchIndex.ETag](#), have an `accessCondition` class.

Every time you update a resource, its ETag changes automatically. When you implement concurrency management, all you're doing is putting a precondition on the update request that requires the remote resource to have the same ETag as the copy of the resource that you modified on the client. If another process changes the remote resource, the ETag doesn't match the precondition and the request fails with HTTP 412 or 409. If you're using the .NET SDK, this failure manifests as an exception where the `IsAccessConditionFailed()` extension method returns true.

Note

There is only one mechanism for concurrency. It's always used regardless of which API or SDK is used for resource updates. Starting July 18, 2025, Azure AI Search began enforcing serialization for index creation and update operations to ensure consistency and reliability.

Example

The following code demonstrates optimistic concurrency for an update operation. It fails the second update because the object's ETag is changed by a previous update. More specifically, when the ETag in the request header no longer matches the ETag of the object, the search service return a status code of 400 (bad request), and the update fails.

C#

```
using Azure;
using Azure.Search.Documents;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;
using System;
using System.Net;
using System.Threading.Tasks;

namespace AzureSearch.SDKHowTo
{
    class Program
    {
        // This sample shows how ETags work by performing conditional updates and
        // deletes
        // on an Azure Search index.
        static void Main(string[] args)
        {
            string serviceName = "PLACEHOLDER FOR YOUR SEARCH SERVICE NAME";
            string apiKey = "PLACEHOLDER FOR YOUR SEARCH SERVICE ADMIN API KEY";

            // Create a SearchIndexClient to send create/delete index commands
            Uri serviceEndpoint = new
Uri($"https://'{serviceName}'.search.windows.net/");
            AzureKeyCredential credential = new AzureKeyCredential(apiKey);
            SearchIndexClient adminClient = new SearchIndexClient(serviceEndpoint,
            credential);

            // Delete index if it exists
            Console.WriteLine("Check for index and delete if it already
exists...\n");
            DeleteTestIndexIfExists(adminClient);

            // Every top-level resource in Azure Search has an associated ETag
            // that keeps track of which version
            // of the resource you're working on. When you first create a resource
            such as an index, its ETag is
            // empty.
```

```

    SearchIndex index = DefineTestIndex();

    Console.WriteLine(
        $"Test searchIndex hasn't been created yet, so its ETag should be
blank. ETag: '{index.ETag}'");

        // Once the resource exists in Azure Search, its ETag is populated.
Make sure to use the object
        // returned by the SearchIndexClient. Otherwise, you will still have
the old object with the
        // blank ETag.
        Console.WriteLine("Creating index...\n");
        index = adminClient.CreateIndex(index);
        Console.WriteLine($"Test index created; Its ETag should be populated.
ETag: '{index.ETag}'");

        // ETags prevent concurrent updates to the same resource. If another
        // client tries to update the resource, it will fail as long as all
clients are using the right
        // access conditions.
        SearchIndex indexForClientA = index;
        SearchIndex indexForClientB = adminClient.GetIndex("test-idx");

        Console.WriteLine("Simulating concurrent update. To start, clients A
and B see the same ETag.");
        Console.WriteLine($"ClientA ETag: '{indexForClientA.ETag}' ClientB
ETag: '{indexForClientB.ETag}'");

        // indexForClientA successfully updates the index.
        indexForClientA.Fields.Add(new SearchField("a",
SearchFieldDataType.Int32));
        indexForClientA = adminClient.CreateOrUpdateIndex(indexForClientA);

        Console.WriteLine($"Client A updates test-idx by adding a new field.
The new ETag for test-idx is: '{indexForClientA.ETag}'");

        // indexForClientB tries to update the index, but fails due to the
ETag check.
        try
        {
            indexForClientB.Fields.Add(new SearchField("b",
SearchFieldDataType.Boolean));
            adminClient.CreateOrUpdateIndex(indexForClientB);

            Console.WriteLine("Whoops; This shouldn't happen");
            Environment.Exit(1);
        }
        catch (RequestFailedException e) when (e.Status == 400)
        {
            Console.WriteLine("Client B failed to update the index, as
expected.");
        }

        // Uncomment the next line to remove test-idx

```

```

        //adminClient.DeleteIndex("test-idx");
        Console.WriteLine("Complete. Press any key to end application...\n");
        Console.ReadKey();
    }

private static void DeleteTestIndexIfExists(SearchIndexClient adminClient)
{
    try
    {
        if (adminClient.GetIndex("test-idx") != null)
        {
            adminClient.DeleteIndex("test-idx");
        }
    }
    catch (RequestFailedException e) when (e.Status == 404)
    {
        //if an exception occurred and status is "Not Found", this is
        working as expected
        Console.WriteLine("Failed to find index and this is because it's
not there.");
    }
}

private static SearchIndex DefineTestIndex() =>
    new SearchIndex("test-idx", new[] { new SearchField("id",
SearchFieldDataType.String) { IsKey = true } });
}

```

Design pattern

A design pattern for implementing optimistic concurrency should include a loop that retries the access condition check, a test for the access condition, and optionally retrieves an updated resource before attempting to reapply the changes.

This code snippet illustrates the addition of a synonymMap to an index that already exists.

The snippet gets the hotels-sample-index index, checks the object version on an update operation, throws an exception if the condition fails, and then retries the operation (up to three times), starting with index retrieval from the server to get the latest version.

C#

```

private static void EnableSynonymsInHotelsIndexSafely(SearchIndexClient
indexClient)
{
    int MaxNumTries = 3;

    for (int i = 0; i < MaxNumTries; ++i)

```

```

{
    try
    {
        SearchIndex index = indexClient.GetIndex("hotels-sample-index");
        index = AddSynonymMapsToFields(index);

        // The onlyIfUnchanged condition ensures that the index is updated only
        // if the ETags match.
        indexClient.CreateOrUpdateIndex(index, onlyIfUnchanged: true);

        Console.WriteLine("Updated the index successfully.\n");
        break;
    }
    catch (RequestFailedException e) when (e.Status == 412)
    {
        Console.WriteLine($"Index update failed : {e.Message}.

Attempt{i}/{MaxNumTries}.\n");
    }
}

private static SearchIndex AddSynonymMapsToFields(SearchIndex index)
{
    index.Fields.First(f => f.Name == "category").SynonymMapNames.Add("desc-
synonymmap");
    index.Fields.First(f => f.Name == "tags").SynonymMapNames.Add("desc-
synonymmap");
    return index;
}

```

Monitor Azure AI Search

07/25/2025

This article describes:

- The types of monitoring data you can collect for this service.
- Ways to analyze that data.

 **Note**

If you're already familiar with this service and/or Azure Monitor and just want to know how to analyze monitoring data, see the [Analyze](#) section near the end of this article.

When you have critical applications and business processes that rely on Azure resources, you need to monitor and get alerts for your system. The Azure Monitor service collects and aggregates metrics and logs from every component of your system. Azure Monitor provides you with a view of availability, performance, and resilience, and notifies you of issues. You can use the Azure portal, PowerShell, Azure CLI, REST API, or client libraries to set up and view monitoring data.

- For more information on Azure Monitor, see the [Azure Monitor overview](#).
- For more information on how to monitor Azure resources in general, see [Monitor Azure resources with Azure Monitor](#).

 **Note**

Azure AI Search doesn't log the identity of the person or app accessing content or operations on the search service. If you require this level of monitoring, you need to implement it in your client application.

Resource types

Azure uses the concept of resource types and IDs to identify everything in a subscription. Resource types are also part of the resource IDs for every resource running in Azure. For example, one resource type for a virtual machine is `Microsoft.Compute/virtualMachines`. For a list of services and their associated resource types, see [Resource providers](#).

Azure Monitor similarly organizes core monitoring data into metrics and logs based on resource types, also called *namespaces*. Different metrics and logs are available for different resource types. Your service might be associated with more than one resource type.

For more information about the resource types for Azure AI Search, see [Azure AI Search monitoring data reference](#).

Data storage

For Azure Monitor:

- Metrics data is stored in the Azure Monitor metrics database.
- Log data is stored in the Azure Monitor logs store. Log Analytics is a tool in the Azure portal that can query this store.
- The Azure activity log is a separate store with its own interface in the Azure portal.

You can optionally route metric and activity log data to the Azure Monitor logs store. You can then use Log Analytics to query the data and correlate it with other log data.

Many services can use diagnostic settings to send metric and log data to other storage locations outside Azure Monitor. Examples include Azure Storage, [hosted partner systems](#), and [non-Azure partner systems](#), by using Event Hubs.

For detailed information on how Azure Monitor stores data, see [Azure Monitor data platform](#).

Azure Monitor platform metrics

Azure Monitor provides platform metrics for most services. These metrics are:

- Individually defined for each namespace.
- Stored in the Azure Monitor time-series metrics database.
- Lightweight and capable of supporting near real-time alerting.
- Used to track the performance of a resource over time.

Collection: Azure Monitor collects platform metrics automatically. No configuration is required.

Routing: You can also route some platform metrics to Azure Monitor Logs / Log Analytics so you can query them with other log data. Check the **DS export** setting for each metric to see if you can use a diagnostic setting to route the metric to Azure Monitor Logs / Log Analytics.

- For more information, see the [Metrics diagnostic setting](#).
- To configure diagnostic settings for a service, see [Create diagnostic settings in Azure Monitor](#).

For a list of all metrics it's possible to gather for all resources in Azure Monitor, see [Supported metrics in Azure Monitor](#).

In Azure AI Search, platform metrics measure query performance, indexing volume, and skillset invocation. For a list of available metrics for Azure AI Search, see [Azure AI Search monitoring data reference](#).

To learn how to analyze query and index performance, see [Analyze performance in Azure AI Search](#).

Azure Monitor resource logs

Resource logs provide insight into operations that were done by an Azure resource. Logs are generated automatically, but you must route them to Azure Monitor logs to save or query them. Logs are organized in categories. A given namespace might have multiple resource log categories.

Collection: Resource logs aren't collected and stored until you create a *diagnostic setting* and route the logs to one or more locations. When you create a diagnostic setting, you specify which categories of logs to collect. There are multiple ways to create and maintain diagnostic settings, including the Azure portal, programmatically, and through Azure Policy.

Routing: The suggested default is to route resource logs to Azure Monitor Logs so you can query them with other log data. Other locations such as Azure Storage, Azure Event Hubs, and certain Microsoft monitoring partners are also available. For more information, see [Azure resource logs](#) and [Resource log destinations](#).

For detailed information about collecting, storing, and routing resource logs, see [Diagnostic settings in Azure Monitor](#).

For a list of all available resource log categories in Azure Monitor, see [Supported resource logs in Azure Monitor](#).

All resource logs in Azure Monitor have the same header fields, followed by service-specific fields. The common schema is outlined in [Azure Monitor resource log schema](#).

For the available resource log categories, their associated Log Analytics tables, and the logs schemas for Azure AI Search, see [Azure AI Search monitoring data reference](#).

Azure activity log

The activity log contains subscription-level events that track operations for each Azure resource as seen from outside that resource; for example, creating a new resource or starting a virtual machine.

Collection: Activity log events are automatically generated and collected in a separate store for viewing in the Azure portal.

Routing: You can send activity log data to Azure Monitor Logs so you can analyze it alongside other log data. Other locations such as Azure Storage, Azure Event Hubs, and certain Microsoft monitoring partners are also available. For more information on how to route the activity log, see [Overview of the Azure activity log](#).

In Azure AI Search, activity logs reflect control plane activity such as service creation and configuration, or API key usage or management. Entries often include **Get Admin Key**, one entry for every call that [provided an admin API key](#) on the request. There are no details about the call itself, just a notification that the admin key was used.

API keys can be disabled for data plane operations, such as creating or querying an index, but on the control plane they're used in the Azure portal to return service information. Control plane operations can request API keys so you continue to see key-related requests in the Activity log even if you disable key-based authentication.

The following screenshot shows Azure AI Search activity log signals you can configure in an alert.

The screenshot shows a configuration interface for setting up an alert. At the top, there's a note: "Choose a signal below and configure the logic on the next screen to define the alert condition." Below this, there are two dropdown menus: "Signal type" set to "Activity Log" and "Monitor service" set to "All". A message indicates "Displaying 1 - 9 signals out of total 9 signals". A search bar labeled "Search by signal name" is present. A table lists nine signals, each with a small icon, the signal name, its type, and the monitor service it belongs to. The signals listed are: All Administrative operations, Set Search Service (Microsoft.Search/searchServices), Delete Search Service (Microsoft.Search/searchServices), Start Search Service (Microsoft.Search/searchServices), Stop Search Service (Microsoft.Search/searchServices), Get Admin Key (Microsoft.Search/searchServices), Regenerate Admin Key (Microsoft.Search/searchServices), Get Query Keys (Microsoft.Search/searchServices), and Create Query Key (Microsoft.Search/searchServices). All signals are categorized under the "Activity log" type and belong to the "Administrative" monitor service.

Signal name	Signal type	Monitor service
All Administrative operations	Activity log	Administrative
Set Search Service (Microsoft.Search/searchServices)	Activity log	Administrative
Delete Search Service (Microsoft.Search/searchServices)	Activity log	Administrative
Start Search Service (Microsoft.Search/searchServices)	Activity log	Administrative
Stop Search Service (Microsoft.Search/searchServices)	Activity log	Administrative
Get Admin Key (Microsoft.Search/searchServices)	Activity log	Administrative
Regenerate Admin Key (Microsoft.Search/searchServices)	Activity log	Administrative
Get Query Keys (Microsoft.Search/searchServices)	Activity log	Administrative
Create Query Key (Microsoft.Search/searchServices)	Activity log	Administrative

For other entries, see the [Management REST API reference](#) for control plane activity that might appear in the log.

Analyze monitoring data

There are many tools for analyzing monitoring data.

Azure Monitor tools

Azure Monitor supports the following basic tools:

- [Metrics explorer](#), a tool in the Azure portal that allows you to view and analyze metrics for Azure resources. For more information, see [Analyze metrics with Azure Monitor metrics explorer](#).
- [Log Analytics](#), a tool in the Azure portal that allows you to query and analyze log data by using the [Kusto query language \(KQL\)](#). For more information, see [Get started with log queries in Azure Monitor](#).
- The [activity log](#), which has a user interface in the Azure portal for viewing and basic searches. To do more in-depth analysis, you have to route the data to Azure Monitor logs and run more complex queries in Log Analytics.

Tools that allow more complex visualization include:

- [Dashboards](#) that let you combine different kinds of data into a single pane in the Azure portal.
- [Workbooks](#), customizable reports that you can create in the Azure portal. Workbooks can include text, metrics, and log queries.
- [Grafana](#), an open platform tool that excels in operational dashboards. You can use Grafana to create dashboards that include data from multiple sources other than Azure Monitor.
- [Power BI](#), a business analytics service that provides interactive visualizations across various data sources. You can configure Power BI to automatically import log data from Azure Monitor to take advantage of these visualizations.

Azure Monitor export tools

You can get data out of Azure Monitor into other tools by using the following methods:

- **Metrics:** Use the [REST API for metrics](#) to extract metric data from the Azure Monitor metrics database. The API supports filter expressions to refine the data retrieved. For more information, see [Azure Monitor REST API reference](#).
- **Logs:** Use the REST API or the [associated client libraries](#).
- Another option is the [workspace data export](#).

To get started with the REST API for Azure Monitor, see [Azure monitoring REST API walkthrough](#).

Kusto queries

You can analyze monitoring data in the Azure Monitor Logs / Log Analytics store by using the Kusto query language (KQL).

Important

When you select **Logs** from the service's menu in the portal, Log Analytics opens with the query scope set to the current service. This scope means that log queries will only include data from that type of resource. If you want to run a query that includes data from other Azure services, select **Logs** from the **Azure Monitor** menu. See [Log query scope and time range in Azure Monitor Log Analytics](#) for details.

For a list of common queries for any service, see the [Log Analytics queries interface](#).

The following queries can get you started. See [Analyze performance in Azure AI Search](#) for more examples and guidance specific to search service.

List metrics by name

Return a list of metrics and the associated aggregation. The query is scoped to the current search service over the time range that you specify.

```
Kusto
```

```
AzureMetrics  
| project MetricName, Total, Count, Maximum, Minimum, Average
```

List operations by name

Return a list of operations and a count of each one.

```
Kusto
```

```
AzureDiagnostics  
| summarize count() by OperationName
```

Long-running queries

This Kusto query against AzureDiagnostics returns `Query.Search` operations, sorted by duration (in milliseconds). For more examples of `Query.Search` queries, see [Analyze performance in Azure AI Search](#).

Kusto

```
AzureDiagnostics
| project OperationName, resultSignature_d, DurationMs, Query_s, Documents_d,
IndexName_s
| where OperationName == "Query.Search"
| sort by DurationMs
```

Indexer status

This Kusto query returns the status of indexer operations. Results include the operation name, description of the request (which includes the name of the indexer), result status (Success or Failure), and the [HTTP status code](#). For more information about indexer execution, see [Monitor indexer status](#).

Kusto

```
AzureDiagnostics
| project OperationName, Description_s, Documents_d, ResultType, resultSignature_d
| where OperationName == "Indexers.Status"
```

Alerts

Azure Monitor alerts proactively notify you when specific conditions are found in your monitoring data. Alerts allow you to identify and address issues in your system before your customers notice them. For more information, see [Azure Monitor alerts](#).

There are many sources of common alerts for Azure resources. For examples of common alerts for Azure resources, see [Sample log alert queries](#). The [Azure Monitor Baseline Alerts \(AMBA\)](#) site provides a semi-automated method of implementing important platform metric alerts, dashboards, and guidelines. The site applies to a continually expanding subset of Azure services, including all services that are part of the Azure Landing Zone (ALZ).

The common alert schema standardizes the consumption of Azure Monitor alert notifications. For more information, see [Common alert schema](#).

Types of alerts

You can alert on any metric or log data source in the Azure Monitor data platform. There are many different types of alerts depending on the services you're monitoring and the monitoring data you're collecting. Different types of alerts have various benefits and drawbacks. For more information, see [Choose the right monitoring alert type](#).

The following list describes the types of Azure Monitor alerts you can create:

- [Metric alerts](#) evaluate resource metrics at regular intervals. Metrics can be platform metrics, custom metrics, logs from Azure Monitor converted to metrics, or Application Insights metrics. Metric alerts can also apply multiple conditions and dynamic thresholds.
- [Log alerts](#) allow users to use a Log Analytics query to evaluate resource logs at a predefined frequency.
- [Activity log alerts](#) trigger when a new activity log event occurs that matches defined conditions. Resource Health alerts and Service Health alerts are activity log alerts that report on your service and resource health.

Some Azure services also support [smart detection alerts](#), [Prometheus alerts](#), or [recommended alert rules](#).

For some services, you can monitor at scale by applying the same metric alert rule to multiple resources of the same type that exist in the same Azure region. Individual notifications are sent for each monitored resource. For supported Azure services and clouds, see [Monitor multiple resources with one alert rule](#).

Azure AI Search alert rules

The following table lists common and recommended alert rules for Azure AI Search. On a search service, throttling or query latency that exceeds a given threshold are the most commonly used alerts, but you might also want to be notified if a search service is deleted.

[] [Expand table](#)

Alert type	Condition	Description
Search Latency (metric alert)	Whenever the average search latency is greater than a user-specified threshold (in seconds)	Send an SMS alert when average query response time exceeds the threshold.
Throttled search queries percentage (metric alert)	Whenever the total throttled search queries percentage is greater than or equal to a user-specified threshold	Send an SMS alert when dropped queries begin to exceed the threshold.

Alert type	Condition	Description
Delete Search Service (activity log alert)	Whenever the Activity Log has an event with Category='Administrative', Signal name='Delete Search Service (searchServices)', Level='critical'	Send an email if a search service is deleted in the subscription.

Advisor recommendations

For some services, if critical conditions or imminent changes occur during resource operations, an alert displays on the service **Overview** page in the portal. You can find more information and recommended fixes for the alert in **Advisor recommendations** under **Monitoring** in the left menu. During normal operations, no advisor recommendations display.

For more information on Azure Advisor, see [Azure Advisor overview](#).

Configure diagnostic logging for Azure AI Search

08/08/2025

Diagnostic logs provide insight into operations that occur in your Azure AI Search resource. In contrast to Activity Logs that track operations performed on Azure resources at the subscription level, known as the [control plane](#), diagnostic logging monitors operations on the search service itself. Diagnostic logging is essential for effective oversight of service operations like indexing and queries.

This article explains how to enable diagnostic logging and find information about system and user operations on an Azure AI Search resource.

ⓘ Note

Azure AI Search doesn't log the identity of the person or app accessing content or operations on the search service. If you require this level of monitoring, you need to implement it in your client application.

Prerequisites

- An [Azure Log Analytics workspace](#) in the same subscription.

Enable diagnostic logging

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. Under **Monitoring > Diagnostic settings**, select **Add diagnostic setting**.
3. Provide a descriptive name that identifies the service and level of logging, such as "my-search-service-all-logs" or "my-search-service-audit-logs".
4. Under **Logs**, choose a category:
 - **Audit logs** capture user or app interactions with data or the settings of the service, but don't include user or groups identities.
 - **Operation logs** capture information about operations on a search service.
 - **allLogs** collect everything.

Verbose logging can be expensive to store and complex to manage and store. You might want to start with **allLogs** and then switch to more scoped logging if it meets your information requirements. For more information about these categories, see [Diagnostic settings in Azure Monitor](#).

5. For a destination, we recommend **Send to Log Analytics workspace** so that you can run Kusto queries against the data. Provide an existing Log Analytics workspace to store your logs.
6. Save the settings.

Repeat these steps if you require a more [comprehensive data collection strategy](#).

Each diagnostic setting you create requires separate storage. If you use the Azure portal to review logs, the first diagnostic setting is used by default. You can navigate to specific workspaces for visualization support.

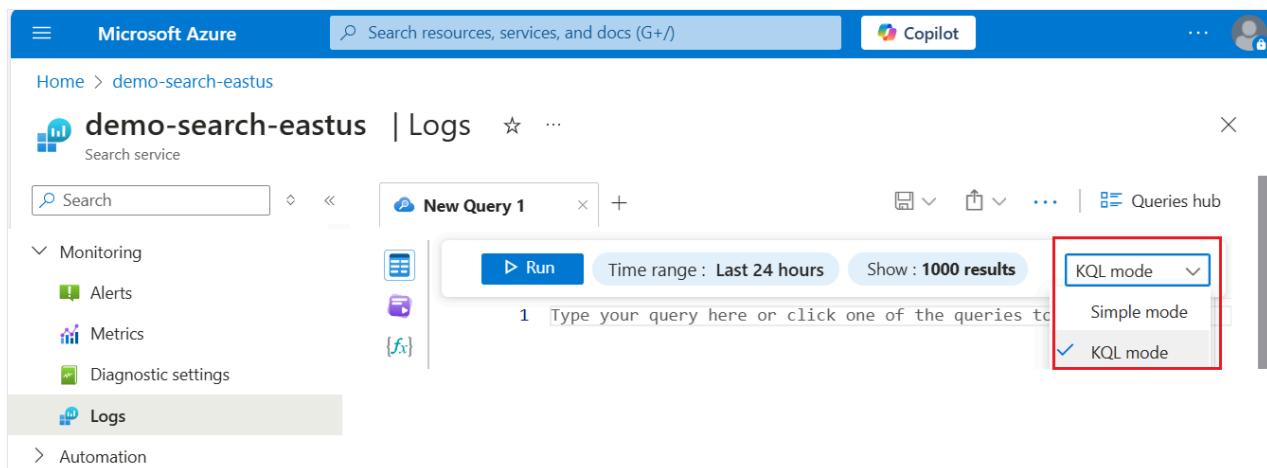

Note

If you're using [key-based authentication](#), Azure AI Search can't monitor individual user access to content on the search service. If you require this level of monitoring, you need to implement it in your client application.

View logs in Log Analytics

Follow these instructions to explore log analytics data for your search service.

1. Under **Monitoring**, select **Logs**. Query hub opens by default. You can try the available queries, or close the hub and open a query window in KQL mode to run queries written in the [Kusto Query Language \(KQL\)](#).

2. In a query window, you can run Kusto queries against your logs.

The screenshot shows the Azure Kusto Query Editor interface. At the top, there's a header bar with a 'New Query 1*' tab, a '+' button, and several icons for saving, opening, and queries hub. Below the header is a toolbar with a 'Run' button, a time range selector set to 'Last 24 hours', a result count selector set to '1000 results', and a 'KQL mode' dropdown. On the left, there are icons for file operations, a function editor, and a refresh. The main area contains a code editor with the following KQL query:

```
1 AzureDiagnostics
2 | where ResourceProvider == "MICROSOFT.SEARCH"
3 | summarize avg(DurationMs)
4 by OperationName
```

Below the code editor is a results table with two columns: 'OperationName' and 'avg_DurationMs'. The data is as follows:

OperationName	avg_DurationMs
> ServiceStats	19.285714285714285
> Indexes.ListIndexStatsSummaries	30.428571428571427
> Indexing.Index	1908.857142857143
> Query.Search	98.2
> Indexes.Get	25.333333333333332
> Indexers.Status	23
> Indexers.List	22
> CORS.Preflight	19.333333333333332

Sample Kusto queries

Here are a few basic Kusto queries you can use to explore your log data.

Run this query for all diagnostic logs from Azure AI Search services over the specified time period:

```
Kusto

AzureDiagnostics
| where ResourceProvider == "MICROSOFT.SEARCH"
```

Run this query to see the 10 most recent logs:

```
Kusto

AzureDiagnostics
| where ResourceProvider == "MICROSOFT.SEARCH"
| take 10
```

Run this query to group operations by Resource:

```
Kusto
```

```
AzureDiagnostics  
| where ResourceProvider == "MICROSOFT.SEARCH" |  
summarize count() by Resource
```

Run this query to find the average time it takes to perform an operation:

Kusto

```
AzureDiagnostics  
| where ResourceProvider == "MICROSOFT.SEARCH"  
| summarize avg(DurationMs)  
by OperationName
```

Run this query to view the volume of operations over time split by OperationName with counts binned for every 10 seconds.

Kusto

```
AzureDiagnostics  
| where ResourceProvider == "MICROSOFT.SEARCH"  
| summarize count()  
by bin(TimeGenerated, 10s), OperationName  
| render areachart kind=unstacked
```

Monitor query requests in Azure AI Search

08/08/2025

This article explains how to measure query performance and volume using built-in metrics and diagnostic logging. It also explains how to get the query strings entered by application users.

The Azure portal shows basic metrics about query latency, query load (QPS), and throttling. Historical data that feeds into these metrics can be accessed in the Azure portal for 30 days. For longer retention, or to report on operational data and query strings, you must [enable diagnostic logging](#) and choose a storage option for persisting logged operations and metrics. We recommend **Log Analytics workspace** as a destination for logged operations. Kusto queries and data exploration target a Log Analytics workspace.

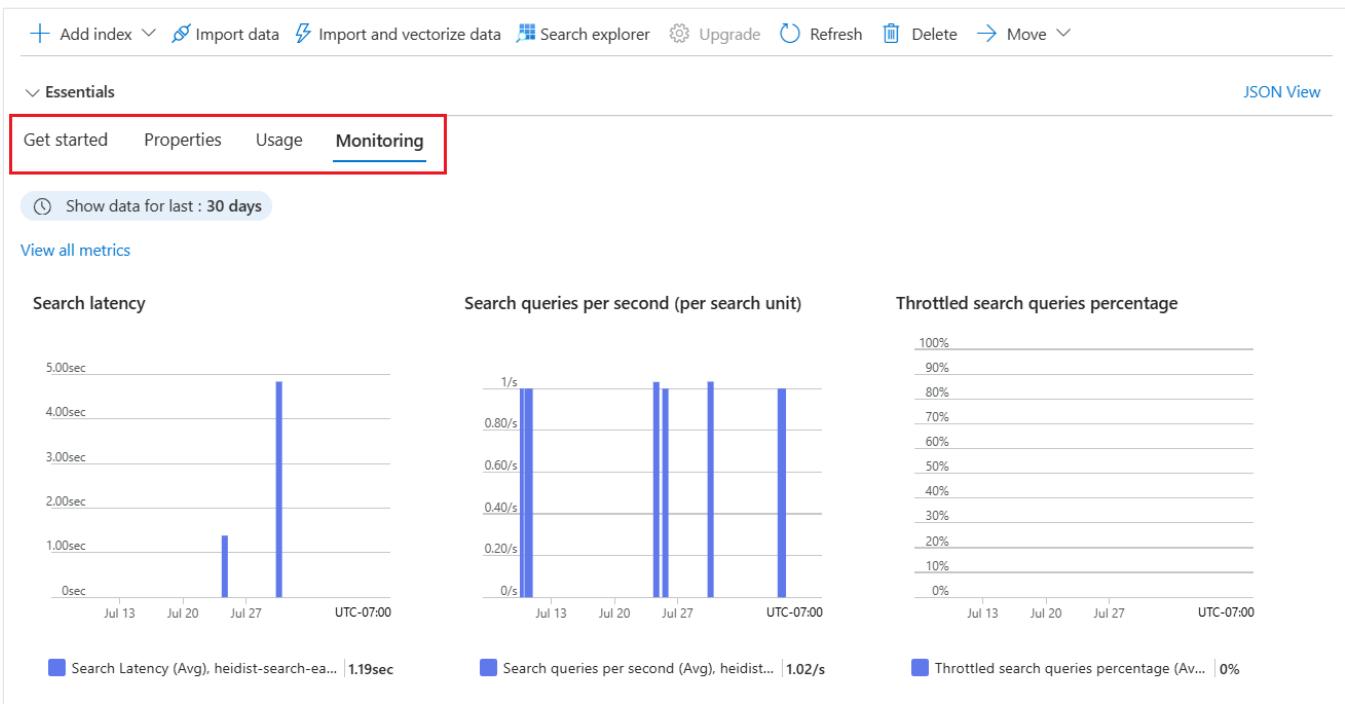

Conditions that maximize the integrity of data measurement include:

- Use a billable service (a service created at either the Basic or a Standard tier). The free service is shared by multiple subscribers, which introduces a certain amount of volatility as loads shift.
- Use a single replica and partition, if possible, to create a contained and isolated environment. If you use multiple replicas, query metrics are averaged across multiple nodes, which can lower the precision of results. Similarly, multiple partitions mean that data is divided, with the potential that some partitions might have different data if indexing is also underway. When you tune query performance, a single node and partition gives a more stable environment for testing.

Query volume (QPS)

Volume is measured as **Search Queries Per Second** (QPS), a built-in metric that can be reported as an average, count, minimum, or maximum values of queries that execute within a one-minute window. One-minute intervals (`TimeGrain = "PT1M"`) for metrics is fixed within the system.

Azure AI Search retains 30-days of metrics data by default. You can enable logging for longer retention. QPS is available in the Azure portal, in the **Monitoring** tab of your search service.

To learn more about the `SearchQueriesPerSecond` metric, see [Search queries per second](#).

Query performance

Service-wide, query performance is measured as *search latency* and *throttled queries*. These metrics are also available on the **Monitoring** tab.

Search latency

Search latency indicates how long a query takes to complete. To learn more about the `SearchLatency` metric, see [Search latency](#).

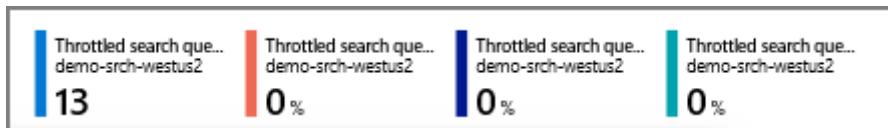

Consider the following example of **Search Latency** metrics: 86 queries were sampled, with an average duration of 23.26 milliseconds. A minimum of 0 indicates some queries were dropped. The longest running query took 1000 milliseconds to complete. Total execution time was 2 seconds.

Search Latency (Avg) demo-srch-westus2 23.26 ms	Search Latency (Min) demo-srch-westus2 0 sec	Search Latency (Max) demo-srch-westus2 1000.00 ms	Search Latency (Sum) demo-srch-westus2 2.00 sec	Search Latency (Count) demo-srch-westus2 86
--	---	--	--	--

Throttled queries

Throttled queries refers to queries that are dropped instead of processed. In most cases, throttling is a normal part of running the service. It isn't necessarily an indication that there's something wrong. To learn more about the `ThrottledSearchQueriesPercentage` metric, see [Throttled search queries percentage](#).

In the following screenshot, the first number is the count (or number of metrics sent to the log). Other aggregations, which appear at the top or when hovering over the metric, include average, maximum, and total. In this sample, no requests were dropped.

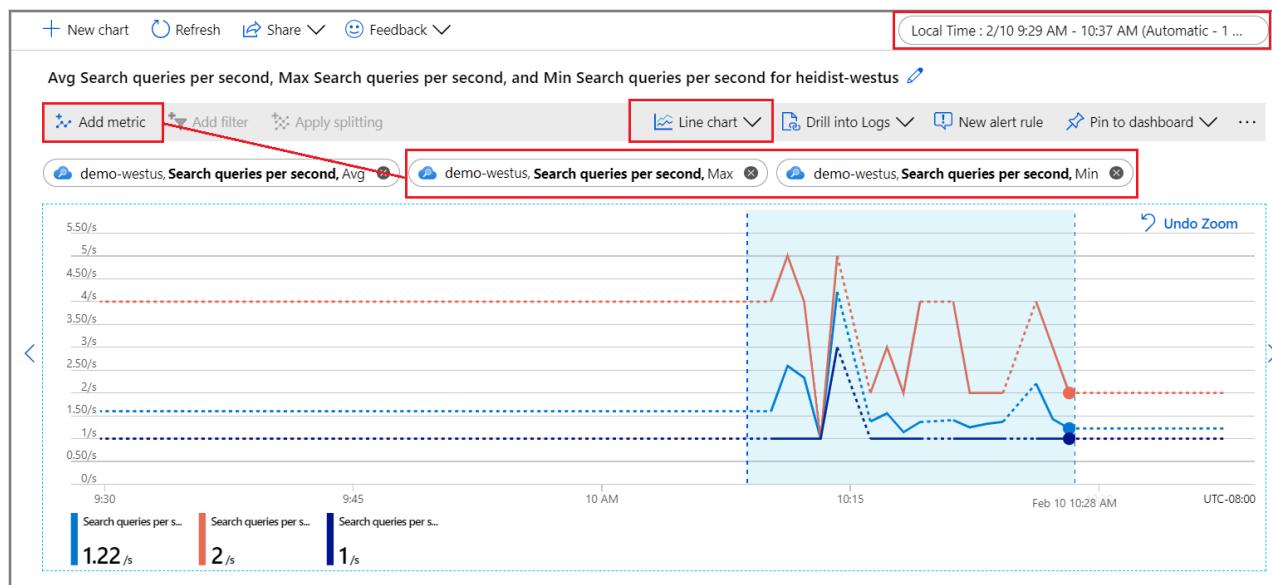

Explore metrics in the Azure portal

For a quick look at the current numbers, the **Monitoring** tab on the service Overview page shows three metrics (**Search latency**, **Search queries per second (per search unit)**, **Throttled Search Queries Percentage**) over fixed intervals measured in hours, days, and weeks, with the option of changing the aggregation type.

For deeper exploration, open metrics explorer from the **Monitoring** menu so that you can layer, zoom in, and visualize data to explore trends or anomalies. Learn more about metrics explorer by completing this [tutorial on creating a metrics chart](#).

1. Under the Monitoring section, select **Metrics** to open the metrics explorer with the scope set to your search service.
2. Under Metric, choose one from the dropdown list and review the list of available aggregations for a preferred type. The aggregation defines how the collected values are sampled over each time interval.

3. In the top-right corner, set the time interval.
4. Choose a visualization. The default is a line chart.
5. Layer more aggregations by choosing **Add metric** and selecting different aggregations.

6. Zoom into an area of interest on the line chart. Put the mouse pointer at the beginning of the area, select and hold the left mouse button, drag to the other side of area, and release the button. The chart zooms in on that time range.

Return query strings entered by users

When you enable resource logging, the system captures query requests in the **AzureDiagnostics** table. As a prerequisite, you must have already specified a destination for [logged operations](#), either a log analytics workspace or another storage option.

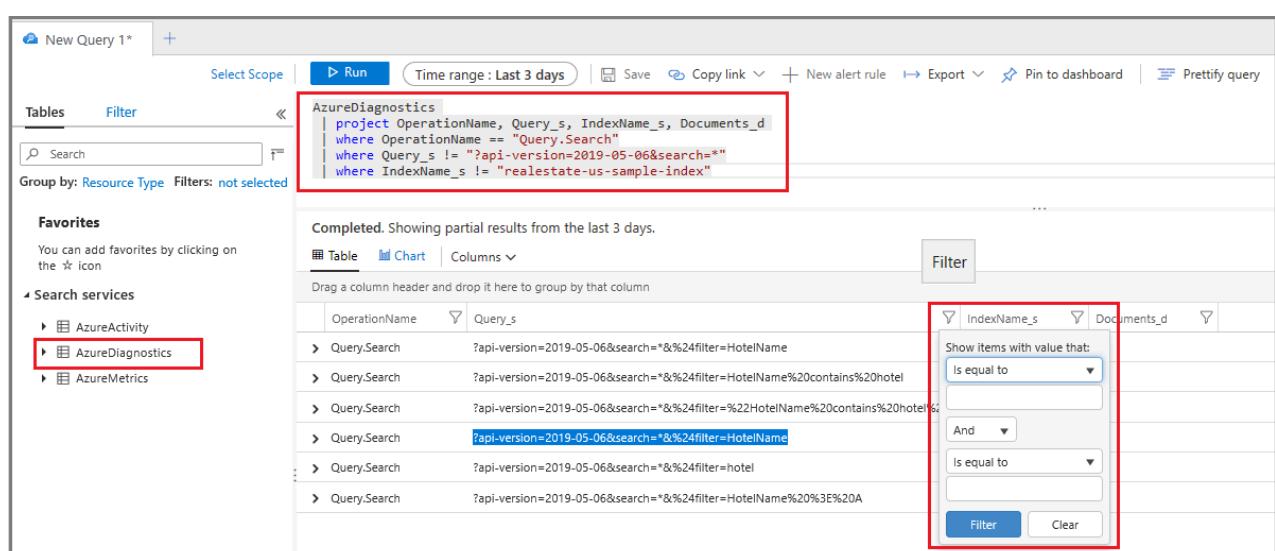

1. Under the Monitoring section, select **Logs** to open up an empty query window in Log Analytics.
2. Run the following expression to search `Query.Search` operations, returning a tabular result set consisting of the operation name, query string, the index queried, and the number of documents found. The last two statements exclude query strings consisting of an empty or unspecified search, over a sample index, which cuts down the noise in your results.

```
Kusto

AzureDiagnostics
| project OperationName, Query_s, IndexName_s, Documents_d
| where OperationName == "Query.Search"
| where Query_s != "?api-version=2024-07-01&search=*&filter=HotelName"
| where IndexName_s != "hotels-sample-index"
```

3. Optionally, set a Column filter on `Query_s` to search over a specific syntax or string. For example, you could filter over `is equal to ?api-version=2024-07-01&search=*&%24filter=HotelName`.

The screenshot shows the Azure Log Analytics workspace with the Kusto Query Editor open. The query in the editor is:

```
AzureDiagnostics
| project OperationName, Query_s, IndexName_s, Documents_d
| where OperationName == "Query.Search"
| where Query_s != "?api-version=2019-05-06&search=*&%24filter=HotelName"
| where IndexName_s != "realestate-us-sample-index"
```

The 'Tables' pane on the left has 'AzureDiagnostics' selected. The 'Filter' pane on the right shows a 'Filter' dialog for the 'IndexName_s' column. The 'Show items with value that:' dropdown is set to 'Is equal to'. Below it, there is a text input field and a 'Filter' button. The 'And' dropdown is set to 'Is equal to' with a second input field and a 'Filter' button.

While this technique works for ad hoc investigation, building a report lets you consolidate and present the query strings in a layout more conducive to analysis.

Identify long-running queries

Add the duration column to get the numbers for all queries, not just those that are picked up as a metric. Sorting this data shows you which queries take the longest to complete.

1. Under the Monitoring section, select **Logs** to query for log information.
2. Run the following basic query to return queries, sorted by duration in milliseconds. The longest-running queries are at the top.

```
Kusto

AzureDiagnostics
| project OperationName, resultSignature_d, DurationMs, Query_s, Documents_d,
IndexName_s
| where OperationName == "Query.Search"
| sort by DurationMs
```

The screenshot shows the Azure Kusto Query Editor interface. At the top, there's a code editor with the following query:

```
AzureDiagnostics
| project OperationName, resultSignature_d, DurationMs, Query_s, Documents_d, IndexName_s
| where OperationName == "Query.Search"
| sort by DurationMs
```

Below the code editor, the results pane displays the query results. It shows a table with the following columns: OperationName, result..., DurationMs, Query_s, Do..., and IndexName_s. The results are as follows:

OperationName	result...	DurationMs	Query_s	Do...	IndexName_s
Query.Search	200	636	?api-version=2019-05-06&search=restaurant&%24count=true&%24select=HotelId...	1	hotels-quickstart
Query.Search	200	357	?api-version=2019-05-06&search=*&%24count=true	14	demoindex
Query.Search	200	181	?api-version=2019-05-06&search=*	14	demoindex
Query.Search	200	154	?api-version=2019-05-06-Preview&search=*&%24count=true	14	demoindex
Query.Search	200	148	?api-version=2019-05-06&search=*&%24count=true&%24select=HotelId%2C%	4	hotels-quickstart
Query.Search	200	139	?api-version=2019-05-06&search=*	19	hotel-reviews-idx

Create a metric alert

A [metric alert](#) establishes a threshold for sending a notification or triggering a corrective action that you define in advance. You can create alerts related to query execution, but you can also create them for resource health, search service configuration changes, skill execution, and document processing (indexing).

All thresholds are user-defined, so you should have an idea of what activity level should trigger the alert.

For query monitoring, it's common to create a metric alert for search latency and throttled queries. If you know *when* queries are dropped, you can look for remedies that reduce load or increase capacity. For example, if throttled queries increase during indexing, you could postpone it until query activity subsides.

If you're pushing the limits of a particular replica-partition configuration, setting up alerts for query volume thresholds (QPS) is also helpful.

1. Under **Monitoring**, select **Alerts** and then select **Create alert rule**.
2. Under Condition, select **Add**.
3. Configure signal logic. For signal type, choose **metrics** and then select the signal.
4. After selecting the signal, you can use a chart to visualize historical data for an informed decision on how to proceed with setting up conditions.
5. Next, scroll down to Alert logic. For proof-of-concept, you could specify an artificially low value for testing purposes.
6. Next, specify or create an Action Group. This is the response to invoke when the threshold is met. It might be a push notification or an automated response.
7. Last, specify Alert details. Name and describe the alert, assign a severity value, and specify whether to create the rule in an enabled or disabled state.

If you specified an email notification, you receive an email from "Microsoft Azure" with a subject line of "Azure: Activated Severity: 3 <your rule name>".

Next steps

If you haven't done so already, review the fundamentals of search service monitoring to learn about the full range of oversight capabilities.

[Monitor operations and activity in Azure AI Search](#)

Monitor indexer status and results in Azure AI Search

08/08/2025

You can monitor indexer processing in the Azure portal, or programmatically through REST calls or an Azure SDK. In addition to status about the indexer itself, you can review start and end times, and detailed errors and warnings from a particular run.

Monitor using Azure portal

You can see the current status of all of your indexers in your search service portal page. Azure portal pages refresh every few minutes, so you don't see evidence of a new indexer run right away. Select Refresh at the top of the page to immediately retrieve the most recent view.

The screenshot shows the Azure portal interface for managing a search service. The top navigation bar includes 'Microsoft Azure', a search bar, and a 'Copilot' button. The main content area is titled 'demo-search-eastus | Indexers' and shows a table of indexers:

Status	Name	Last run	Docs succeeded	Errors/Warnings
Success	chunkingsample-indexer	5 months ago	0/0	0/0
Success	demoindexer	27 days ago	14/14	0/2
Success	cog-search-demo-idxr	1 day ago	14/14	0/5
Reset	vector-images-ai-vision-...	3 minutes ago	0/0	0/0
Failed	vector-nasa-ai-vision-m...	2 minutes ago	0/0	0/0
Success	hotels-sample-indexer	1 minute ago	50/50	0/0
In progress	doc-extraction-multimo...	44 seconds ago	0/0	0/0

The left sidebar lists various service components: Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Resource visualizer, Search management (with Indexes selected), Data sources, Aliases, Skillsets, and Debug sessions. A 'Filter by name...' search bar is also present above the table.

[Expand table](#)

Status	Description
In Progress	Indicates active execution. the Azure portal reports on partial information. As indexing progresses, you can watch the Docs Succeeded value grow in response. Indexers that process large volumes of data can take a long time to run. For example, indexers that handle millions of source documents can run for 24 hours, and then restart almost immediately to pick up where it left off. As such, the status for high-volume indexers might always say In Progress in the Azure portal. Even when an indexer is running, details are available about ongoing progress and previous runs.

Status	Description
Success	Indicates the run was successful. An indexer run can be successful even if individual documents have errors, if the number of errors is less than the indexer's Max failed items setting.
Failed	The number of errors exceeded Max failed items and indexing stops.
Reset	The indexer's internal change tracking state was reset. The indexer runs in full, refreshing all documents, and not just those with newer timestamps.

You can select on an indexer in the list to see more details about the indexer's current and recent runs.

hotel-rooms-blob-indexer

🔵	6/28, 03:28 UTC	Reset	0/0
🟢	6/28, 00:00 UTC	Success	0/0
🟢	6/27, 22:02 UTC	Success	7/7
🔵	6/27, 22:02 UTC	Reset	0/0
🟢	6/27, 22:00 UTC	Success	7/7
🔵	6/27, 22:00 UTC	Reset	0/0
🟢	6/27, 21:23 UTC	Success	7/7
🔵	6/27, 21:23 UTC	Reset	0/0
🟢	6/27, 21:14 UTC	Success	7/7

1 2 3 4 5 < >

The **Indexer summary** chart displays a graph of the number of documents processed in its most recent runs.

The **Execution details** list shows up to 50 of the most recent execution results. Select on an execution result in the list to see specifics about that run. This includes its start and end times, and any errors and warnings that occurred.

The screenshot shows a modal window titled "myindexer" under the "Execution" tab. The main section is titled "Execution result" and displays the message "0 Errors/Warnings" with a green checkmark icon. Below this, a table lists execution details:

Status	Success
Datasource	test-cosmos-src
Target index	test-cosmosdb-index
Start	6/28, 03:27 UTC
End	6/28, 03:27 UTC
Documents succeeded	50
Documents failed	0

Below the table, there is a section titled "Errors" which contains an empty list [].

If there were document-specific problems during the run, they are listed in the Errors and Warnings fields.

hotel-rooms-blob-indexer

X

Execution

Execution result

1 Errors/Warnings !

Status	Failed
Datasource	sampleblobstore
Target index	hotel-rooms-sample
Start	6/28, 03:29 UTC
End	6/28, 03:29 UTC
Documents succeeded	0
Documents failed	1

Errors

```
[{"key": "https://sampleblobstore.blob.core.windows.net/hotel-rooms/Rooms11.json", "errorMessage": "Document key cannot be missing or empty.\r\n"}]
```

Warnings

```
[]
```

Warnings are common with some types of indexers, and don't always indicate a problem. For example indexers that use Azure AI services can report warnings when image or PDF files don't contain any text to process.

For more information about investigating indexer errors and warnings, see [Indexer troubleshooting guidance](#).

Monitor with Azure Monitoring Metrics

Azure AI Search is a monitored resource in Azure Monitor, which means that you can use [Metrics Explorer](#) to see basic metrics about the number of indexer-processed documents and

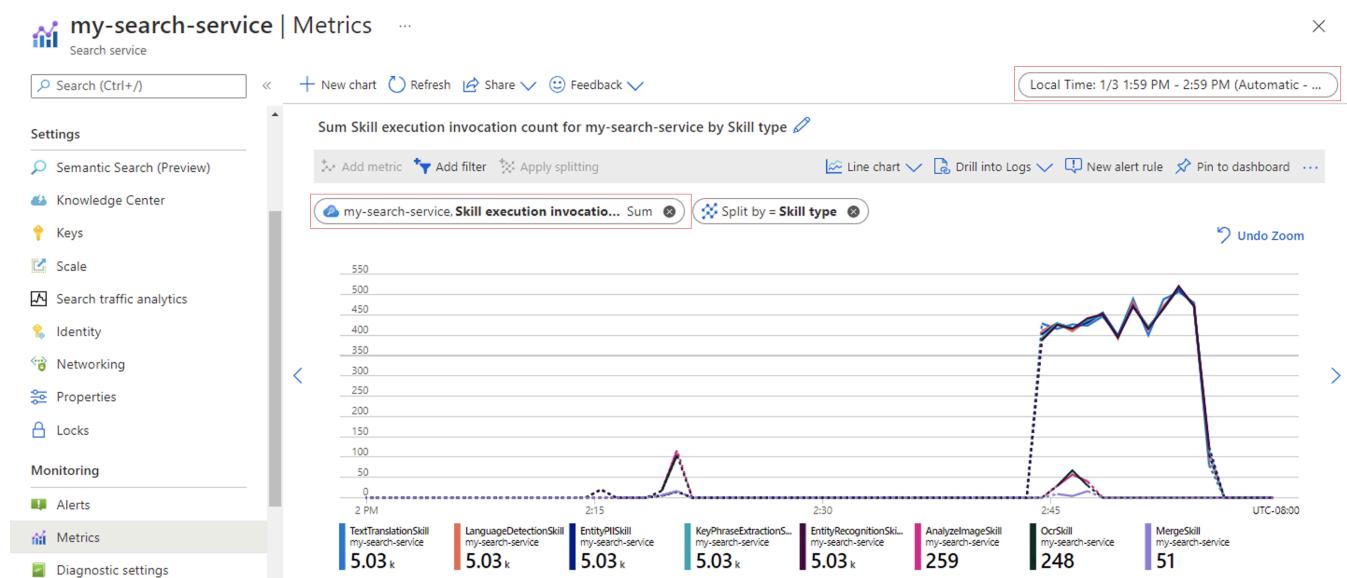

skill invocations. These metrics can be used to monitor indexer progress and [set up alerts](#).

Metric views can be filtered or split up by a set of predefined dimensions. To learn about the dimensions associated with the metrics *Document processed count* and *Skill execution invocation count*, see [Metric dimensions](#).

The following screenshot shows the number of documents processed by indexers within a service over an hour, split up by indexer name.

You can also configure the graph to see the number of skill invocations over the same hour interval.

Monitor using Get Indexer Status (REST API)

You can retrieve the status and execution history of an indexer using the [Get Indexer Status command](#):

HTTP

```
GET https://[service name].search.windows.net/indexers/[indexer name]/status?api-version=2024-07-01  
api-key: [Search service admin key]
```

The response contains overall indexer status, the last (or in-progress) indexer invocation, and the history of recent indexer invocations.

Output

```
{  
    "status": "running",  
    "lastResult": {  
        "status": "success",  
        "errorMessage": null,  
        "startTime": "2018-11-26T03:37:18.853Z",  
        "endTime": "2018-11-26T03:37:19.012Z",  
        "errors": [],  
        "itemsProcessed": 11,  
        "itemsFailed": 0,  
        "initialTrackingState": null,  
        "finalTrackingState": null  
    },  
    "executionHistory": [  
        {  
            "status": "success",  
            "errorMessage": null,  
            "startTime": "2018-11-26T03:37:18.853Z",  
            "endTime": "2018-11-26T03:37:19.012Z",  
            "errors": [],  
            "itemsProcessed": 11,  
            "itemsFailed": 0,  
            "initialTrackingState": null,  
            "finalTrackingState": null  
        }]  
}
```

Execution history contains up to the 50 most recent runs, which are sorted in reverse chronological order (most recent first).

Note there are two different status values. The top level status is for the indexer itself. An indexer status of **running** means the indexer is set up correctly and available to run, but not that it's currently running.

Each run of the indexer also has its own status that indicates whether that specific execution is ongoing (**running**), or already completed with a **success**, **transientFailure**, or **persistentFailure** status.

When an indexer is reset to refresh its change tracking state, a separate execution history entry is added with a **Reset** status.

For more information about status codes and indexer monitoring data, see [Get Indexer Status](#).

Monitor using .NET

The following C# example writes information about an indexer's status and the results of its most recent (or ongoing) run to the console.

C#

```
static void CheckIndexerStatus(SearchIndexerClient indexerClient, SearchIndexer
indexer)
{
    try
    {
        string indexerName = "hotels-sql-idxr";
        SearchIndexerStatus execInfo =
indexerClient.GetIndexerStatus(indexerName);

        Console.WriteLine("Indexer has run {0} times.",
execInfo.ExecutionHistory.Count);
        Console.WriteLine("Indexer Status: " + execInfo.Status.ToString());

        IndexerExecutionResult result = execInfo.LastResult;

        Console.WriteLine("Latest run");
        Console.WriteLine("Run Status: {0}", result.Status.ToString());
        Console.WriteLine("Total Documents: {0}, Failed: {1}", result.ItemCount,
result.FailedItemCount);

        TimeSpan elapsed = result.EndTime.Value - result.StartTime.Value;
        Console.WriteLine("StartTime: {0:T}, EndTime: {1:T}, Elapsed: {2:t}",
result.StartTime.Value, result.EndTime.Value, elapsed);

        string errorMsg = (result.ErrorMessage == null) ? "none" :
result.ErrorMessage;
        Console.WriteLine("ErrorMessage: {0}", errorMsg);
        Console.WriteLine(" Document Errors: {0}, Warnings: {1}\n",
result.Errors.Count, result.Warnings.Count);
    }
    catch (Exception e)
    {
        // Handle exception
    }
}
```

The output in the console looks something like this:

Output

```
Indexer has run 18 times.  
Indexer Status: Running  
Latest run  
  Run Status: Success  
  Total Documents: 7, Failed: 0  
  StartTime: 11:29:31 PM, EndTime: 11:29:31 PM, Elapsed: 00:00:00.2560000  
  ErrorMessage: none  
  Document Errors: 0, Warnings: 0
```

Note there are two different status values. The top-level status is the status of the indexer itself. An indexer status of **Running** means that the indexer is set up correctly and available for execution, but not that it's currently executing.

Each run of the indexer also has its own status for whether that specific execution is ongoing (**Running**), or was already completed with a **Success** or **TransientError** status.

When an indexer is reset to refresh its change tracking state, a separate history entry is added with a **Reset** status.

Next steps

Visualize Azure AI Search Logs and Metrics with Power BI

05/29/2025

Azure AI Search can send operation logs and service metrics to an Azure Storage account, which can then be visualized in Power BI. This article explains the steps and how to use a Power BI template app to visualize the data. The template covers information about queries, indexing, operations, and service metrics.

(!) Note

The Power BI template currently uses a former product name, Azure Cognitive Search. The product name will be updated on the next template refresh.

Set up logging and install the template

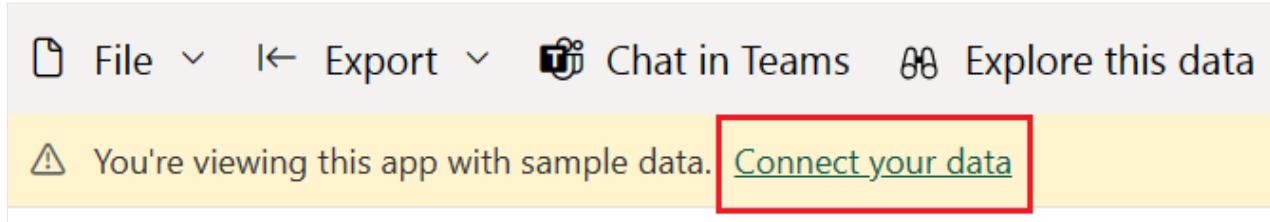

1. Enable metric and resource logging for your search service:
 - a. Create or identify an existing [Azure Storage account](#) where you can archive the logs.
 - b. Navigate to your search service in the Azure portal.
 - c. Under Monitoring, select **Diagnostic settings**.
 - d. Select **Add diagnostic setting**.
 - e. Check **Archive to a storage account**, provide your storage account information, and check **OperationLogs** and **AllMetrics**.
 - f. Select **Save**.
2. Once logging is enabled, logs and metrics are generated as you use the search service. It can take up to an hour before logged events show up in Azure Storage. Look for a **insights-logs-operationlogs** container for operations and a **insights-metrics-pt1m** container for metrics. Check your storage account for these containers to make sure you have data to visualize.
3. Find the Power BI app template in the [Power BI Apps marketplace](#) and install it into a new workspace or an existing workspace. The template is called **Azure Cognitive Search: Analyze Logs and Metrics**.
4. After installing the template, select it from your list of apps in Power BI.

Apps

Apps are collections of dashboards and reports in one easy-to-find place.

File	Name	Publisher	Published	App type	Version
	Azure Cognitive Search	4/24/2024 11:54:57 PM	4/24/24, 11:55:04 PM	Template app	Version 4

5. Select **Connect your data**.

6. Provide the name of the storage account that contains your logs and metrics. By default, the app looks at the last 10 days of data, but this value can be changed with the Days parameter.

X

Connect to Azure Cognitive Search

Get started setting up your app! Start by filling in the parameters. Then, you'll authenticate to all the data sources this app connects to.

Parameters

Make sure all required (*) parameters are filled in before connecting to your data.

StorageAccount *

The Azure Storage account name you use for Azure Cognitive Search Logs and Metrics. More information on how to enable logging can be found here:
<https://docs.microsoft.com/azure/search/search-monitor-usage>

Days *

Number of days of data to query.

Next

Cancel

7. Select **Key** as the authentication method and provide your storage account key. Select **None** or **Private** as the privacy level. Select **Sign In** to begin the loading process.

You are connecting to

Account

Domain

Authentication method

Key

Account key

< Enter your storage account key here >

Privacy level setting for this data source [Learn more](#)

None

Back

Sign in and connect

Cancel

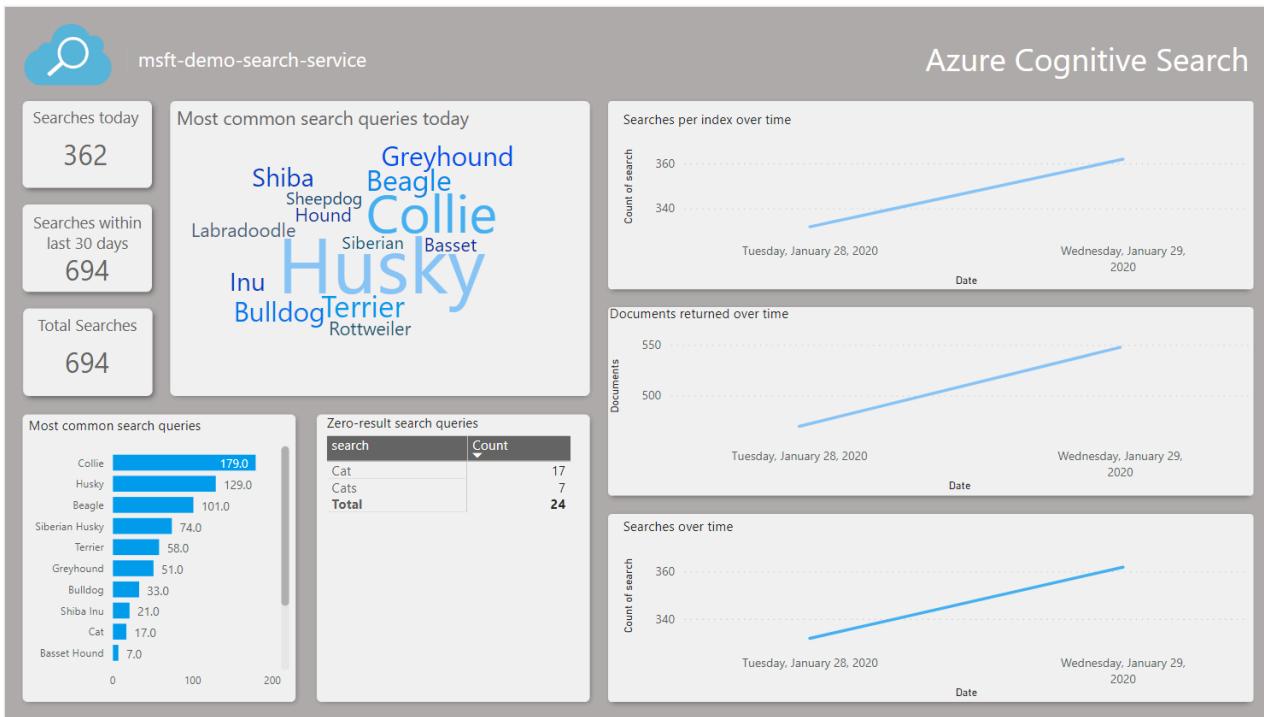

8. Wait for the data to refresh. This might take some time depending on how much data you have. You can see if the data is still being refreshed based on the below indicator.

Name	Type	Sensitivity (preview)	Owner	Refreshed	Endorsement	Include in app
Azure Cognitive Search Dataset	Dataset	—	Azure Cognitive Sear...	2/7/20, 4:01:01 PM	—	
Azure Cognitive Search Report	Report	—	Azure Cognitive Sear...	2/7/20, 4:01:01 PM	—	Yes

9. Select **Azure Cognitive Search Report** to view the report.

Name	Type	Sensitivity (preview)	Owner	Refreshed	Endorsement	Include in app
Azure Cognitive Search Dataset	Dataset	—	Azure Cognitive Sear...	2/7/20, 4:01:01 PM	—	
Azure Cognitive Search Report	Report	—	Azure Cognitive Sear...	2/7/20, 4:01:01 PM	—	Yes

10. Refresh the page after opening the report so that it opens with your data.

Modify app parameters

If you would like to visualize data from a different storage account or change the number of days of data to query, follow the below steps to change the **Days** and **StorageAccount** parameters.

1. Navigate to your Power BI apps, find your search app, and select the **Edit** action to continue to the workspace.
2. Select **Settings** from the Dataset options.

Name	Type	Sensitivity (preview)
 Azure Cognitive Search Dataset	Dataset	—
 Azure Cognitive Search Report		<ul style="list-style-type: none"> Analyze in Excel Create report Delete Get quick insights Refresh now Rename Schedule refresh Settings Download .pbix Manage permissions View related

3. While in the Datasets tab, change the parameter values and select **Apply**. If there's an issue with the connection, update the data source credentials on the same page.
4. Navigate back to the workspace and select **Refresh now** from the Dataset options.

Name	Type	Sensitivity (preview)
 Azure Cognitive Search Dataset	Dataset	—
 Azure Cognitive Search Report		<ul style="list-style-type: none"> Analyze in Excel Create report Delete Get quick insights Refresh now Rename Schedule refresh Settings Download .pbix Manage permissions View related

5. Open the report to view the updated data. You might also need to refresh the report to view the latest data.

Troubleshooting report issues

If you can't see your data, try these troubleshooting steps:

1. Open the report and refresh the page to make sure you're viewing the latest data. There's an option in the report to refresh the data. Select this to get the latest data.
2. Ensure the storage account name and access key you provided are correct. The storage account name should correspond to the account configured with your search service logs.
3. Confirm that your storage account contains the containers **insights-logs-operationlogs** and **insights-metrics-pt1m** and each container has data. The logs and metrics will be within a couple layers of folders.
4. Check to see if the dataset is still refreshing. The refresh status indicator is shown in step 8 above. If it's still refreshing, wait until the refresh is complete to open and refresh the report.

Analyze performance in Azure AI Search

Article • 01/16/2025

This article describes the tools, behaviors, and approaches for analyzing query and indexing performance in Azure AI Search.

Develop baseline numbers

In any large implementation, it's critical to do a performance benchmarking test of your Azure AI Search service before you roll it into production. You should test both the search query load that you expect, but also the expected data ingestion workloads (if possible, run both workloads simultaneously). Having benchmark numbers helps to validate the proper [search tier](#), [service configuration](#), and expected [query latency](#).

To isolate the effects of a distributed service architecture, try testing on service configurations of one replica and one partition.

 **Note**

For the Storage Optimized tiers (L1 and L2), you should expect a lower query throughput and higher latency than the Standard tiers.

Use resource logging

The most important diagnostic tool at an administrator's disposal is [resource logging](#). Resource logging is the collection of operational data and metrics about your search service. Resource logging is enabled through [Azure Monitor](#). There are costs associated with using Azure Monitor and storing data, but if you enable it for your service, it can be instrumental in investigating performance issues.

The following image shows the chain of events in a query request and response. Latency can occur at any one of them, whether during a network transfer, processing of content in the app services layer, or on a search service. A key benefit of resource logging is that activities are logged from the search service perspective, which means that the log can help you determine if the performance issue is due to problems with the query or indexing, or some other point of failure.

Resource logging gives you options for storing logged information. We recommend using [Log Analytics](#) so that you can execute advanced Kusto queries against the data to answer many questions about usage and performance.

On your search service portal pages, you can enable logging through [Diagnostic settings](#), and then issue Kusto queries against Log Analytics by choosing [Logs](#). To learn how to send resource logs to a Log Analytics workspace where you can analyze them with log queries, see [Collect and analyze resource logs from an Azure resource](#).

Throttling behaviors

Throttling occurs when the search service is at capacity. Throttling can occur during queries or indexing. From the client side, an API call results in a 503 HTTP response when it has been throttled. During indexing, there's also the possibility of receiving a 207 HTTP response, which indicates that one or more items failed to index. This error is an indicator that the search service is getting close to capacity.

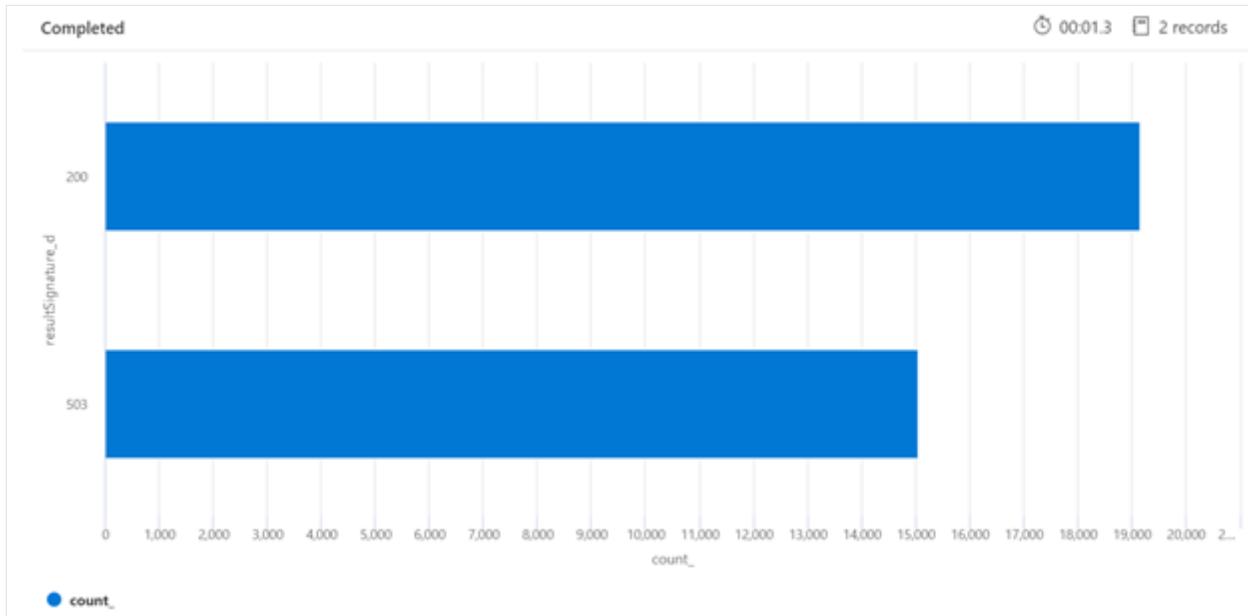

As a rule of thumb, try to quantify the amount of throttling and any patterns. For example, if one search query out of 500,000 is throttled, it might not be worth investigating. However, if a large percentage of queries is throttled over a period, this would be a greater concern. By looking at throttling over a period, it also helps to identify time frames where throttling might more likely occur and help you decide how to best accommodate that.

A simple fix to most throttling issues is to throw more resources at the search service (typically replicas for query-based throttling, or partitions for indexing-based throttling). However, increasing replicas or partitions adds cost, which is why it's important to know the reason why throttling is occurring at all. Investigating the conditions that cause throttling will be explained in the next several sections.

Below is an example of a Kusto query that can identify the breakdown of HTTP responses from the search service that has been under load. Over a 7-day period, the rendered bar chart shows that a relatively large percentage of the search queries were throttled, in comparison to the number of successful (200) responses.

Kusto

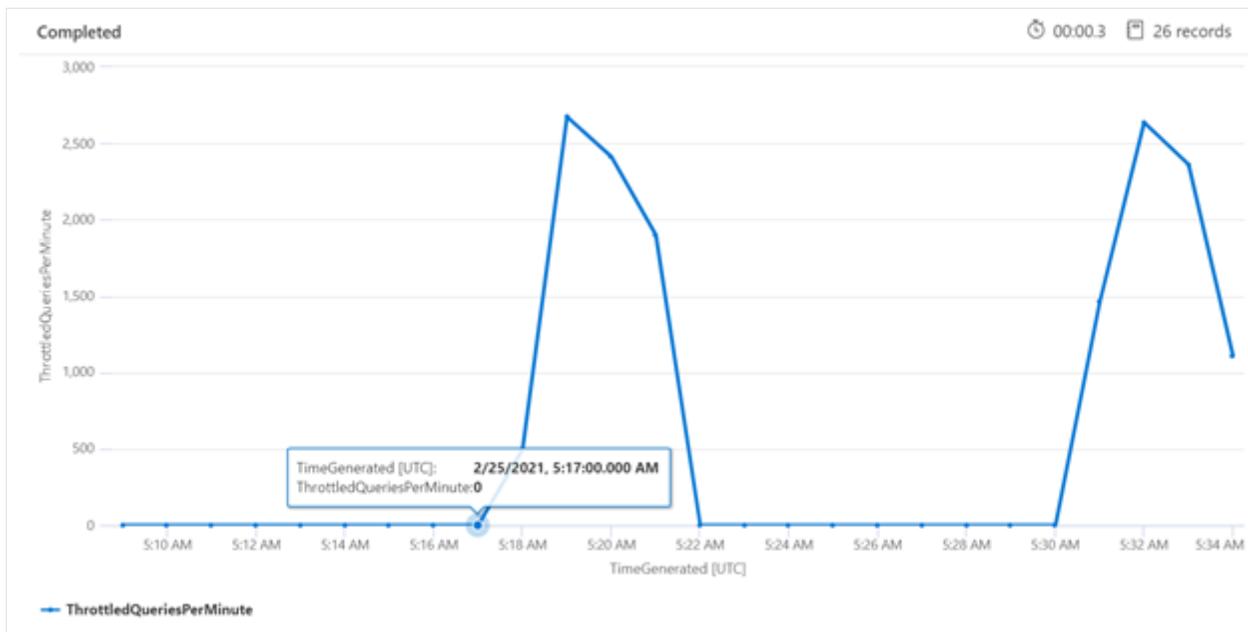

```
AzureDiagnostics
| where TimeGenerated > ago(7d)
| summarize count() by resultSignature_d
| render barchart
```

Examining throttling over a specific time period can help you identify the times where throttling might occur more frequently. In the below example, a time series chart is used to show the number of throttled queries that occurred over a specified time frame. In this case, the throttled queries correlated with the times in with the performance benchmarking was performed.

Kusto

```
let [_startTime]=datetime('2024-02-25T20:45:07Z');
let [_endTime]=datetime('2024-03-03T20:45:07Z');
let intervalsize = 1m;
AzureDiagnostics
| where TimeGenerated > ago(7d)
| where resultSignature_d != 403 and resultSignature_d != 404 and
OperationName in ("Query.Search", "Query.Suggest", "Query.Lookup",
"Query.Autocomplete")
| summarize
    ThrottledQueriesPerMinute=bin(countif(OperationName in ("Query.Search",
"Query.Suggest", "Query.Lookup", "Query.Autocomplete") and resultSignature_d
== 503)/(intervalsize/1m), 0.01)
    by bin(TimeGenerated, intervalsize)
| render timechart
```

Measure individual queries

In some cases, it can be useful to test individual queries to see how they're performing. To do this, it's important to be able to see how long the search service takes to complete the work, as well as how long it takes to make the round-trip request from the client and back to the client. The diagnostics logs could be used to look up individual operations, but it might be easier to do this all from a REST client.

In the example below, a REST-based search query was executed. Azure AI Search includes in every response the number of milliseconds it takes to complete the query, visible in the Headers tab, in "elapsed-time". Next to Status at the top of the response, you'll find the round-trip duration, in this case, 418 milliseconds (ms). In the results section, the "Headers" tab was chosen. Using these two values, highlighted with a red box in the image below, we see the search service took 21 ms to complete the search query and the entire client round-trip request took 125 ms. By subtracting these two numbers we can determine that it took 104-ms additional time to transmit the search query to the search service and to transfer the search results back to the client.

This technique helps you isolate network latencies from other factors impacting query performance.

The screenshot shows a POST request to `https://.search.windows.net/indexes/test/docs?api-version=2020-06-30&search="quick brown foxes"`. The request includes two query parameters: `api-version` (value: 2020-06-30) and `search` (value: "quick brown foxes"). The response status is 200 OK, time: 125 ms, and size: 709 B. A red box highlights the `elapsed-time` header value of 21.

Header	Value

Date	Thu, 04 Mar 2021 00:43:30 GMT
Content-Length	270

Query rates

One potential reason for your search service to throttle requests is due to the sheer number of queries being performed where volume is captured as queries per second (QPS) or queries per minute (QPM). As your search service receives more QPS, it will typically take longer and longer to respond to those queries until it can no longer keep up, at which it will send back a throttling 503 HTTP response.

The following Kusto query shows query volume as measured in QPM, along with average duration of a query in milliseconds (AvgDurationMS) and the average number of documents (AvgDocCountReturned) returned in each one.

```

Kusto

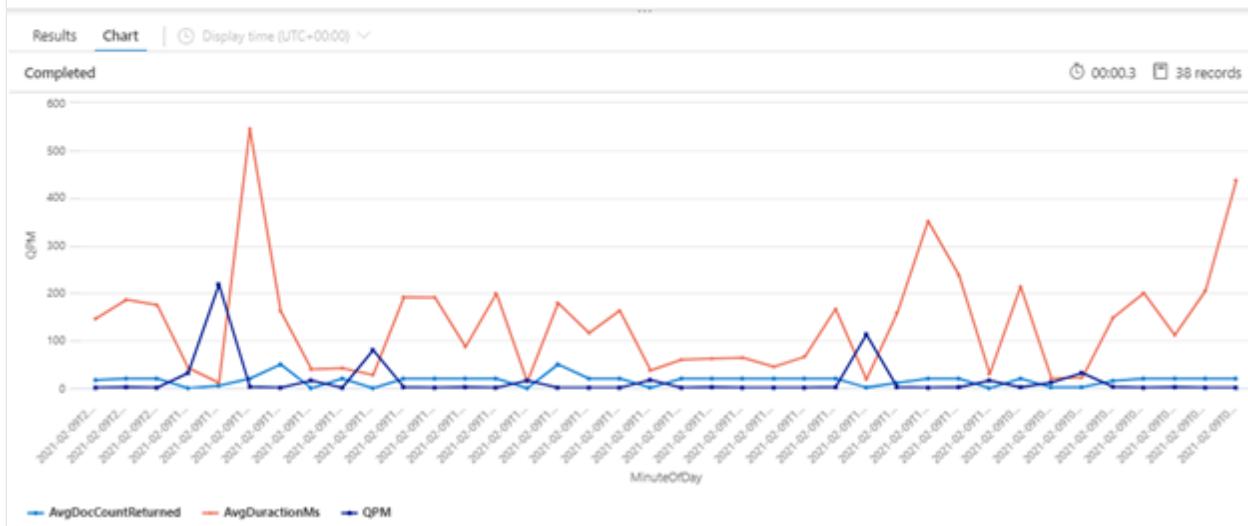

AzureDiagnostics
| where OperationName == "Query.Search" and TimeGenerated > ago(1d)
| extend MinuteOfDay = substring(TimeGenerated, 0, 16)
| project MinuteOfDay, DurationMs, Documents_d, IndexName_s
| summarize QPM=count(), AvgDurationMs=avg(DurationMs),
AvgDocCountReturned=avg(Documents_d) by MinuteOfDay
| order by MinuteOfDay desc
| render timechart

```

```

1 AzureDiagnostics
2 | where OperationName == "Query.Search" and TimeGenerated > ago(1d)
3 | extend MinuteOfDay = substring(TimeGenerated, 0, 16)
4 | project MinuteOfDay, DurationMs, Documents_d, IndexName_s
5 | summarize QPM=count(), AvgDurationMs=avg(DurationMs), AvgDocCountReturned=avg(Documents_d) by MinuteOfDay
6 | order by MinuteOfDay desc
7 | render timechart
8

```

💡 Tip

To reveal the data behind this chart, remove the line `| render timechart` and then rerun the query.

Impact of indexing on queries

An important factor to consider when looking at performance is that indexing uses the same resources as search queries. If you're indexing a large amount of content, you can expect to see latency grow as the service tries to accommodate both workloads.

If queries are slowing down, look at the timing of indexing activity to see if it coincides with query degradation. For example, perhaps an indexer is running a daily or hourly job that correlates with the decreased performance of the search queries.

This section provides a set of queries that can help you visualize the search and indexing rates. For these examples, the time range is set in the query. Be sure to indicate **Set in query** when running the queries in Azure portal.

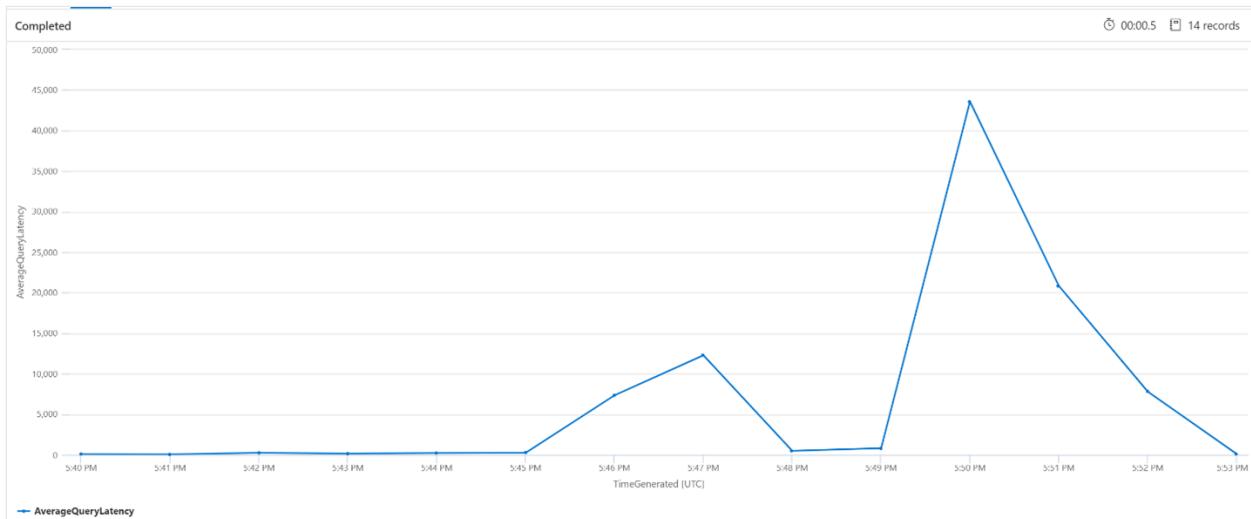

Average Query Latency

In the below query, an interval size of 1 minute is used to show the average latency of the search queries. From the chart, we can see that the average latency was low until 5:45pm and lasted until 5:53pm.

Kusto

```
let intervalsize = 1m;
let _startTime = datetime('2024-02-23 17:40');
let _endTime = datetime('2024-02-23 18:00');
AzureDiagnostics
| where TimeGenerated between(['_startTime']..['_endTime']) // Time range filtering
| summarize AverageQueryLatency = avg(DurationMs, OperationName in ("Query.Search", "Query.Suggest", "Query.Lookup", "Query.AutoComplete"))
    by bin(TimeGenerated, intervalsize)
| render timechart
```

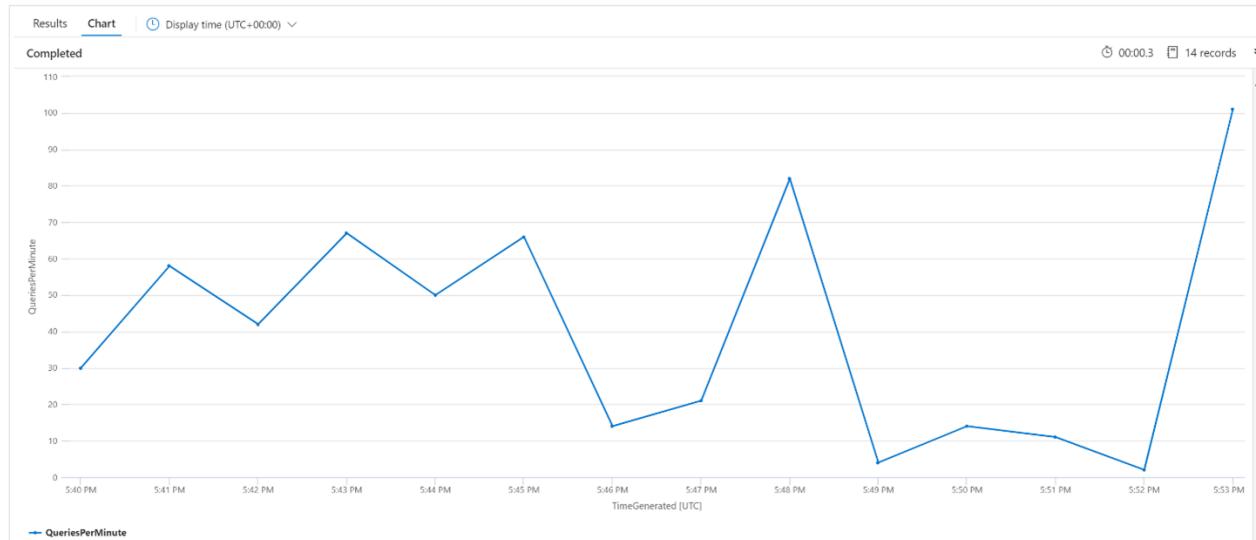

Average Queries Per Minute (QPM)

The following query looks at the average number of queries per minute to ensure that there wasn't a spike in search requests that might have affected the latency. From the chart, we can see there's some variance, but nothing to indicate a spike in request count.

```
Kusto

let intervalsize = 1m;
let _startTime = datetime('2024-02-23 17:40');
let _endTime = datetime('2024-02-23 18:00');
AzureDiagnostics
| where TimeGenerated between([ '_startTime'] .. [ '_endTime']) // Time range filtering
| summarize QueriesPerMinute=bin(countif(OperationName in ("Query.Search", "Query.Suggest", "Query.Lookup", "Query.AutoComplete"))/(intervalsize/1m), 0.01)
    by bin(TimeGenerated, intervalsize)
| render timechart
```

Indexing Operations Per Minute (OPM)

Here we'll look at the number of Indexing operations per minute. From the chart, we can see that a large amount of data was indexed started at 5:42 pm and ended at 5:50pm. This indexing began 3 minutes before the search queries started becoming latent and ended 3 minutes before the search queries were no longer latent.

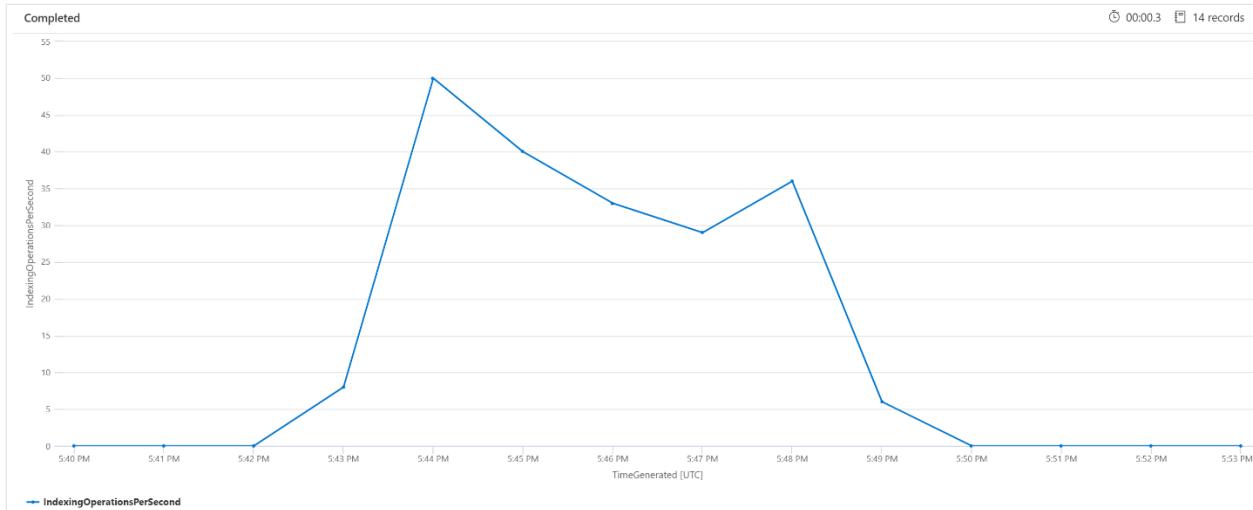

From this insight, we can see that it took about 3 minutes for the search service to become busy enough for indexing to affect query latency. We can also see that after indexing completed, it took another 3 minutes for the search service to complete all the work from the newly indexed content, and for query latency to resolve.

```
Kusto
```

```

let intervalsize = 1m;
let _startTime = datetime('2024-02-23 17:40');
let _endTime = datetime('2024-02-23 18:00');
AzureDiagnostics
| where TimeGenerated between([ '_startTime' ] .. [ '_endTime' ]) // Time range
filtering
| summarize IndexingOperationsPerSecond=bin(countif(OperationName ==
"Indexing.Index")/ (intervalsize/1m), 0.01)
    by bin(TimeGenerated, intervalsize)
| render timechart

```

Background service processing

It's common to see occasional spikes in query or indexing latency. Spikes might occur in response to indexing or high query rates, but could also occur during merge operations. Search indexes are stored in chunks - or shards. Periodically, the system merges smaller shards into large shards, which can help optimize service performance. This merge process also cleans up documents that have previously been marked for deletion from the index, resulting in the recovery of storage space.

Merging shards is fast, but also resource intensive and thus has the potential to degrade service performance. If you notice short bursts of query latency, and those bursts coincide with recent changes to indexed content, you can assume the latency is due to shard merge operations.

Tips for better performance in Azure AI Search

08/01/2025

This article is a collection of tips and best practices for boosting query and indexing performance for keyword search. Knowing which factors are most likely to affect search performance can help you avoid inefficiencies and get the most out of your search service. Some key factors include:

- Index composition (schema and size)
- Query design
- Service capacity (tier, and the number of replicas and partitions)

! Note

Looking for strategies on high volume indexing? See [Index large data sets in Azure AI Search](#).

Index size and schema

Queries run faster on smaller indexes. This is partly a function of having fewer fields to scan, but it's also due to how the system caches content for future queries. After the first query, some content remains in memory where it's searched more efficiently. Because index size tends to grow over time, one best practice is to periodically revisit index composition, both schema and documents, to look for content reduction opportunities. However, if the index is right-sized, the only other calibration you can make is to increase capacity by [upgrading your service, adding replicas, or switching to a higher pricing tier](#). The section "[Tip: Switch to a Standard S2 tier](#)" discusses the scale up versus scale out decision.

Schema complexity can also adversely affect indexing and query performance. Excessive field attribution builds in limitations and processing requirements. [Complex types](#) take longer to index and query. The next few sections explore each condition.

Tip: Be selective in field attribution

A common mistake that administrators and developers make when creating a search index is selecting all available properties for the fields, as opposed to only selecting just the properties that are needed. For example, if a field doesn't need to be full text searchable, skip that field when setting the searchable attribute.

Field name	Type	Retrievable	Filterable	Sortable	Facetable	Searchable
HotelId	Edm.String	<input checked="" type="checkbox"/>				
HostName	Edm.String	<input checked="" type="checkbox"/>				
Description	Edm.String	<input checked="" type="checkbox"/>				
Description_fr	Edm.String	<input checked="" type="checkbox"/>

id	Edm.String	<input type="checkbox"/>				
rid	Edm.String	<input type="checkbox"/>				

Support for filters, facets, and sorting can quadruple storage requirements. If you add suggesters, storage requirements go up even more. For an illustration on the impact of attributes on storage, see [Attributes and index size](#).

Summarized, the ramifications of over-attribution include:

- Degradation of indexing performance due to the extra work required to process the content in the field, and then store it within the search inverted index (set the "searchable" attribute only on fields that contain searchable content).
- Creates a larger surface that each query has to cover. All fields marked as searchable are scanned in a full text search.
- Increases operational costs due to extra storage. Filtering and sorting requires additional space for storing original (non-analyzed) strings. Avoid setting filterable or sortable on fields that don't need it.
- In many cases, over attribution limits the capabilities of the field. For example, if a field is facetable, filterable, and searchable, you can only store 16 KB of text within a field, whereas a searchable field can hold up to 16 MB of text.

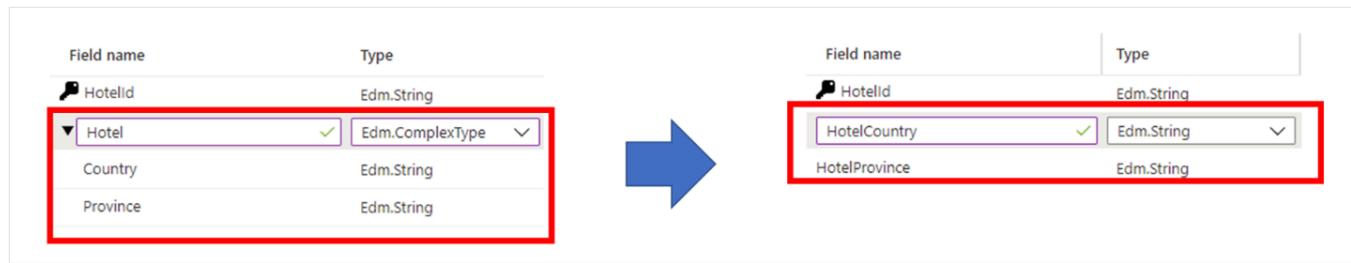

! Note

Only unnecessary attribution should be avoided. Filters and facets are often essential to the search experience, and in cases where filters are used, you frequently need sorting so that you can order the results (filters by themselves return in an unordered set).

Tip: Consider alternatives to complex types

Complex data types are useful when data has a complicated nested structure, such as the parent-child elements found in JSON documents. The downside of complex types is the extra storage requirements and additional resources required to index the content, in comparison to non-complex data types.

In some cases, you can avoid these tradeoffs by mapping a complex data structure to a simpler field type, such as a Collection. Alternatively, you might opt for flattening a field hierarchy into individual root-level fields.

Query design

Query composition and complexity are one of the most important factors for performance, and query optimization can drastically improve performance. When designing queries, think about the following points:

- **Number of searchable fields.** Each additional searchable field results in more work for the search service. You can limit the fields being searched at query time using the "searchFields" parameter. It's best to specify only the fields that you care about to improve performance.
- **Amount of data being returned.** Retrieving a large amount content can make queries slower. When structuring a query, return only those fields that you need to render the results page, and then retrieve remaining fields using the [Lookup API](#) once a user selects a match.
- **Use of partial term searches.** [Partial term searches](#), such as prefix search, fuzzy search, and regular expression search, are more computationally expensive than typical keyword searches, as they require full index scans to produce results.
- **Number of facets.** Adding facets to queries requires aggregations for each query. Requesting a higher "count" for a facet also requires extra work by the service. In general, only add the facets that you plan to render in your app and avoid requesting a high count for facets unless necessary.
- **High skip values.** Setting the `$skip` parameter to a high value (for example, in the thousands) increases search latency because the engine is retrieving and ranking a larger volume of documents for each request. For performance reasons, it's best to avoid high `$skip` values and use other techniques instead, such as filtering, to retrieve large numbers of documents.

- **Limit high cardinality fields.** A *high cardinality field* refers to a facetable or filterable field that has a significant number of unique values, and as a result, consumes significant resources when computing results. For example, setting a Product ID or Description field as facetable and filterable would count as high cardinality because most of the values from document to document are unique.

Tip: Use search functions instead overloading filter criteria

As a query uses increasingly [complex filter criteria](#), the performance of the search query will degrade. Consider the following example that demonstrates the use of filters to trim results based on a user identity:

JSON

```
$filter= userid eq 123 or userid eq 234 or userid eq 345 or userid eq 456 or  
userid eq 567
```

In this case, the filter expressions are used to check whether a single field in each document is equal to one of many possible values of a user identity. You're most likely to find this pattern in applications that implement [security trimming](#) (checking a field containing one or more principal IDs against a list of principal IDs representing the user issuing the query).

A more efficient way to execute filters that contain a large number of values is to use [search.in function](#), as shown in this example:

JSON

```
search.in(userid, '123,234,345,456,567', ',')
```

Tip: Add partitions for slow individual queries

When query performance is slowing down in general, adding more replicas frequently solves the issue. But what if the problem is a single query that takes too long to complete? In this scenario, adding replicas won't help, but more partitions might. A partition splits data across extra computing resources. Two partitions split data in half, a third partition splits it into thirds, and so forth.

One positive side-effect of adding partitions is that slower queries sometimes perform faster due to parallel computing. We've noted parallelization on low selectivity queries, such as queries that match many documents, or facets providing counts over a large number of documents. Since significant computation is required to score the relevancy of the documents, or to count the numbers of documents, adding extra partitions helps queries complete faster.

To add partitions, use the [Azure portal](#), [PowerShell](#), [Azure CLI](#), or a management SDK.

Service capacity

A service is overburdened when queries take too long or when the service starts dropping requests. If this happens, you can address the problem by upgrading the service or by adding capacity.

The tier of your search service and the number of replicas/partitions also have a large impact on performance. Each progressively higher tier provides faster CPUs and more memory, both of which have a positive impact on performance.

Tip: Create a new high capacity search service

Basic and Standard services created [in supported regions](#) after April 3, 2024 have more storage per partition than older services. If you have an older service, check if you can [upgrade your service](#) to benefit from more capacity at the same billing rate. If an upgrade isn't available, review the [tier service limits](#) to see if the same tier on a newer service gives you the necessary storage.

Tip: Switch to a Standard S2 tier

The Standard S1 search tier is often where customers start. A common pattern for S1 services is that indexes grow over time, which requires more partitions. More partitions lead to slower response times, so more replicas are added to handle the query load. As you can imagine, the cost of running an S1 service has now progressed to levels beyond the initial configuration.

At this juncture, an important question to ask is whether it would be beneficial to [switch to a higher pricing tier](#), as opposed to progressively increasing the number of partitions or replicas of the current service.

Consider the following topology as an example of a service that has taken on increasing levels of capacity:

- Standard S1 tier
- Index Size: 190 GB
- Partition Count: 8 (on S1, partition size is 25 GB per partition)
- Replica Count: 2
- Total Search Units: 16 (8 partitions x 2 replicas)
- Hypothetical Retail Price: ~\$4,000 USD / month (assume 250 USD x 16 search units)

Suppose the service administrator is still seeing higher latency rates and is considering adding another replica. This would change the replica count from 2 to 3 and as a result change the Search Unit count to 24 and a resulting price of \$6,000 USD/month.

However, if the administrator chose to move to a Standard S2 tier the topology would look like:

- Standard S2 tier
- Index Size: 190 GB
- Partition Count: 2 (on S2, partition size is 100 GB per partition)
- Replica Count: 2
- Total Search Units: 4 (2 partitions x 2 replicas)
- Hypothetical Retail Price: ~\$4,000 USD / month (1,000 USD x 4 search units)

As this hypothetical scenario illustrates, you can have configurations on lower tiers that result in similar costs as if you had opted for a higher tier in the first place. However, higher tiers come with premium storage, which makes indexing faster. Higher tiers also have much more compute power, as well as extra memory. For the same costs, you could have more powerful infrastructure backing the same index.

An important benefit of added memory is that more of the index can be cached, resulting in lower search latency, and a greater number of queries per second. With this extra power, the administrator might not need to even need to increase the replica count and could potentially pay less than by staying on the S1 service.

Tip: Consider alternatives to regular expression queries

[Regular expression queries](#) or regex can be particularly expensive. While they can be very useful for advanced searches, execution can require a lot of processing power, especially if the regular expression is complicated or if you're searching through a large amount of data. All of these factors contribute to high search latency. As a mitigation, try to simplify the regular expression or break the complex query down into smaller, more manageable queries.

Knowledge store "projections" in Azure AI Search

! Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in agentic retrieval workflows.

Projections define the physical tables, objects, and files in a **knowledge store** that accept content from an Azure AI Search enrichment pipeline. If you're creating a knowledge store, defining and shaping projections is most of the work.

This article introduces projection concepts and workflow so that you have some background before you start coding.

Projections are defined in Azure AI Search skillsets, but the end results are the table, object, and image file projections in Azure Storage.

The screenshot shows the Azure Storage browser (preview) interface for a storage account named 'demoblobstorage'. The left sidebar has a 'Storage browser (preview)' section highlighted with a red box. The main area shows a list of storage entities: blobstorage, Favorites, Recently viewed, Blob containers, File shares, Queues, and Tables. The 'Tables' item is also highlighted with a red box. On the right, a table list is displayed with three entries highlighted by a red box: 'kstoreProjectionDemoDocument', 'kstoreProjectionDemoEntities', and 'kstoreProjectionDemoKeyPhrases'. A search bar and a message about authentication method are also visible.

Types of projections and usage

A knowledge store is a logical construction that's physically expressed as a loose collection of tables, JSON objects, or binary image files in Azure Storage.

Projection	Storage	Usage
Tables	Azure Table Storage	Used for data that's best represented as rows and columns, or whenever you need granular representations of your data (for example, as data frames). Table projections allow you to define a schematized shape, using a Shaper skill or use inline shaping to specify columns and rows. You can organize content into multiple tables based on familiar normalization principles. Tables that are in the same group are automatically related.
Objects	Azure Blob Storage	Used when you need the full JSON representation of your data and enrichments in one JSON document. As with table projections, only valid JSON objects can be projected as objects, and shaping can help you do that.
Files	Azure Blob Storage	Used when you need to save normalized, binary image files.

Projection definition

Projections are specified under the "knowledgeStore" property of a [skillset](#). Projection definitions are used during indexer invocation to create and load objects in Azure Storage with enriched content. If you're unfamiliar with these concepts, start with [AI enrichment](#) for an introduction.

The following example illustrates the placement of projections under knowledgeStore, and the basic construction. The name, type, and content source make up a projection definition.

JSON

```
"knowledgeStore" : {
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct Name>;AccountKey=<Acct Key>;",
    "projections": [
        {
            "tables": [
                { "tableName": "ks-museums-main", "generatedKeyName": "ID", "source": "/document/tableprojection" },
                { "tableName": "ks-museumEntities", "generatedKeyName": "ID", "source": "/document/tableprojection/Entities/*" }
            ],
            "objects": [
                { "storageContainer": "ks-museums", "generatedKeyName": "ID", "source": "/document/objectprojection" }
            ],
            "files": [ ]
```

```
}
```

Projection groups

Projections are an array of complex collections, which means that you can specify multiple sets of each type. It's common to use just one projection group, but you might use multiple if storage requirements include supporting different tools and scenarios. For example, you might use one group for design and debug of a skillset, while a second set collects output used for an online app, with a third for data science workloads.

The same skillset output is used to populate all groups under projections. The following example shows two.

JSON

```
"knowledgeStore" : {
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct
Name>;AccountKey=<Acct Key>;",
    "projections": [
        {
            "tables": [],
            "objects": [],
            "files": []
        },
        {
            "tables": [],
            "objects": [],
            "files": []
        }
    ]
}
```

Projection groups have the following key characteristics of mutual exclusivity and relatedness.

 Expand table

Principle	Description
Mutual exclusivity	Each group is fully isolated from other groups to support different data shaping scenarios. For example, if you're testing different table structures and combinations, you would put each set in a different projection group for AB testing. Each group obtains data from the same source (enrichment tree) but is fully isolated from the table-object-file combination of any peer projection groups.
Relatedness	Within a projection group, content in tables, objects, and files are related. Knowledge store uses generated keys as reference points to a common parent node. For example, consider a scenario where you have a document containing images and text. You could

Principle	Description
	project the text to tables and the images to binary files, and both tables and objects have a column/property containing the file URL.

Projection "source"

The source parameter is the third component of a projection definition. Because projections store data from an AI enrichment pipeline, the source of a projection is always the output of a skill. As such, output might be a single field (for example, a field of translated text), but often it's a reference to a data shape.

Data shapes come from your skillset. Among all of the built-in skills provided in Azure AI Search, there's a utility skill called the [Shaper skill](#) that's used to create data shapes. You can include Shaper skills (as many as you need) to support the projections in the knowledge store.

Shapes are frequently used with table projections, where the shape not only specifies which rows go into the table, but also which columns are created (you can also pass a shape to an object projection).

Shapes can be complex and it's out of scope to discuss them in depth here, but the following example briefly illustrates a basic shape. The output of the Shaper skill is specified as the source of a table projection. Within the table projection itself will be columns for "metadata_storage_path", "reviews_text", "reviews_title", and so forth, as specified in the shape.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "ShaperForTables",
  "description": null,
  "context": "/document",
  "inputs": [
    {
      "name": "metadata_storage_path",
      "source": "/document/metadata_storage_path",
      "sourceContext": null,
      "inputs": []
    },
    {
      "name": "reviews_text",
      "source": "/document/reviews_text"
    },
    {
      "name": "reviews_title",
      "source": "/document/reviews_title"
    }
  ]
}
```

```
        "name": "reviews_username",
        "source": "/document/reviews_username"
    },
],
"outputs": [
{
    "name": "output",
    "targetName": "mytableprojection"
}
]
}
```

Projection lifecycle

Projections have a lifecycle that is tied to the source data in your data source. As source data is updated and reindexed, projections are updated with the results of the enrichments, ensuring your projections are eventually consistent with the data in your data source. However, projections are also independently stored in Azure Storage. They won't be deleted when the indexer or the search service itself is deleted.

Consume in apps

After the indexer is run, connect to projections and consume the data in other apps and workloads.

- Use Azure portal to verify object creation and content in Azure Storage.
- Use [Power BI for data exploration](#). This tool works best when the data is in Azure Table Storage. Within Power BI, you can manipulate data into new tables that are easier to query and analyze.
- Use enriched data in blob container in a data science pipeline. For example, you can [load the data from blobs into a Pandas DataFrame](#).
- Finally, if you need to export your data from the knowledge store, Azure Data Factory has connectors to export the data and land it in the database of your choice.

Checklist for getting started

Recall that projections are exclusive to knowledge stores, and aren't used to structure a search index.

1. In Azure Storage, get a connection string from [Access Keys](#) and verify the account is StorageV2 (general purpose V2).

2. While in Azure Storage, familiarize yourself with existing content in containers and tables so that you choose nonconflicting names for the projections. A knowledge store is a loose collection of tables and containers. Consider adopting a naming convention to keep track of related objects.
3. In Azure AI Search, [enable enrichment caching \(preview\)](#) in the indexer and then [run the indexer](#) to execute the skillset and populate the cache. This is a preview feature, so be sure to use the preview REST API on the indexer request. Once the cache is populated, you can modify projection definitions in a knowledge store free of charge (as long as the skills themselves aren't modified).
4. In your code, all projections are defined solely in a skillset. There are no indexer properties (such as field mappings or output field mappings) that apply to projections. Within a skillset definition, you'll focus on two areas: knowledgeStore property and skills array.
 - a. Under knowledgeStore, specify table, object, file projections in the `projections` section. Object type, object name, and quantity (per the number of projections you define) are determined in this section.
 - b. From the skills array, determine which skill outputs should be referenced in the `source` of each projection. All projections have a source. The source can be the output of an upstream skill, but is often the output of a Shaper skill. The composition of your projection is determined through shapes.
5. If you're adding projections to an existing skillset, [update the skillset](#) and [run the indexer](#).
6. Check your results in Azure Storage. On subsequent runs, avoid naming collisions by deleting objects in Azure Storage or changing project names in the skillset.
7. If you're using [Table projections](#) check [Understanding the Table Service data model](#) and [Scalability and performance targets for Table storage](#) to make sure your data requirements are within Table storage documented limits.

Next steps

Review syntax and examples for each projection type.

[Define projections in a knowledge store](#)

Create a knowledge store using REST

(!) Note

Knowledge stores exist in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge agents, which are used in [agentic retrieval](#) workflows.

In Azure AI Search, a [knowledge store](#) is a repository of [AI-generated content](#) that's used for non-search scenarios. You create the knowledge store using an indexer and skillset, and specify Azure Storage to store the output. After the knowledge store is populated, use tools like [Storage Explorer](#) or [Power BI](#) to explore the content.

In this article, you use the REST API to ingest, enrich, and explore a set of customer reviews of hotel stays in a knowledge store. The knowledge store contains original text content pulled from the source, plus AI-generated content that includes a sentiment score, key phrase extraction, language detection, and text translation of non-English customer comments.

To make the initial data set available, the hotel reviews are first imported into Azure Blob Storage. Post-processing, the results are saved as a knowledge store in Azure Table Storage.

💡 Tip

This article uses REST for detailed explanations of each step. [Download the REST file](#) if you want to just run the commands. Alternatively, you can also [create a knowledge store in Azure portal](#).

Prerequisites

- Visual Studio Code [with a REST client](#). If you need help with getting started, see [Quickstart: Full-text search using REST](#).
- Azure AI Search. [Create a service](#) or [find an existing one](#). You can use the free service for this exercise.
- Azure Storage. [Create an account](#) or [find an existing one](#). The account type must be **StorageV2 (general purpose V2)**.

The skillset in this example uses Azure AI Services for enrichments. Because the workload is so small, Azure AI services is tapped behind the scenes to provide free processing for up to 20

transactions daily. A small workload means that you can skip creating or attaching an Azure AI services multi-service resource.

Upload data to Azure Storage and get a connection string

1. Download [HotelReviews_Free.csv](#). This CSV contains 19 pieces of customer feedback about a single hotel (originates from Kaggle.com).
 2. In Azure portal, find your storage account and use **Storage Browser** to create a blob container named **hotel-reviews**.
 3. Select **Upload** at the top of the page to load the **HotelReviews-Free.csv** file you downloaded from the previous step.
- Screenshot of Storage Browser with uploaded file and left nav pane
4. On the left, select **Access Keys**, select **Show Keys**, and then copy the connection string for either key1 or key2. A full access connection string has the following format:

JSON

```
"knowledgeStore": {  
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<YOUR-  
ACCOUNT-NAME>;AccountKey=<YOUR-ACCOUNT-KEY>;EndpointSuffix=core.windows.net;"  
}
```

ⓘ Note

See [Connect using a managed identity](#) if you don't want to provide sensitive data on the connection string.

Copy a key and URL

In this example, REST calls require the search service endpoint and use an API key on every request. You can get these values from the Azure portal.

1. Sign in to the [Azure portal](#), navigate to the **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

The screenshot displays two windows from the Microsoft Azure portal. The top window is titled 'new-demo-search-svc' and shows the 'Overview' tab selected. It includes a URL field labeled 'Url' with the value 'https://new-demo-search-svc.search.windows.net'. The bottom window is also titled 'new-demo-search-svc' and shows the 'Keys' tab selected. It displays 'API access control' settings with 'API keys' selected. Below this, the 'Manage admin keys' section is shown, featuring fields for 'Primary admin key' and 'Secondary admin key', each containing placeholder text '<your-primary-admin-key-here>' and '<your-secondary-admin-key-here>'. Red boxes and numbers highlight specific areas: 'Overview' at 1, 'Url' at 1, 'Keys' at 2, and the key fields at 2.

A valid API key establishes trust, on a per request basis, between the application sending the request and the search service handling it.

Create an index

[Create Index \(REST\)](#) creates a search index on the search service. A search index is unrelated to a knowledge store, but the indexer requires one. The search index contains the same content as the knowledge store, which you can explore by sending query requests.

1. Open a new text file in Visual Studio Code.
2. Set variables to the search endpoint and the API key you collected earlier.

HTTP

```
@baseUrl = PUT-YOUR-SEARCH-SERVICE-URL-HERE
@apiKey = PUT-YOUR-ADMIN-API-KEY-HERE
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE
@blobContainer = PUT-YOUR-CONTAINER-NAME-HERE (hotel-reviews)
```

3. Save the file with a `.rest` file extension.
4. Paste in the following example to create the index request.

HTTP

```
### Create a new index
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1
```

```

Content-Type: application/json
api-key: {{apiKey}}

{
    "name": "hotel-reviews-kstore-idx",
    "fields": [
        { "name": "name", "type": "Edm.String", "filterable": false,
"sortable": false, "facetable": false },
        { "name": "reviews_date", "type": "Edm.DateTimeOffset",
"searchable": false, "filterable": false, "sortable": false, "facetable": false
},
        { "name": "reviews_rating", "type": "Edm.String", "searchable": false,
"filterable": false, "sortable": false, "facetable": false },
        { "name": "reviews_text", "type": "Edm.String", "filterable": false,
"sortable": false, "facetable": false },
        { "name": "reviews_title", "type": "Edm.String", "searchable": false,
"filterable": false, "sortable": false, "facetable": false },
        { "name": "reviews_username", "type": "Edm.String", "searchable": false,
"filterable": false, "sortable": false, "facetable": false },
        { "name": "AzureSearch_DocumentKey", "type": "Edm.String",
"searchable": false, "filterable": false, "sortable": false, "facetable": false,
"key": true },
        { "name": "language", "type": "Edm.String", "filterable": true,
"sortable": false, "facetable": true },
        { "name": "translated_text", "type": "Edm.String", "filterable": false,
"sortable": false, "facetable": false },
        { "name": "sentiment", "type": "Collection(Edm.String)",
"searchable": false, "filterable": true, "retrievable": true, "sortable": false,
"facetable": true },
        { "name": "keyphrases", "type": "Collection(Edm.String)",
"filterable": true, "sortable": false, "facetable": true }
    ]
}

```

5. Select **Send request**. You should have an `HTTP/1.1 201 Created` response and the response body should include the JSON representation of the index schema.

Create a data source

[Create Data Source](#) creates a data source connection on Azure AI Search.

- Paste in the following example to create the data source.

HTTP

```

### Create a data source
POST {{baseUrl}}/datasources?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

```

{

```

"name": "hotel-reviews-kstore-ds",
"description": null,
"type": "azureblob",
"subtype": null,
"credentials": {
    "connectionString": "{{storageConnectionString}}"
},
"container": {
    "name": "{{blobContainer}}",
    "query": null
},
"dataChangeDetectionPolicy": null,
"dataDeletionDetectionPolicy": null
}

```

2. Select **Send request**.

Create a skillset

A skillset defines enrichments (skills) and your knowledge store. [Create Skillset](#) creates the object on your search service.

1. Paste in the following example to create the skillset.

HTTP

```

### Create a skillset
POST {{baseUrl}}/skillsets?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "name": "hotel-reviews-kstore-ss",
    "description": "Skillset to detect language, translate text, extract key phrases, and score sentiment",
    "skills": [
        {
            "@odata.type": "#Microsoft.Skills.Text.SplitSkill",
            "context": "/document/reviews_text", "textSplitMode": "pages",
            "maximumPageLength": 5000,
            "inputs": [
                { "name": "text", "source": "/document/reviews_text" }
            ],
            "outputs": [
                { "name": "textItems", "targetName": "pages" }
            ]
        },
        {
            "@odata.type": "#Microsoft.Skills.Text.V3.SentimentSkill",
            "context": "/document/reviews_text/pages/*",
            "inputs": [

```

```
        { "name": "text", "source":  
"/document/reviews_text/pages/*" },  
            { "name": "languageCode", "source": "/document/language" }  
        ],  
        "outputs": [  
            { "name": "sentiment", "targetName": "sentiment" }  
        ]  
    },  
    {  
        "@odata.type": "#Microsoft.Skills.Text.LanguageDetectionSkill",  
        "context": "/document",  
        "inputs": [  
            { "name": "text", "source": "/document/reviews_text" }  
        ],  
        "outputs": [  
            { "name": "languageCode", "targetName": "language" }  
        ]  
    },  
    {  
        "@odata.type": "#Microsoft.Skills.Text.TranslationSkill",  
        "context": "/document/reviews_text/pages/*",  
        "defaultFromLanguageCode": null,  
        "defaultToLanguageCode": "en",  
        "inputs": [  
            { "name": "text", "source":  
"/document/reviews_text/pages/*" }  
        ],  
        "outputs": [  
            { "name": "translatedText", "targetName": "translated_text" }  
        ]  
    },  
    {  
        "@odata.type":  
"#Microsoft.Skills.Text.KeyPhraseExtractionSkill",  
        "context": "/document/reviews_text/pages/*",  
        "inputs": [  
            { "name": "text", "source":  
"/document/reviews_text/pages/*" },  
            { "name": "languageCode", "source": "/document/language" }  
        ],  
        "outputs": [  
            { "name": "keyPhrases" , "targetName": "keyphrases" }  
        ]  
    },  
    {  
        "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",  
        "context": "/document",  
        "inputs": [  
            { "name": "name", "source": "/document/name" },  
            { "name": "reviews_date", "source":  
"/document/reviews_date" },  
            { "name": "reviews_rating", "source":  
"/document/reviews_rating" },  
            { "name": "reviews_text", "source":  
"/document/reviews_text" }  
        ]  
    }  
]
```

```

        "/document/reviews_text" },
            { "name": "reviews_title", "source": "/document/reviews_title" },
            { "name": "reviews_username", "source": "/document/reviews_username" },
            { "name": "AzureSearch_DocumentKey", "source": "/document/AzureSearch_DocumentKey" },
            {
                "name": "pages",
                "sourceContext": "/document/reviews_text/pages/*",
                "inputs": [
                    {
                        "name": "languageCode",
                        "source": "/document/language"
                    },
                    {
                        "name": "translatedText",
                        "source": "/document/reviews_text/pages/*/translated_text"
                    },
                    {
                        "name": "sentiment",
                        "source": "/document/reviews_text/pages/*/sentiment"
                    },
                    {
                        "name": "keyPhrases",
                        "source": "/document/reviews_text/pages/*/keyphrases/*"
                    },
                    {
                        "name": "Page",
                        "source": "/document/reviews_text/pages/*"
                    }
                ]
            }
        ],
        "outputs": [
            { "name": "output" , "targetName": "tableprojection" }
        ]
    }
],
"knowledgeStore": {

                { "name": "reviews_username", "source": "/document/reviews_username" },
                { "name": "reviews_title", "source": "/document/reviews_title" },
                { "name": "reviews_text", "source": "/document/reviews_text" },
                { "name": "AzureSearch_DocumentKey", "source": "/document/AzureSearch_DocumentKey" }
            ]
        },
        {
            "tableName": "hotelReviews5InlineProjectionPages",
            "generatedKeyName": "Pagesid", "sourceContext": "/document/reviews_text/pages/*",
            "inputs": [
                { "name": "Sentiment", "source": "/document/reviews_text/pages/*/sentiment" },
                { "name": "LanguageCode", "source": "/document/language" },
                { "name": "Keyphrases", "source": "/document/reviews_text/pages/*/keyphrases" },
                { "name": "TranslatedText", "source": "/document/reviews_text/pages/*/translated_text" },
                { "name": "Page", "source": "/document/reviews_text/pages/*" }
            ]
        },
        {
            "tableName": "hotelReviews6InlineProjectionKeyPhrases", "generatedKeyName": "kpidv2",
            "sourceContext": "/document/reviews_text/pages/*/keyphrases/*",
            "inputs": [
                { "name": "Keyphrases", "source": "/document/reviews_text/pages/*/keyphrases/*" }
            ]
        },
        "objects": []
    ]
}

```

Key points:

- The **Shaper skill** is important to knowledge store definition. It specifies how the data flows into the tables of the knowledge store. The inputs are the parts of the enriched document that you want to store. The output is a consolidation of the nodes into a single structure.
- Projections specify the tables, objects, and blobs of your knowledge store. Each projection item specifies the `"name"` of column or field to create in Azure Storage. The `"source"` specifies which part of the shaper output is assigned to that field or column.

Create an indexer

[Create Indexer](#) creates and runs the indexer. Indexer execution starts by cracking the documents, extracting text and images, and initializing the skillset. The indexer checks for the other objects that you created: the datasource, the index, and the skillset.

1. Paste in the following example to create the indexer.

HTTP

```
### Create indexer
POST {{baseUrl}}/indexers?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "name": "hotel-reviews-kstore-idxr",
    "dataSourceName": "hotel-reviews-kstore-ds",
    "skillsetName": "hotel-reviews-kstore-ss",
    "targetIndexName": "hotel-reviews-kstore-idx",
    "parameters": {
        "configuration": {
            "dataToExtract": "contentAndMetadata",
            "parsingMode": "delimitedText",
            "firstLineContainsHeaders": true,
            "delimitedTextDelimiter": ","
        }
    },
    "fieldMappings": [
        {
            "sourceFieldName": "AzureSearch_DocumentKey",
            "targetFieldName": "AzureSearch_DocumentKey",
            "mappingFunction": { "name": "base64Encode" }
        }
    ],
    "outputFieldMappings": [
        { "sourceFieldName": "/document/reviews_text/pages/*/Keyphrases/*",
        "targetFieldName": "Keyphrases" },
        { "sourceFieldName": "/document/Language", "targetFieldName": "Language" },
    ]
}
```

```
        { "sourceFieldName": "/document/reviews_text/pages/*/Sentiment",
  "targetFieldName": "Sentiment" }
]
```

2. Select **Send request** to create and run the indexer. This step takes several minutes to complete.

Key points:

- The `parameters/configuration` object controls how the indexer ingests the data. In this case, the input data is in a single CSV file that has a header line and comma-separated values.
- Field mappings create "AzureSearch_DocumentKey" is a unique identifier for each document that's generated by the blob indexer (based on metadata storage path).
- Output field mappings specify how enriched fields are mapped to fields in a search index. Output field mappings aren't used in knowledge stores (knowledge stores use shapes and projections to express the physical data structures).

Check status

After you send each request, the search service should respond with a 201 success message.

HTTP

```
### Get Indexer Status (wait several minutes for the indexer to complete)
GET {{baseUrl}}/indexers/hotel-reviews-kstore-idxr/status?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}
```

After several minutes, you can query the index to inspect the content. Even if you're not using the index, this step is a convenient way to confirm that the skillset produced the expected output.

HTTP

```
### Query the index (indexer status must be "success" before querying the index)
POST {{baseUrl}}/indexes/hotel-reviews-kstore-idxn/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "search": "*",
```

```

    "select": "reviews_title, reviews_username, language, translated_text,
sentiment",
    "count": true
}

```

Check tables in Azure portal

In the Azure portal, switch to your Azure Storage account and use **Storage Browser** to view the new tables. You should see six tables, one for each projection defined in the skillset.

Each table is generated with the IDs necessary for cross-linking the tables in queries. When you open a table, scroll past these fields to view the content fields added by the pipeline.

The screenshot shows the Azure Storage Explorer interface. On the left, there's a sidebar with icons for blob storage, favorites, recently viewed, blob containers, file shares, queues, and tables. Under 'Tables', 'hotelReviewsPages' is selected. At the top, there are buttons for 'Add entity', 'Refresh', 'Delete', and 'Edit columns'. Below the buttons, the navigation path 'Tables > hotelReviewsPages' is shown, with 'hotelReviewsPages' highlighted by a red box. To the right of the path, it says 'Authentication method: Access key (Switch to Azure AD User Account)'. Below that is a 'Query builder' section with instructions and a link to 'Switch to advanced text editor'. The main area shows a table with 19 items. The columns are 'Pagesid', 'languageCode', 'sentimentScore', and 'translatedText'. The first three rows of data are:

Pagesid	languageCode	sentimentScore	translatedText
aHR0cHM6Ly9oZWlkaw...	en	mixed	Pleasant 10 min walk al...
aHR0cHM6Ly9oZWlkaw...	en	positive	Nice hotel , with very fri...
aHR0cHM6Ly9oZWlkaw...	en	positive	It was a 10 min+ walk to...

In this walkthrough, the knowledge store is composed of a various tables showing different ways of shaping and structuring a table. Tables one through three use output from a Shaper skill to determine the columns and rows. Tables four through six are created from inline shaping instructions, embedded within the projection itself. You can use either approach to achieve the same outcome.

[\[\] Expand table](#)

Table	Description
hotelReviews1Document	Contains fields carried forward from the CSV, such as reviews_date and reviews_text.
hotelReviews2Pages	Contains enriched fields created by the skillset, such as sentiment score and translated text.
hotelReviews3KeyPhrases	Contains a long list of just the key phrases.

Table	Description
hotelReviews4InlineProjectionDocument	Alternative to the first table, using inline shaping instead of the Shaper skill to shape data for the projection.
hotelReviews5InlineProjectionPages	Alternative to the second table, using inline shaping.
hotelreviews6InlineProjectionKeyPhrases	Alternative to the third table, using inline shaping.

Clean up

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the **All resources** or **Resource groups** link in the left-navigation pane.

Next steps

Now that you've enriched your data by using Azure AI services and projected the results to a knowledge store, you can use Storage Explorer or other apps to explore your enriched data set.

[Get started with Storage Explorer](#)

Shaping data for projection into a knowledge store

! Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in [agentic retrieval](#) workflows.

In Azure AI Search, "shaping data" describes a step in the [knowledge store workflow](#) that creates a data representation of the content that you want to project into tables, objects, and files in Azure Storage.

As skills execute, the outputs are written to an enrichment tree in a hierarchy of nodes, and while you might want to view and consume the enrichment tree in its entirety, it's more likely that you'll want a finer grain, creating subsets of nodes for different scenarios, such as placing the nodes related to translated text or extracted entities in specific tables.

By itself, the enrichment tree doesn't include logic that would inform how its content is represented in a knowledge store. Data shapes fill this gap by providing the schema of what goes into each table, object, and file projection. You can think of a data shape as a custom definition or view of the enriched data. You can create as many shapes as you need, and then assign them to [projections](#) in a knowledge store definition.

Approaches for creating shapes

There are two ways to shape enriched content so that it can be projected into a knowledge store:

- Use the [Shaper skill](#) to create nodes in an enrichment tree that are used expressly for projection. Most skills create new content. In contrast, a Shaper skill works with existing nodes, usually to consolidate multiple nodes into a single complex object. This is useful for tables, where you want the output of multiple nodes to be physically expressed as columns in the table.
- Use an inline shape within the projection definition itself.

Using the Shaper skill externalizes the shape so that it can be used by multiple projections or even other skills. It also ensures that all the mutations of the enrichment tree are contained within the skill, and that the output is an object that can be reused. In contrast, inline shaping

allows you to create the shape you need, but is an anonymous object and is only available to the projection for which it's defined.

The approaches can be used together or separately. This article shows both: a Shaper skill for the table projections, and inline shaping with the key phrases table projection.

Use a Shaper skill

Shaper skills are usually placed at the end of a skillset, creating a view of the data that you want to pass to a projection. This example creates a shape called "tableprojection" containing the following nodes: "reviews_text", "reviews_title", "AzureSearch_DocumentKey", and sentiment scores and key phrases from paged reviews.

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
    "name": "#5",
    "description": null,
    "context": "/document",
    "inputs": [
        {
            "name": "reviews_text",
            "source": "/document/reviews_text",
            "sourceContext": null,
            "inputs": []
        },
        {
            "name": "reviews_title",
            "source": "/document/reviews_title",
            "sourceContext": null,
            "inputs": []
        },
        {
            "name": "AzureSearch_DocumentKey",
            "source": "/document/AzureSearch_DocumentKey",
            "sourceContext": null,
            "inputs": []
        },
        {
            "name": "pages",
            "source": null,
            "sourceContext": "/document/reviews_text/pages/*",
            "inputs": [
                {
                    "name": "Sentiment",
                    "source": "/document/reviews_text/pages/*/Sentiment",
                    "sourceContext": null,
                    "inputs": []
                }
            ],
            "outputs": [
                {
                    "name": "keyPhrases"
                }
            ]
        }
    ],
    "outputs": [
        {
            "name": "tableprojection"
        }
    ]
}
```

```

    },
    "name": "LanguageCode",
    "source": "/document/Language",
    "sourceContext": null,
    "inputs": []
},
{
    "name": "Page",
    "source": "/document/reviews_text/pages/*",
    "sourceContext": null,
    "inputs": []
},
{
    "name": "keyphrase",
    "sourceContext": "/document/reviews_text/pages/*/Keyphrases/*",
    "inputs": [
        {
            "source": "/document/reviews_text/pages/*/Keyphrases/*",
            "name": "Keyphrases"
        }
    ]
}
],
"outputs": [
    {
        "name": "output",
        "targetName": "tableprojection"
    }
]
}

```

SourceContext property

Within a Shaper skill, an input can have a `sourceContext` element. This same property can also be used in inline shapes in projections.

`sourceContext` is used to construct multi-level, nested objects in an enrichment pipeline. If the input is at a *different* context than the skill context, use the `sourceContext`. The `sourceContext` requires you to define a nested input with the specific element being addressed as the source.

In the previous example, sentiment analysis and key phrases extraction was performed on text that was split into pages for more efficient analysis. Assuming you want the scores and phrases projected into a table, you'll now need to set the context to nested input that provides the score and phrase.

Projecting a shape into multiple tables

With the `tableprojection` node defined in the `outputs` in the previous section, you can slice parts of the `tableprojection` node into individual, related tables:

JSON

```
"projections": [
  {
    "tables": [
      {
        "tableName": "hotelReviewsDocument",
        "generatedKeyName": "Documentid",
        "source": "/document/tableprojection"
      },
      {
        "tableName": "hotelReviewsPages",
        "generatedKeyName": "Pagesid",
        "source": "/document/tableprojection/pages/*"
      },
      {
        "tableName": "hotelReviewsKeyPhrases",
        "generatedKeyName": "KeyPhrasesid",
        "source": "/document/tableprojection/pages/*/keyphrase/*"
      }
    ]
  }
]
```

Inline shape for table projections

Inline shaping is the ability to form new shapes within the projection definition itself. Inline shaping has these characteristics:

- The shape is used only by the projection that contains it.
- The shape can be identical to what a Shaper skill produces.

An inline shape is created using `sourceContext` and `inputs`.

 Expand table

Property	Description
<code>sourceContext</code>	Sets the root of the projection.
<code>inputs</code>	Each input is a column in the table. Name is the column name. Source is the enrichment node that provides the value.

To project the same data as the previous example, the inline projection option would look like this:

JSON

```
"projections": [
  {
    "tables": [
      {
        "tableName": "hotelReviewsInlineDocument",
        "generatedKeyName": "Documentid",
        "sourceContext": "/document",
        "inputs": [
          {
            "name": "reviews_text",
            "source": "/document/reviews_text"
          },
          {
            "name": "reviews_title",
            "source": "/document/reviews_title"
          },
          {
            "name": "AzureSearch_DocumentKey",
            "source": "/document/AzureSearch_DocumentKey"
          }
        ]
      },
      {
        "tableName": "hotelReviewsInlinePages",
        "generatedKeyName": "Pagesid",
        "sourceContext": "/document/reviews_text/pages/*",
        "inputs": [
          {
            "name": "Sentiment",
            "source": "/document/reviews_text/pages/*/Sentiment"
          },
          {
            "name": "LanguageCode",
            "source": "/document/Language"
          },
          {
            "name": "Page",
            "source": "/document/reviews_text/pages/*"
          }
        ]
      },
      {
        "tableName": "hotelReviewsInlineKeyPhrases",
        "generatedKeyName": "KeyPhraseId",
        "sourceContext": "/document/reviews_text/pages/*/Keyphrases/*",
        "inputs": [
          {
            "name": "Keyphrases",
            "source": "/document/reviews_text/pages/*/Keyphrases/*"
          }
        ]
      }
    ]
  }
]
```

```
    }  
]
```

One observation from both the approaches is how values of "Keyphrases" are projected using the "sourceContext". The "Keyphrases" node, which contains a collection of strings, is itself a child of the page text. However, because projections require a JSON object and the page is a primitive (string), the "sourceContext" is used to wrap the key phrase into an object with a named property. This technique enables even primitives to be projected independently.

Inline shape for object projections

You can generate a new shape using the Shaper skill or use inline shaping of the object projection. While the tables example demonstrated the approach of creating a shape and slicing, this example demonstrates the use of inline shaping.

Inline shaping is the ability to create a new shape in the definition of the inputs to a projection. Inline shaping creates an anonymous object that is identical to what a Shaper skill would produce (in this case, `projectionShape`). Inline shaping is useful if you're defining a shape that you don't plan to reuse.

The `projections` property is an array. This example adds a new projection instance to the array, where the `knowledgeStore` definition contains inline projections. When using inline projections, you can omit the Shaper skill.

JSON

```
"knowledgeStore" : {  
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct  
Name>;AccountKey=<Acct Key>;",  
    "projections": [  
        {  
            "tables": [ ],  
            "objects": [  
                {  
                    "storageContainer": "sampleobject",  
                    "source": null,  
                    "generatedKeyName": "myobject",  
                    "sourceContext": "/document",  
                    "inputs": [  
                        {  
                            "name": "metadata_storage_name",  
                            "source": "/document/metadata_storage_name"  
                        },  
                        {  
                            "name": "metadata_storage_path",  
                            "source": "/document/metadata_storage_path"  
                        },  
                        {  
                            "name": "metadata_storage_type",  
                            "source": "/document/metadata_storage_type"  
                        }  
                    ]  
                }  
            ]  
        }  
    ]  
}
```

```
        {
          "name": "content",
          "source": "/document/content"
        },
        {
          "name": "keyPhrases",
          "source": "/document/merged_content/keyphrases/*"
        },
        {
          "name": "entities",
          "source": "/document/merged_content/entities/*/name"
        },
        {
          "name": "ocrText",
          "source": "/document/normalized_images/*/text"
        },
        {
          "name": "ocrLayoutText",
          "source": "/document/normalized_images/*/layoutText"
        }
      ]
    }
  ],
  "files": []
}
]
```

Next steps

This article describes the concepts and principles of projection shapes. As a next step, see how these are applied in patterns for table, object, and file projections.

[Define projections in a knowledge store](#)

Last updated on 10/21/2025

Define projections in a knowledge store

(!) Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in [agentic retrieval](#) workflows.

Projections are the component of a [knowledge store definition](#) that determines how AI enriched content is stored in Azure Storage. Projections determine the type, quantity, and composition of the data structures containing your content.

In this article, learn the syntax for each type of projection:

- [Table projections](#)
- [Object projections](#)
- [File projections](#)

Recall that projections are defined under the `knowledgeStore` property of a skillset.

JSON

```
"knowledgeStore" : {  
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct  
Name>;AccountKey=<Acct Key>;",  
    "projections": [  
        {  
            "tables": [ ],  
            "objects": [ ],  
            "files": [ ]  
        }  
    ]  
}
```

If you need more background before getting started, review [this check list](#) for tips and workflow.

💡 Tip

When developing projections, [enable enrichment caching \(preview\)](#) so that you can reuse existing enrichments while editing projection definitions. Enrichment caching is a preview feature, so be sure to use the preview REST API on the indexer request. Without caching, simple edits to a projection will result in a full reprocess of enriched content. By caching

the enrichments, you can iterate over projections without incurring any skillset processing charges.

Requirements

All projections have source and destination properties. The source is always internal content from an enrichment tree created during skillset execution. The destination is the name and type of an external object that's created and populated in Azure Storage.

Except for file projections, which only accept binary images, the source must be:

- Valid JSON
- A path to a node in the enrichment tree (for example, `"source": "/document/objectprojection"`)

While a node might resolve to a single field, a more common representation is a reference to a complex shape. Complex shapes are created through a shaping methodology, either a [Shaper skill](#) or an [inline shaping definition](#), but usually a Shaper skill. The fields or elements of the shape determine the fields in containers and tables.

Shaper skills are favored because it outputs JSON, whereas most skills don't output valid JSON on their own. In many cases, the same data shape created by a Shaper skill can be used equally by both table and object projections.

Given source input requirements, knowing how to [shape data](#) becomes a practical requirement for projection definition, especially if you're working with tables.

Define a table projection

Table projections are recommended for scenarios that call for data exploration, such as analysis with Power BI or workloads that consume data frames. The tables section of a projections array is a list of tables that you want to project.

To define a table projection, use the `tables` array in the `projections` property. A table projection has three required properties:

 [Expand table](#)

Property	Description
tableName	Determines the name of a new table created in Azure Table Storage.

Property	Description
generatedKeyName	Column name for the key that uniquely identifies each row. The value is system-generated. If you omit this property, a column is created automatically that uses the table name and "key" as the naming convention.
source	A path to a node in an enrichment tree. The node should be a reference to a complex shape that determines which columns are created in the table.

In table projections, "source" is usually the output of a [Shaper skill](#) that defines the shape of the table. Tables have rows and columns, and shaping is the mechanism by which rows and columns are specified. You can use a [Shaper skill or inline shapes](#). The Shaper skill produces valid JSON, but the source could be the output from any skill, if valid JSON.

(!) Note

Table projections are subject to the [storage limits](#) imposed by Azure Storage. The entity size can't exceed 1 MB and a single property can be no bigger than 64 KB. These constraints make tables a good solution for storing a large number of small entities.

Single table example

The schema of a table is specified partly by the projection (table name and key), and also by the source that provides the shape of table (columns). This example shows just one table so that you can focus on the details of the definition.

JSON

```
"projections" : [
  {
    "tables": [
      { "tableName": "Hotels", "generatedKeyName": "HotelId", "source":
"/document/tableprojection" }
    ]
  }
]
```

Columns are derived from the "source". The following data shape containing HotelId, HotelName, Category, and Description will result in creation of those columns in the table.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "#3",
```

```

"description": null,
"context": "/document",
"inputs": [
{
  "name": "HotelId",
  "source": "/document/HotelId"
},
{
  "name": "HotelName",
  "source": "/document/HotelName"
},
{
  "name": "Category",
  "source": "/document/Category"
},
{
  "name": "Description",
  "source": "/document/Description"
},
],
"outputs": [
{
  "name": "output",
  "targetName": "tableprojection"
}
]
}

```

Multiple table (slicing) example

A common pattern for table projections is to have multiple related tables, where system-generated partitionKey and rowKey columns are created to support cross-table relationships for all tables under the same projection group.

Creating multiple tables can be useful if you want control over how related data is aggregated. If enriched content has unrelated or independent components, for example the keywords extracted from a document might be unrelated from the entities recognized in the same document, you can split out those fields into adjacent tables.

When you're projecting to multiple tables, the complete shape is projected into each table, unless a child node is the source of another table within the same group. Adding a projection with a source path that is a child of an existing projection results in the child node being sliced out of the parent node and projected into the new yet related table. This technique allows you to define a single node in a Shaper skill that can be the source for all of your projections.

The pattern for multiple tables consists of:

- One table as the parent or main table
- Other tables to contain slices of the enriched content

For example, assume a Shaper skill outputs an "EnrichedShape" that contains hotel information, plus enriched content like key phrases, locations, and organizations. The main table would include fields that describe the hotel (ID, name, description, address, category). Key phrases would get the key phrase column. Entities would get the entity columns.

JSON

```
"projections" : [
  {
    "tables": [
      { "tableName": "MainTable", "generatedKeyName": "HotelId", "source": "/document/EnrichedShape" },
      { "tableName": "KeyPhrases", "generatedKeyName": "KeyPhraseId", "source": "/document/EnrichedShape/*/KeyPhrases/*" },
      { "tableName": "Entities", "generatedKeyName": "EntityId", "source": "/document/EnrichedShape/*/Entities/*" }
    ]
  }
]
```

Naming relationships

The `generatedKeyName` and `referenceKeyName` properties are used to relate data across tables or even across projection types. Each row in the child table has a property pointing back to the parent. The name of the column or property in the child is the `referenceKeyName` from the parent. When the `referenceKeyName` isn't provided, the service defaults it to the `generatedKeyName` from the parent.

Power BI relies on these generated keys to discover relationships within the tables. If you need the column in the child table named differently, set the `referenceKeyName` property on the parent table. One example would be to set the `generatedKeyName` as ID on the `tblDocument` table and the `referenceKeyName` as `DocumentID`. This would result in the column in the `tblEntities` and `tblKeyPhrases` tables containing the document ID being named `DocumentID`.

Define an object projection

Object projections are JSON representations of the enrichment tree that can be sourced from any node. In comparison with table projections, object projections are simpler to define and are used when projecting whole documents. Object projections are limited to a single projection in a container and can't be sliced.

To define an object projection, use the `objects` array in the `projections` property. An object projection has three required properties:

Property	Description
storageContainer	Determines the name of a new container created in Azure Storage.
generatedKeyName	Column name for the key that uniquely identifies each row. The value is system-generated. If you omit this property, a column is created automatically that uses the table name and "key" as the naming convention.
source	A path to a node in an enrichment tree that is the root of the projection. The node is usually a reference to a complex data shape that determines blob structure.

The following example projects individual hotel documents, one hotel document per blob, into a container called `hotels`.

JSON

```
"knowledgeStore": {
  "storageConnectionString": "an Azure storage connection string",
  "projections" : [
    {
      "tables": [ ]
    },
    {
      "objects": [
        {
          "storageContainer": "hotels",
          "source": "/document/objectprojection",
        }
      ]
    },
    {
      "files": [ ]
    }
  ]
}
```

The source is the output of a Shaper skill, named `"objectprojection"`. Each blob has a JSON representation of each field input.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "#3",
  "description": null,
  "context": "/document",
  "inputs": [
    {
      "name": "HotelId",
      "type": "Edm.Int32"
    }
  ],
  "outputs": [
    {
      "name": "Hotel"
    }
  ],
  "constraints": [
    {
      "name": "HotelId"
    }
  ],
  "skills": [
    {
      "name": "Hotel"
    }
  ],
  "parameters": [
    {
      "name": "HotelId"
    }
  ],
  "version": "1.0"
}
```

```

        "source": "/document/HotelId"
    },
    {
        "name": "HotelName",
        "source": "/document/HotelName"
    },
    {
        "name": "Category",
        "source": "/document/Category"
    },
    {
        "name": "keyPhrases",
        "source": "/document/HotelId/keyphrases/*"
    },
],
"outputs": [
{
    "name": "output",
    "targetName": "objectprojection"
}
]
}
}

```

Define a file projection

File projections are always binary, normalized images, where normalization refers to potential resizing and rotation for use in skillset execution. File projections, similar to object projections, are created as blobs in Azure Storage, and contain binary data (as opposed to JSON).

To define a file projection, use the `files` array in the `projections` property. A files projection has three required properties:

[Expand table](#)

Property	Description
storageContainer	Determines the name of a new container created in Azure Storage.
generatedKeyName	Column name for the key that uniquely identifies each row. The value is system-generated. If you omit this property, a column is created automatically that uses the table name and "key" as the naming convention.
source	A path to a node in an enrichment tree that is the root of the projection. For images files, the source is always <code>/document/normalized_images/*</code> . File projections only act on the <code>normalized_images</code> collection. Neither indexers nor a skillset will pass through the original non-normalized image.

The destination is always a blob container, with a folder prefix of the base64 encoded value of the document ID. If there are multiple images, they're placed together in the same folder. File

projections can't share the same container as object projections and need to be projected into a different container.

The following example projects all normalized images extracted from the document node of an enriched document, into a container called `myImages`.

JSON

```
"projections": [
  {
    "tables": [ ],
    "objects": [ ],
    "files": [
      {
        "storageContainer": "myImages",
        "source": "/document/normalized_images/*"
      }
    ]
  }
]
```

Test projections

You can process projections by following these steps:

1. Set the knowledge store's `storageConnectionString` property to a valid V2 general purpose storage account connection string.
2. [Update the skillset](#) by issuing a PUT request with your projection definition in the body of the skillset.
3. [Run the indexer](#) to put the skillset into execution.
4. [Monitor indexer execution](#) to check progress and catch any errors.
5. Use Azure portal to verify object creation in Azure Storage.
6. If you're projecting tables, [import them into Power BI](#) for table manipulation and visualization. In most cases, Power BI autodiscovers the relationships among tables.

Common issues

Omitting any of the following steps can result in unexpected outcomes. Check for the following conditions if your output doesn't look right.

- String enrichments aren't shaped into valid JSON. When strings are enriched, for example `merged_content` enriched with key phrases, the enriched property is represented as a child of `merged_content` within the enrichment tree. The default representation isn't well-formed JSON. At projection time, make sure to transform the enrichment into a valid JSON object with a name and a value. Using a Shaper skill or defining inline shapes help resolve this issue.
- Omission of `/*` at the end of a source path. If the source of a projection is `/document/projectionShape/keyPhrases`, the key phrases array is projected as a single object/row. Instead, set the source path to `/document/projectionShape/keyPhrases/*` to yield a single row or object for each of the key phrases.
- Path syntax errors. [Path selectors](#) are case-sensitive and can lead to missing input warnings if you don't use the exact case for the selector.

Next steps

The next step walks you through shaping and projection of output from a rich skillset. If your skillset is complex, the following article provides examples of both shapes and projections.

[Detailed example of shapes and projections](#)

Last updated on 10/21/2025

Example of shapes and projections in a knowledge store

! Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in [agentic retrieval](#) workflows.

This article provides a detailed example that supplements [high-level concepts](#) and [syntax-based articles](#) by walking you through the shaping and projection steps required for fully expressing the output of a rich skillset in a [knowledge store](#) in Azure Storage.

If your application requirements call for multiple skills and projections, this example can give you a better idea of how shapes and projections interact.

Set up sample data

Sample documents aren't included with the Projections collection, but the [AI enrichment demo data files](#) ↗ contain text and images that work with the projections described in this example. If you use this sample data, you can skip step that [attaches a Microsoft Foundry resource](#) because you stay under the daily indexer limit for free enrichments.

Create a blob container in Azure Storage and upload all 14 items.

While in Azure Storage, copy a connection string.

You can use the [projections.rest](#) ↗ file to run the examples in this article.

Example skillset

To understand the dependency between shapes and projections, review the following skillset that creates enriched content. This skillset processes both raw images and text, producing outputs that will be referenced in shapes and projections.

Pay close attention to skill outputs (targetNames). Outputs written to the enriched document tree are referenced in projections and in shapes (via Shaper skills).

JSON

```
{
  "name": "projections-demo-ss",
  "description": "Skillset that enriches blob data found in the merged_content field. The enrichment granularity is a document.",
  "skills": [
    {
      "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
      "name": "#1",
      "description": null,
      "context": "/document/merged_content",
      "categories": [
        "Person",
        "Quantity",
        "Organization",
        "URL",
        "Email",
        "Location",
        "DateTime"
      ],
      "defaultLanguageCode": "en",
      "minimumPrecision": null,
      "inputs": [
        {
          "name": "text",
          "source": "/document/merged_content"
        },
        {
          "name": "languageCode",
          "source": "/document/language"
        }
      ],
      "outputs": [
        {
          "name": "persons",
          "targetName": "people"
        },
        {
          "name": "organizations",
          "targetName": "organizations"
        },
        {
          "name": "locations",
          "targetName": "locations"
        }
      ]
    },
    {
      "@odata.type": "#Microsoft.Skills.Text.KeyPhraseExtractionSkill",
      "name": "#2",
      "description": null,
      "context": "/document/merged_content",
      "defaultLanguageCode": "en",
      "maxKeyPhraseCount": null,
      "inputs": [
        {
          "name": "keyPhrases"
        }
      ]
    }
  ]
}
```

```
{
    "name": "text",
    "source": "/document/merged_content"
},
{
    "name": "languageCode",
    "source": "/document/language"
}
],
"outputs": [
{
    "name": "keyPhrases",
    "targetName": "keyphrases"
}
]
},
{
    "@odata.type": "#Microsoft.Skills.Text.LanguageDetectionSkill",
    "name": "#3",
    "description": null,
    "context": "/document",
    "inputs": [
{
    "name": "text",
    "source": "/document/merged_content"
}
],
"outputs": [
{
    "name": "languageCode",
    "targetName": "language"
}
]
},
{
    "@odata.type": "#Microsoft.Skills.Text.MergeSkill",
    "name": "#4",
    "description": null,
    "context": "/document",
    "insertPreTag": " ",
    "insertPostTag": " ",
    "inputs": [
{
    "name": "text",
    "source": "/document/content"
},
{
    "name": "itemsToInsert",
    "source": "/document/normalized_images/*/text"
},
{
    "name": "offsets",
    "source": "/document/normalized_images/*/contentOffset"
}
],
},
```

```

    "outputs": [
      {
        "name": "mergedText",
        "targetName": "merged_content"
      }
    ]
  },
  {
    "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",
    "name": "#5",
    "description": null,
    "context": "/document/normalized_images/*",
    "textExtractionAlgorithm": "printed",
    "lineEnding": "Space",
    "defaultLanguageCode": "en",
    "detectOrientation": true,
    "inputs": [
      {
        "name": "image",
        "source": "/document/normalized_images/*"
      }
    ],
    "outputs": [
      {
        "name": "text",
        "targetName": "text"
      },
      {
        "name": "layoutText",
        "targetName": "layoutText"
      }
    ]
  }
],
"cognitiveServices": {
  "@odata.type": "#Microsoft.Azure.Search.CognitiveServicesByKey",
  "description": "A Foundry resource in the same region as Search.",
  "key": ""
},
"knowledgeStore": null
}

```

Note

Under `"cognitiveServices"`, the key field is unspecified because the indexer can use a Foundry resource in the same region as your search service and process up to 20 transactions daily at no charge. The sample data for this example stays under the 20 transaction limit.

Example Shaper skill

A [Shaper skill](#) is a utility for working with existing enriched content instead of creating new enriched content. Adding a Shaper to a skillset lets you create a custom shape that you can project into table or blob storage. Without a custom shape, projections are limited to referencing a single node (one projection per output), which isn't suitable for tables. Creating a custom shape aggregates various elements into a new logical whole that can be projected as a single table, or sliced and distributed across a collection of tables.

In this example, the custom shape combines blob metadata and identified entities and key phrases. The custom shape is called `projectionShape` and is parented under `/document`.

One purpose of shaping is to ensure that all enrichment nodes are expressed in well-formed JSON, which is required for projecting into knowledge store. This is especially true when an enrichment tree contains nodes that aren't well-formed JSON (for example, when an enrichment is parented to a primitive like a string).

Notice the last two nodes, `KeyPhrases` and `Entities`. These are wrapped into a valid JSON object with the `sourceContext`. This is required as `keyphrases` and `entities` are enrichments on primitives and need to be converted to valid JSON before they can be projected.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "ShaperForTables",
  "description": null,
  "context": "/document",
  "inputs": [
    {
      "name": "metadata_storage_content_type",
      "source": "/document/metadata_storage_content_type",
      "sourceContext": null,
      "inputs": []
    },
    {
      "name": "metadata_storage_name",
      "source": "/document/metadata_storage_name",
      "sourceContext": null,
      "inputs": []
    },
    {
      "name": "metadata_storage_path",
      "source": "/document/metadata_storage_path",
      "sourceContext": null,
      "inputs": []
    },
    {
      "name": "keyphrases",
      "source": "/document/keyphrases",
      "sourceContext": {
        "key": "keyphrases"
      },
      "inputs": []
    },
    {
      "name": "entities",
      "source": "/document/entities",
      "sourceContext": {
        "key": "entities"
      },
      "inputs": []
    }
  ]
}
```

```

        "name": "metadata_content_type",
        "source": "/document/metadata_content_type",
        "sourceContext": null,
        "inputs": []
    },
    {
        "name": "keyPhrases",
        "source": null,
        "sourceContext": "/document/merged_content/keyphrases/*",
        "inputs": [
            {
                "name": "KeyPhrases",
                "source": "/document/merged_content/keyphrases/*"
            }
        ]
    },
    {
        "name": "Entities",
        "source": null,
        "sourceContext": "/document/merged_content/entities/*",
        "inputs": [
            {
                "name": "Entities",
                "source": "/document/merged_content/entities/*/name"
            }
        ]
    }
],
"outputs": [
    {
        "name": "output",
        "targetName": "projectionShape"
    }
]
}

```

Add Shapers to a skillset

The example skillset introduced at the start of this article didn't include the Shaper skill, but Shaper skills belong in a skillset and are often placed towards the end.

Within a skillset, a Shaper skill might look like this:

JSON

```
{
    "name": "projections-demo-ss",
    "skills": [
        {
            <Shaper skill goes here>
        }
    ]
}
```

```

        }
    ],
    "cognitiveServices": "A key goes here",
    "knowledgeStore": []
}

```

Projecting to tables

Drawing on the examples above, there's a known quantity of enrichments and data shapes that can be referenced in table projections. In the tables projection below, three tables are defined by setting the `tableName`, `source` and `generatedKeyName` properties.

All three of these tables will be related through generated keys and by the shared parent `/document/projectionShape`.

JSON

```

"knowledgeStore" : {
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct
Name>;AccountKey=<Acct Key>;",
    "projections": [
        {
            "tables": [
                {
                    "tableName": "tblDocument",
                    "generatedKeyName": "Documentid",
                    "source": "/document/projectionShape"
                },
                {
                    "tableName": "tblKeyPhrases",
                    "generatedKeyName": "KeyPhraseid",
                    "source": "/document/projectionShape/keyPhrases/*"
                },
                {
                    "tableName": "tblEntities",
                    "generatedKeyName": "Entityid",
                    "source": "/document/projectionShape/Entities/*"
                }
            ],
            "objects": [],
            "files": []
        }
    ]
}

```

Test your work

You can check projection definitions by following these steps:

1. Set the knowledge store's `storageConnectionString` property to a valid V2 general purpose storage account connection string.
2. Update the skillset by issuing the PUT request.
3. After updating the skillset, run the indexer.

You now have a working projection with three tables. [Importing these tables into Power BI](#) should result in Power BI discovering the relationships.

Before moving on to the next example, let's revisit aspects of the table projection to understand the mechanics of slicing and relating data.

Slicing a table into multiple child tables

Slicing is a technique that subdivides a whole consolidated shape into constituent parts. The outcome consists of separate but related tables that you can work with individually.

In the example, `projectionShape` is the consolidated shape (or enrichment node). In the projection definition, `projectionShape` is sliced into additional tables, which enables you to pull out parts of the shape, `keyPhrases` and `Entities`. In Power BI, this is useful as multiple entities and keyPhrases are associated with each document, and you'll get more insights if you can see entities and keyPhrases as categorized data.

Slicing implicitly generates a relationship between the parent and child tables, using the `generatedKeyName` in the parent table to create a column with the same name in the child table.

Naming relationships

The `generatedKeyName` and `referenceKeyName` properties are used to relate data across tables or even across projection types. Each row in the child table has a property pointing back to the parent. The name of the column or property in the child is the `referenceKeyName` from the parent. When the `referenceKeyName` isn't provided, the service defaults it to the `generatedKeyName` from the parent.

Power BI relies on these generated keys to discover relationships within the tables. If you need the column in the child table named differently, set the `referenceKeyName` property on the parent table. One example would be to set the `generatedKeyName` as ID on the `tblDocument` table and the `referenceKeyName` as `DocumentID`. This would result in the column in the `tblEntities` and `tblKeyPhrases` tables containing the document ID being named `DocumentID`.

Projecting blob documents

Object projections are JSON representations of the enrichment tree that can be sourced from any node. In comparison with table projections, object projections are simpler to define and are used when projecting whole documents. Object projections are limited to a single projection in a container and can't be sliced.

To define an object projection, use the `objects` array in the `projections` property.

The source is the path to a node of the enrichment tree that is the root of the projection. Although it isn't required, the node path is usually the output of a Shaper skill. This is because most skills don't output valid JSON objects on their own, which means that some form of shaping is necessary. In many cases, the same Shaper skill that creates a table projection can be used to generate an object projection. Alternatively, the source can also be set to a node with [an inline shaping](#) to provide the structure.

The destination is always a blob container.

The following example projects individual hotel documents, one hotel document per blob, into a container called `hotels`.

JSON

```
"knowledgeStore": {
  "storageConnectionString": "an Azure storage connection string",
  "projections" : [
    {
      "tables": [ ]
    },
    {
      "objects": [
        {
          "storageContainer": "hotels",
          "source": "/document/objectprojection",
        }
      ]
    },
    {
      "files": [ ]
    }
  ]
}
```

The source is the output of a Shaper skill, named `"objectprojection"`. Each blob will have a JSON representation of each field input.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "#3",
  "description": null,
  "context": "/document",
  "inputs": [
    {
      "name": "HotelId",
      "source": "/document/HotelId"
    },
    {
      "name": "HotelName",
      "source": "/document/HotelName"
    },
    {
      "name": "Category",
      "source": "/document/Category"
    },
    {
      "name": "keyPhrases",
      "source": "/document/HotelId/keyphrases/*"
    }
  ],
  "outputs": [
    {
      "name": "output",
      "targetName": "objectprojection"
    }
  ]
}
```

Projecting an image file

File projections are always binary, normalized images, where normalization refers to potential resizing and rotation for use in skillset execution. File projections, similar to object projections, are created as blobs in Azure Storage, and contain the image.

To define a file projection, use the `files` array in the `projections` property.

The source is always `/document/normalized_images/*`. File projections only act on the `normalized_images` collection. Neither indexers nor a skillset will pass through the original non-normalized image.

The destination is always a blob container, with a folder prefix of the base64 encoded value of the document ID. File projections can't share the same container as object projections and need to be projected into a different container.

The following example projects all normalized images extracted from the document node of an enriched document, into a container called `myImages`.

JSON

```
"knowledgeStore" : {
  "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct
Name>;AccountKey=<Acct Key>;",
  "projections": [
    {
      "tables": [ ],
      "objects": [ ],
      "files": [
        {
          "storageContainer": "myImages",
          "source": "/document/normalized_images/*"
        }
      ]
    }
  ]
}
```

Projecting to multiple types

A more complex scenario might require you to project content across projection types. For example, projecting key phrases and entities to tables, saving OCR results of text and layout text as objects, and then projecting the images as files.

Steps for multiple projection types:

1. Create a table with a row for each document.
2. Create a table related to the document table with each key phrase identified as a row in this table.
3. Create a table related to the document table with each entity identified as a row in this table.
4. Create an object projection with the layout text for each image.
5. Create a file projection, projecting each extracted image.
6. Create a cross-reference table that contains references to the document table, object projection with the layout text, and the file projection.

Shape data for cross-projection

To get the shapes needed for these projections, start by adding a new Shaper skill that creates a shaped object called `crossProjection`.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
  "name": "ShaperForCrossProjection",
  "description": null,
  "context": "/document",
  "inputs": [
    {
      "name": "metadata_storage_name",
      "source": "/document/metadata_storage_name",
      "sourceContext": null,
      "inputs": []
    },
    {
      "name": "keyPhrases",
      "source": null,
      "sourceContext": "/document/merged_content/keyphrases/*",
      "inputs": [
        {
          "name": "KeyPhrases",
          "source": "/document/merged_content/keyphrases/*"
        }
      ]
    },
    {
      "name": "entities",
      "source": null,
      "sourceContext": "/document/merged_content/entities/*",
      "inputs": [
        {
          "name": "Entities",
          "source": "/document/merged_content/entities/*/name"
        }
      ]
    },
    {
      "name": "images",
      "source": null,
      "sourceContext": "/document/normalized_images/*",
      "inputs": [
        {
          "name": "image",
          "source": "/document/normalized_images/*"
        },
        {
          "name": "layoutText",
          "source": "/document/normalized_images/*/layoutText"
        },
        {
          "name": "ocrText",
          "source": "/document/normalized_images/*/text"
        }
      ]
    }
  ]
}
```

```

        ],
        "outputs": [
            {
                "name": "output",
                "targetName": "crossProjection"
            }
        ]
    }
}

```

Define table, object, and file projections

From the consolidated crossProjection object, slice the object into multiple tables, capture the OCR output as blobs, and then save the image as files (also in Blob storage).

JSON

```

"knowledgeStore" : {
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct
Name>;AccountKey=<Acct Key>;",
    "projections": [
        {
            "tables": [
                {
                    "tableName": "crossDocument",
                    "generatedKeyName": "Id",
                    "source": "/document/crossProjection"
                },
                {
                    "tableName": "crossEntities",
                    "generatedKeyName": "EntityId",
                    "source": "/document/crossProjection/entities/*"
                },
                {
                    "tableName": "crossKeyPhrases",
                    "generatedKeyName": "KeyPhraseId",
                    "source": "/document/crossProjection/keyPhrases/*"
                },
                {
                    "tableName": "crossReference",
                    "generatedKeyName": "CrossId",
                    "source": "/document/crossProjection/images/*"
                }
            ],
            "objects": [
                {
                    "storageContainer": "crossobject",
                    "generatedKeyName": "crosslayout",
                    "source": null,

```

```

        "sourceContext":  

        "/document/crossProjection/images/*/layoutText",  

        "inputs": [  

            {  

                "name": "OcrLayoutText",  

                "source":  

                "/document/crossProjection/images/*/layoutText"  

            }  

        ]  

    },  

    "files": [  

        {  

            "storageContainer": "crossimages",  

            "generatedKeyName": "crossimages",  

            "source": "/document/crossProjection/images/*/image"  

        }  

    ]  

}  

]
}

```

Object projections require a container name for each projection. Object projections and file projections can't share a container.

Relationships among table, object, and file projections

This example also highlights another feature of projections. By defining multiple types of projections within the same projection object, there's a relationship expressed within and across the different types (tables, objects, files). This allows you to start with a table row for a document and find all the OCR text for the images within that document in the object projection.

If you don't want the data related, define the projections in different projection groups. For example, the following snippet will result in the tables being related, but without relationships between the tables and the object (OCR text) projections.

Projection groups are useful when you want to project the same data in different shapes for different needs. For example, a projection group for the Power BI dashboard, and another projection group for capturing data used to train a machine learning model wrapped in a custom skill.

When building projections of different types, file and object projections are generated first, and the paths are added to the tables.

JSON

```
"knowledgeStore" : {
    "storageConnectionString": "DefaultEndpointsProtocol=https;AccountName=<Acct
Name>;AccountKey=<Acct Key>;",
    "projections": [
        {
            "tables": [
                {
                    "tableName": "unrelatedDocument",
                    "generatedKeyName": "Documentid",
                    "source": "/document/projectionShape"
                },
                {
                    "tableName": "unrelatedKeyPhrases",
                    "generatedKeyName": "KeyPhraseid",
                    "source": "/document/projectionShape/keyPhrases"
                }
            ],
            "objects": [
                ],
            "files": []
        },
        {
            "tables": [],
            "objects": [
                {
                    "storageContainer": "unrelatedocrtext",
                    "source": null,
                    "sourceContext": "/document/normalized_images/*/text",
                    "inputs": [
                        {
                            "name": "ocrText",
                            "source": "/document/normalized_images/*/text"
                        }
                    ]
                },
                {
                    "storageContainer": "unrelatedocrlayout",
                    "source": null,
                    "sourceContext": "/document/normalized_images/*/layoutText",
                    "inputs": [
                        {
                            "name": "ocrLayoutText",
                            "source": "/document/normalized_images/*/layoutText"
                        }
                    ]
                }
            ],
            "files": []
        }
    ]
}
```

Next steps

The example in this article demonstrates common patterns on how to create projections. Now that you have a good understanding of the concepts, you're better equipped to build projections for your specific scenario.

[Configure caching for incremental enrichment](#)

Last updated on 10/21/2025

Connect a knowledge store with Power BI

Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in [agentic retrieval](#) workflows.

In this article, learn how to connect to and query a knowledge store using Power Query in the Power BI Desktop app. You can get started faster with templates, or build a custom dashboard from scratch.

A knowledge store that's composed of tables in Azure Storage work best in Power BI. If the tables contain projections from the same skillset and projection group, you can easily "join" them to build table visualizations that include fields from related tables.

Follow the steps in this article using sample data and a knowledge store as [created in this portal quickstart](#) or through [REST APIs](#).

Connect to Azure Storage

1. Start [Power BI Desktop](#) and select **Get data**.
2. In **Get Data**, select **Azure**, and then select **Azure Table Storage**.
3. Select **Connect**.
4. For **Account Name or URL**, enter in your Azure Storage account name (the full URL is created for you).
5. If prompted, enter the storage account key.

Set up tables

1. Select the checkbox next to all of the tables that were created from the same skillset, and then select **Load**.

2. On the top ribbon, select **Transform Data** to open the **Power Query Editor**.

3. Open *hotelReviewsDocument* and remove its *PartitionKey*, *RowKey*, and *Timestamp* columns. Those columns are used for table relationships in Azure Table Storage. Power BI doesn't need them. You should be left with one column named "Content" showing *Record* in each one.

4. Select the icon with opposing arrows at the upper right side of the table to expand *Content*. When the list of columns appears, select all columns. Clear columns starting with 'metadata'. Select **OK** to include the selected columns.

A screenshot of the Microsoft Power Query Editor interface. The title bar says "Untitled - Power Query Editor". The ribbon has tabs: File, Home, Transform, Add Column, View, and Help. The "Transform" tab is selected. On the left, there's a list of columns under "Search Columns to Expand": latitude, longitude, metadata_storage_content_type, metadata_storage_last_modified, metadata_storage_name, metadata_storage_path, metadata_storage_size, name, postalCode, province, reviews_date. A red box highlights the first four items. Below this list is a checked checkbox for "Use original column name as prefix". At the bottom left is a warning message: "⚠ List may be incomplete." with a "Load more" link, and two buttons: "OK" (highlighted with a red box) and "Cancel". On the right, there's a preview pane showing a table with four rows, each labeled "Record". The first row is highlighted with a yellow background. Above the preview are icons for "Data source settings", "Manage Parameters", "Refresh Preview", and "Parameters".

Content
1 Record
2 Record
3 Record
4 Record

5. Change the data type for the following columns by clicking the ABC-123 icon at the top left of the column.

- For *content.latitude* and *Content.longitude*, select **Decimal Number**.
- For *Content.reviews_date* and *Content.reviews_dateAdded*, select **Date/Time**.

	ABC 123	Content.latitude	ABC 123	Content.longitude
1	1.2	Decimal Number	5187	
2	\$	Fixed decimal number	5187	
3	1 ² 3	Whole Number	5187	
4	%	Percentage	5187	
5		Date/Time	5187	
6		Date	5187	
7			5187	

6. Open *hotelReviewsSsPages* and repeat column deletion steps, expanding *Content* to select columns from the records. There are no data type modifications for this table.
7. Open *hotelReviewsSsKeyPhrases* and repeat column deletion steps, expanding *Content* to select columns from the records. There are no data type modifications for this table.
8. On the command bar, select **Close and Apply**.

Check table relationships

1. Select on the Model tile on the left pane and validate that Power BI shows relationships between all three tables.
 Validate relationships
2. Double-click each relationship and make sure that the **Cross-filter direction** is set to **Both**. This enables your visuals to refresh when a filter is applied.

Build a report

1. Select on the Report tile on the left pane to explore data through visualizations. For text fields, tables and cards are useful visualizations.
2. Choose fields from each of the three tables to fill in the table or card.

Build a table report

Sample Power BI template - Azure portal only

When creating a [knowledge store using the Azure portal](#), you have the option of downloading a [Power BI template](#) on the second page of the **Import data** wizard. This template gives you several visualizations, such as WordCloud and Network Navigator, for text-based content.

Select **Get Power BI Template** on the **Add cognitive skills** page to retrieve and download the template from its public GitHub location. The wizard modifies the template to accommodate the shape of your data, as captured in the knowledge store projections specified in the wizard. For this reason, the template you download varies each time you run the wizard, assuming different data inputs and skill selections.

Note

The template is downloaded while the wizard is in mid-flight. You'll have to wait until the knowledge store is actually created in Azure Table Storage before you can use it.

Video introduction

For a demonstration of using Power BI with a knowledge store, watch the following video.

C# samples for Azure AI Search

09/23/2025

Learn about C# code samples that demonstrate the functionality and workflow of an Azure AI Search solution. These samples use the [Azure AI Search client library](#) for the [Azure SDK for .NET](#), which you can explore through the following links.

[] [Expand table](#)

Target	Link
Package download	nuget.org/packages/Azure.Search.Documents/ ↗
API reference	Azure.Search.Documents
API test cases	github.com/Azure/azure-sdk-for-net/tree/main/sdk/search/Azure.Search.Documents/tests ↗
Source code	github.com/Azure/azure-sdk-for-net/tree/main/sdk/search/Azure.Search/Documents/src ↗
Change log	github.com/Azure/azure-sdk-for-net/blob/main/sdk/search/Azure.Search/Documents/CHANGELOG.md ↗

SDK samples

Code samples from the Azure SDK development team demonstrate API usage. You can find these samples in [Azure/azure-sdk-for-net/blob/main/sdk/search/Azure.Search/Documents/samples](https://github.com/Azure/azure-sdk-for-net/blob/main/sdk/search/Azure.Search/Documents/samples) ↗ on GitHub.

[] [Expand table](#)

Sample	Description
Hello world (synchronous) ↗	Create a client, authenticate, and handle errors using synchronous methods.
Hello world (asynchronous) ↗	Create a client, authenticate, and handle errors using asynchronous methods.
Service-level operations ↗	Get service statistics and create multiple search objects, including an index, indexer, data source, skillset, and synonym map. Finally, you query the index.
Index operations ↗	Get a count of documents stored in an index.

Sample	Description
FieldBuilderIgnore ↗	Use an attribute to work with unsupported data types.
Indexing documents (push model) ↗	Use the push model to index documents by sending a JSON payload to an index.
Customer-managed encryption keys ↗	Use a customer-managed encryption key to protect sensitive content.
Vector search ↗	Index a vector field and perform vector search.
Semantic ranking ↗	Configure semantic ranker in an index and run semantic queries.

Doc samples

Code samples from the Azure AI Search team demonstrate features and workflows. The following samples are referenced in tutorials, quickstarts, and how-to articles that explain the code in detail. You can find these samples in [Azure-Samples/azure-search-dotnet-samples ↗](#) and [Azure-Samples/search-dotnet-getting-started ↗](#) on GitHub.

[] [Expand table](#)

Sample	Article	Description
quickstart ↗	Quickstart: Full-text search	Create, load, and query an index using sample data.
quickstart-agentic-retrieval ↗	Quickstart: Agentic retrieval	Integrate semantic ranking with LLM-powered query planning and answer generation.
quickstart-rag ↗	Quickstart: Generative search (RAG)	Use grounding data from Azure AI Search with a chat completion model from Azure OpenAI.
quickstart-semantic-search ↗	Quickstart: Semantic ranking	Add semantic ranking to an index schema and run semantic queries.
quickstart-vector-search ↗	Quickstart: Vector search	Index and query vector content.
create-mvc-app ↗	Tutorial: Add search to an ASP.NET Core (MVC) app	Add basic search, pagination, and other server-side behaviors to an MVC web app, unlike the console applications used in most samples.

Sample	Article	Description
search-website	Tutorial: Add search to web apps	Build an end-to-end search app that uses the push API for bulk upload and a rich client for hosting the app and handling search requests.
tutorial-ai-enrichment	Tutorial: AI-generated searchable content from Azure blobs	Create a skillset that iterates over Azure blobs to extract information and infer structure.
multiple-data-sources	Tutorial: Index from multiple data sources	Merge content from two data sources into one index.
optimize-data-indexing	Tutorial: Optimize indexing with the push API	Use optimization techniques for pushing data into an index.
DotNetHowTo	Use the .NET client library	Create and manage multiple search objects while learning about the APIs.
DotNetToIndexers	Tutorial: Index Azure SQL data	Configure an Azure SQL indexer with a schedule, field mappings, and parameters.
DotNetHowToEncryptionUsingCMK	Configure customer-managed keys for data encryption	Create objects that are encrypted with a customer-managed key.

Accelerators

An accelerator is an end-to-end solution that includes code and documentation you can adapt for your own implementation of a specific scenario.

[Expand table](#)

Sample	Description
search-qna-maker-accelerator	Solution that combines Azure AI Search and QnA Maker. See the live demo site.

Demos

A demo repo provides proof-of-concept source code for examples or scenarios shown in demonstrations. Unlike accelerators, demo solutions aren't designed for adaptation.

Transparency note: Azure AI Search

Important

Non-English translations are provided for convenience only. Please consult the [EN-US](#) version of this document for the definitive version.

What is a Transparency Note?

An AI system includes not only the technology, but also the people who will use it, the people who will be affected by it, and the environment in which it is deployed. Creating a system that is fit for its intended purpose requires an understanding of how technology works, what its capabilities and limitations are, and how to achieve the best performance. Microsoft's Transparency Notes are intended to help you understand how our AI technology works, the choices system owners can make that influence system performance and behavior, and the importance of thinking about the whole system, including the technology, the people, and the environment. You can use Transparency Notes when developing or deploying your own system or share them with the people who will use or be affected by your system.

Microsoft's Transparency Notes are part of a broader effort at Microsoft to put our AI Principles into practice. To find out more, see the [Microsoft AI principles](#).

The basics of Azure AI Search

Introduction

Azure AI Search gives developers tools, APIs, and SDKs for building a rich search experience over private, heterogeneous content in web, mobile, and enterprise applications. Search is foundational to any application that surfaces data to users. Common scenarios include catalog or document search, online retail stores, or data exploration over proprietary content.

Searchable data can be in the form of text or vectors and ingested as-is from a data source or enriched by using AI to improve the overall search experience. Developers can convert data into numerical representations (called vectors), by choosing to call an external machine learning models (known as embedding models). Indexers can optionally include skill sets that support a powerful suite of data enrichment via several [Azure Language in Foundry Tools](#) capabilities, such as [Named Entity Recognition \(NER\)](#) and [personally identifiable information \(PII\) detection](#), and [Azure Vision in Foundry Tools](#) capabilities, including [optical character recognition \(OCR\)](#) and image analysis.

See the following tabs for more information about how Azure AI Search improves the search experience by using Foundry Tools or other AI systems to better understand the intent, semantics, and implied structure of a customer's content.

AI enrichment

[AI enrichment](#) is the application of machine learning models from Foundry Tools over content that is not easily searchable in its raw form. Through enrichment, analysis and inference are used to create searchable content and structure where none previously existed.

AI enrichment is an optional extension of the Azure AI Search indexer pipeline that connects to Foundry Tools in the same region as a customer's search service. An enrichment pipeline has the same core components as a typical indexer (indexer, data source, index), plus a skill set that specifies the atomic enrichment steps. A skill set can be assembled by using built-in skills based on the Foundry Tools APIs, such as [Vision](#) and [Language](#), or [custom skills](#) that run external code that you provide.

Capabilities

AI enrichment

System behavior

Several [built-in skills](#) for AI enrichment in Azure AI Search take advantage of Foundry Tools. See the Transparency Notes for each built-in skill linked below for considerations when choosing to use a skill:

- Key Phrase Extraction Skill: [Language - Key Phrase Extraction](#)
- Language Detection Skill: [Language - Language Detection](#)
- Entity Linking Skill: [Language - Entity Linking](#)
- Entity Recognition Skill: [Language - Named Entity Recognition \(NER\)](#)
- PII Detection Skill: [Language - PII Detection](#)
- Sentiment Skill: [Language - Sentiment Analysis](#)
- Image Analysis Skill: [Vision - Image Analysis](#)
- OCR Skill: [Vision - OCR](#)
- Document Layout Skill: [Document Intelligence](#)

See the documentation for each skill to learn more about their respective capabilities, limitations, performance, evaluations, and methods for integration and responsible use. Note that using these skills in combination may lead to compounding effects (for example, errors introduced when using OCR will carry through when using key phrase extraction).

Use cases

Example use cases

Because Azure AI Search is a full text search solution, the purpose of AI enrichment is to improve the search utility of unstructured content. Here are some examples of content enrichment scenarios supported by the built-in skills:

- **Translation** and **language detection** enable multilingual search.
- **Entity recognition** extracts **people**, **places**, and **other entities** from large chunks of text.
- **Key phrase extraction** identifies and then outputs important terms.
- **OCR** recognizes printed and handwritten text in binary files.
- **Image analysis** describes image content and outputs the descriptions as searchable text fields.
- **Integrated vectorization** is a preview feature that calls the Azure OpenAI embeddings model to vectorize data and store embeddings in Azure AI Search for similarity search.

Limitations

AI enrichment

AI enrichment in Azure AI Search uses the indexer and data source features of the service to call Foundry Tools to perform the content enrichment. Limitations of the indexers and data sources used in this process will apply. Review the [indexer and data source documentation](#) for more information about these related limitations. The limitations of each Foundry Tool used by the AI enrichment pipeline in Azure AI Search will also apply. See the [transparency notes for each service](#) for more information about these limitations.

Azure AI Search REST API reference

09/24/2025

Azure AI Search (formerly known as *Azure Cognitive Search*) is a fully managed cloud search service that provides information retrieval over user-owned content.

Data plane REST APIs are used for indexing and query workflows, and are documented in this section.

Control plane operations for service administration are covered in a separate [Search Management REST API](#).

Versioned API docs

A version selector appears above the table of contents when you select an API reference article. The selector becomes available when you choose a page from the **Reference > Data Plane** folder.

The screenshot shows the Azure AI Search REST API reference page. On the left, there is a sidebar with a 'Version' dropdown menu containing the following options:

- 2025-09-01
- 2025-09-01
- 2025-08-01-preview
- 2025-05-01-preview

Below the dropdown is a tree view of API categories:

- Search Service
 - Overview
 - API versions
 - Data types
 - Data type map for indexers
 - Naming rules
 - HTTP status codes
 - HTTP request and response headers
 - OData support
- > Earlier versions
 - Reference
 - Data Plane
 - Overview
 - Data Sources

The main content area is titled 'Data Plane' and shows the following details:

- Learn / Azure / Azure REST API /
- Ask Learn
- Focus mode
- 9/24/2025
- Data Plane
- REST Operation Groups
- Expand table
- Operation Group
 - Data Sources
 - Documents
 - Get Service Statistics
 - Indexes
 - Indexes
 - Skillsets
 - Synonym Maps

Key concepts

Azure AI Search has the concepts of *search services*, *indexes*, *documents*, *indexers*, *data sources*, *skillsets*, and *synonym maps*.

- A search service hosts index, indexers, data sources, skillsets, and synonym maps as top-level objects.

- A search index provides persistent storage of search documents. Search documents are your data, articulated as a collection of fields, loaded from external sources and pushed to an index to make it searchable.
- A search indexer adds automation, reading data in native formats and serializing it into JSON.
- An indexer has a data source and points to an index.
- An indexer might also have a skillset that adds [AI enrichment](#) and [integrated vectorization](#) to the indexing pipeline. Skillsets are always attached to an indexer. They invoke machine learning to extract or chunk text, vectorize content, infer features, or add structure to content for improved indexing by a search service.

Altogether, you can create the following objects on a search service:

[] [Expand table](#)

Objects	Description
Data sources	A data source connection used by an indexer to retrieve and refresh documents for indexing. Data sources have a <code>type</code> . You can use the Microsoft-provided connections for Azure, or partner connectors. See Data sources gallery for the full list.
Documents	Conceptually, a document is an entity in your index. Mapping this concept to more familiar database equivalents: a search index equates to a table, and documents are roughly equivalent to rows in a table. Documents exist only in an index, and are retrieved only through queries that target the documents collection (<code>/docs</code>) of an index. All operations performed on the collection such as uploading, merging, deleting, or querying documents take place in the context of a single index, so the URL format document operations always includes <code>/indexes/[index name]/docs</code> for a given index name.
Indexes	An index is stored on your search service and populated with JSON documents that are indexed and tokenized for information retrieval. The fields collection of an index defines the structure of the search document. Fields have a name, data types, and attributes that determine usage. For example, <code>searchable</code> fields are used in full text search, and thus tokenized during indexing. An index also defines other constructs, such as scoring profiles for relevance tuning, suggesters, semantic configurations, and custom analyzers.
Indexers	Indexers provide indexing automation. An indexer connects to a data source, reads in the data, and passes it to a search engine for indexing into a target search index. Indexers read from an external source using connection information in a data source, and serialize the incoming data into JSON search documents. In addition to a data source, an indexer also requires an index. The index specifies the fields and attributes of the search documents.
Skillsets	A skillset adds external processing steps to indexer execution, and is used for applying AI or deep learning models to analyze or transform content for improved searchability in an index. The contents of a skillset are one or more <i>skills</i> , which can be built-in skills created by Microsoft, custom skills, or a combination of both. Built-in skills exist for image analysis, including OCR, and natural language processing. Other examples of built-in skills include entity recognition, key phrase extraction, chunking text into logical pages, among others. A

Objects	Description
	skillset is high-level standalone object that exists on a level equivalent to indexes, indexers, and data sources, but it's operational only within indexer processing. As a high-level object, you can design a skillset once, and then reference it in multiple indexers.
Synonym maps	A synonym map is service-level object that contains user-defined synonyms. This object is maintained independently from search indexes. Once uploaded, you can point any searchable field to the synonym map (one per field).

Permissions and access control

You can use key-based authentication or role-based through Microsoft Entra ID.

- [Key-based authentication](#) relies on API keys that are generated for the search service. Having a valid key establishes trust, on a per request basis, between the application sending the request and the service that handles it. You can use an [Admin API key](#) for read-write operations or a [Query API key](#) for read access to the documents collection of a search index.
- [Microsoft Entra ID authentication and role-based access control](#) requires that you have an established tenant in Microsoft Entra ID, with security principals and role assignments. Members of the following roles have data plane access. You can create custom roles if the built-in roles are insufficient.

When you use roles on the connection, your client app presents a bearer token in the authorization header. See [Authorize access to a search app using Microsoft Entra ID](#) for help with setting this up.

You can disable key-based authentication or role-based authentication. If you disable role-based authentication, it only applies to data plane operations. Control plane operations, such as service administration, always use role-based authentication. See [Microsoft Entra ID authentication and role-based access control for Azure AI Search](#) for details.

Calling the APIs

The APIs documented in this section provide access to operations on search data, such as index creation and population, document upload, and queries. When calling APIs, keep the following points in mind:

- Requests must be issued over HTTPS (on the default port 443).
- Request URIs must include the **api-version**. The value must be set to a supported version, formatted as shown in this example: `GET https://[search service]`

```
name].search.windows.net/indexes?api-version=2024-07-01
```

- Request headers must include either an api-key or a bearer token for authenticated connections. Optionally, you can set the Accept HTTP header. If the content type header isn't set, the default is assumed to be application/json.

Management REST API reference (Azure AI Search)

08/01/2025

The Management REST APIs of **Azure AI Search** (formerly known as *Azure Cognitive Search*) provide programmatic access to administrative operations:

- Create, update, and delete a search service
- Retrieve search service information
- Create, regenerate, or retrieve `api-keys` (query or admin keys)
- Add or remove replicas and partitions (adjust capacity)
- Configure a search service to use a private endpoint
- Enable or disable Azure role-based access control

For data plane tasks, such as creating and querying an index, use the [Search Service REST APIs](#) instead.

How to work with the management REST APIs

To fully administer your service programmatically, you work with two APIs: the Management REST API of Azure AI Search documented here, plus the common [Azure Resource Manager REST API](#).

The Resource Manager API is used for general-purpose operations that aren't service specific, such as querying subscription data, listing geo-locations, and so forth. All Resource Manager API calls are authenticated using Microsoft Entra ID. You must have membership and a role assignment in a Microsoft Entra tenant to make Resource Manager API calls.

Versioned API docs

REST API docs are versioned. When you open an API reference page, select the API version from the dropdown filter.

The screenshot shows the Azure API Management interface. On the left, there's a sidebar with a 'Version' dropdown and a tree view of service management categories. The 'Admin Keys' node under 'Resource Manager' is selected and highlighted with a red box. A main content area on the right displays the 'Admin Keys - Get' operation details, including the service name ('Search Management'), API version ('2025-05-01'), and a brief description ('Gets the primary and secondary admin API keys for the specified Azure AI Search service'). Below this is an 'HTTP' section with a POST request template: `POST https://management.azure.com/subscriptions/{subscriptionId}/resourceGroups/{resourceGroupName}/providers/Microsoft.Search/searchServices/{serviceName}?api-version=2020-08-01`. There are 'Copy' and 'Try It' buttons next to the template. At the bottom, there's a table for 'URI Parameters'.

Name	In	Required	Type	Description
resourceGroupName	path	True	string	The name of the resource group within the current subscription. You can obtain this value from the Azure Resource Manager API or the portal.

Permissions and access control

Administration rights are conveyed through built-in roles in Microsoft Entra ID:

- **Owner or Contributor** assignments are required for most tasks.
- **Reader** role has limited access to service information (GET operations, except for API keys, which require Owner or Contributor permissions).

For more information, see [Role-based access control in Azure AI Search](#).

A best practice is to assign roles to groups rather than individual users. An Azure subscription owner or global administrator manages these assignments. For more information, see [Assign Microsoft Entra roles to groups](#).

Connect to the management endpoint

When setting up the connection, start with the Resource Manager endpoint

`https://management.azure.com` and then add the subscription ID, provider (`Microsoft.Search`), and API version. Operations are specified in the body of the request.

A fully specified endpoint has the following components:

The screenshot shows the 'HTTP' section of the API operation details. It displays the full URL template: `https://management.azure.com/subscriptions/[subscriptionId]/resourceGroups/[resourceGroupName]/providers/Microsoft.Search/searchServices/[serviceName]?api-version=2020-08-01`.

The following clients are commonly used to call the management REST APIs:

Client	Instructions and examples
Azure PowerShell using the Az.Search module	Manage Azure AI Search using Azure PowerShell
Azure Command-Line Interface (CLI)	Manage Azure AI Search using the Azure CLI
Visual Studio Code  with the REST client 	Manage Azure AI Search using REST

You can also [manage a search service using the Azure portal](#).

Management APIs in other SDKs

The REST APIs are foundational to Azure AI Search, and any changes to the programming model are reflected in the REST APIs first.

Alternatives include the following Azure SDKs, which are independently updated on separate release schedules:

- [Microsoft Azure AI Search management client library for .NET](#)
- [Microsoft Azure SDK for Python](#)
- [Azure Search Management client library for JavaScript](#)
- [Azure Resource Manager Azure AI Search client library for Java](#)

See also

- [Azure AI Search documentation](#)
- [Manage Azure AI Search using REST](#)
- [Manage Azure AI Search using Azure PowerShell](#)
- [Manage Azure AI Search using Azure CLI](#)
- [Manage Azure AI Search using Azure portal](#)

Azure AI Search client library for .NET - version 11.7.0

[Azure AI Search](#) (formerly known as "Azure Cognitive Search") is an AI-powered information retrieval platform that helps developers build rich search experiences and generative AI apps that combine large language models with enterprise data.

The Azure AI Search service is well suited for the following application scenarios:

- Consolidate varied content types into a single searchable index. To populate an index, you can push JSON documents that contain your content, or if your data is already in Azure, create an indexer to pull in data automatically.
- Attach skillsets to an indexer to create searchable content from images and unstructured documents. A skillset leverages APIs from Azure AI Services for built-in OCR, entity recognition, key phrase extraction, language detection, text translation, and sentiment analysis. You can also add custom skills to integrate external processing of your content during data ingestion.
- In a search client application, implement query logic and user experiences similar to commercial web search engines and chat-style apps.

Use the `Azure.Search.Documents` client library to:

- Submit queries using vector, keyword, and hybrid query forms.
- Implement filtered queries for metadata, geospatial search, faceted navigation, or to narrow results based on filter criteria.
- Create and manage search indexes.
- Upload and update documents in the search index.
- Create and manage indexers that pull data from Azure into an index.
- Create and manage skillsets that add AI enrichment to data ingestion.
- Create and manage analyzers for advanced text analysis or multi-lingual content.
- Optimize results through semantic ranking and scoring profiles to factor in business logic or freshness.

[Source code](#) | [Package \(NuGet\)](#) | [API reference documentation](#) | [REST API documentation](#) | [Product documentation](#) | [Samples](#)

Getting started

Install the package

Install the Azure AI Search client library for .NET with [NuGet](#):

.NET CLI

```
dotnet add package Azure.Search.Documents
```

Prerequisites

You need an [Azure subscription](#) and a [search service](#) to use this package.

To create a new search service, you can use the [Azure portal](#), [Azure PowerShell](#), or the [Azure CLI](#). Here's an example using the Azure CLI to create a free instance for getting started:

Powershell

```
az search service create --name <mysearch> --resource-group <mysearch-rg> --sku free  
--location westus
```

See [choosing a pricing tier](#) for more information about available options.

Authenticate the client

To interact with the search service, you'll need to create an instance of the appropriate client class: `SearchClient` for searching indexed documents, `SearchIndexClient` for managing indexes, or `SearchIndexerClient` for crawling data sources and loading search documents into an index. To instantiate a client object, you'll need an [endpoint](#) and [Azure roles](#) or an [API key](#). You can refer to the documentation for more information on [supported authenticating approaches](#) with the search service.

Get an API Key

An API key can be an easier approach to start with because it doesn't require pre-existing role assignments.

You can get the [endpoint](#) and an [API key](#) from the search service in the [Azure portal](#). Please refer the [documentation](#) for instructions on how to get an API key.

Alternatively, you can use the following [Azure CLI](#) command to retrieve the API key from the search service:

Powershell

```
az search admin-key show --service-name <mysearch> --resource-group <mysearch-rg>
```

There are two types of keys used to access your search service: **admin** (*read-write*) and **query** (*read-only*) keys. Restricting access and operations in client apps is essential to safeguarding the search assets on your service. Always use a query key rather than an admin key for any query originating from a client app.

Note: The example Azure CLI snippet above retrieves an admin key so it's easier to get started exploring APIs, but it should be managed carefully.

Create a SearchClient

To instantiate the `SearchClient`, you'll need the **endpoint**, **API key** and **index name**:

C#

```
string indexName = "nycjobs";

// Get the service endpoint and API key from the environment
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
string key = Environment.GetEnvironmentVariable("SEARCH_API_KEY");

// Create a client
AzureKeyCredential credential = new AzureKeyCredential(key);
SearchClient client = new SearchClient(endpoint, indexName, credential);
```

Create a client using Microsoft Entra ID authentication

You can also create a `SearchClient`, `SearchIndexClient`, or `SearchIndexerClient` using Microsoft Entra ID authentication. Your user or service principal must be assigned the "Search Index Data Reader" role. Using the [DefaultAzureCredential](#) you can authenticate a service using Managed Identity or a service principal, authenticate as a developer working on an application, and more all without changing code. Please refer the [documentation](#) for instructions on how to connect to Azure AI Search using Azure role-based access control (Azure RBAC).

Before you can use the `DefaultAzureCredential`, or any credential type from [Azure.Identity](#), you'll first need to [install the Azure.Identity package](#).

To use `DefaultAzureCredential` with a client ID and secret, you'll need to set the `AZURE_TENANT_ID`, `AZURE_CLIENT_ID`, and `AZURE_CLIENT_SECRET` environment variables; alternatively, you can pass those values to the `ClientSecretCredential` also in `Azure.Identity`.

Make sure you use the right namespace for `DefaultAzureCredential` at the top of your source file:

C#

```
using Azure.Identity;
```

Then you can create an instance of `DefaultAzureCredential` and pass it to a new instance of your client:

C#

```
string indexName = "nycjobs";

// Get the service endpoint from the environment
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
DefaultAzureCredential credential = new DefaultAzureCredential();

// Create a client
SearchClient client = new SearchClient(endpoint, indexName, credential);
```

ASP.NET Core

To inject `SearchClient` as a dependency in an ASP.NET Core app, first install the package `Microsoft.Extensions.Azure`. Then register the client in the `Startup.ConfigureServices` method:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddAzureClients(builder =>
    {
        builder.AddSearchClient(Configuration.GetSection("SearchClient"));
    });

    services.AddControllers();
}
```

To use the preceding code, add this to your configuration:

JSON

```
{
  "SearchClient": {
    "endpoint": "https://<resource-name>.search.windows.net",
    "indexname": "nycjobs"
  }
}
```

You'll also need to provide your resource key to authenticate the client, but you shouldn't be putting that information in the configuration. Instead, when in development, use [User-Secrets](#). Add the following to `secrets.json`:

JSON

```
{  
  "SearchClient": {  
    "credential": { "key": "<you resource key>" }  
  }  
}
```

When running in production, it's preferable to use [environment variables](#):

```
SEARCH__CREDENTIAL__KEY="..."
```

Or use other secure ways of storing secrets like [Azure Key Vault](#).

For more details about Dependency Injection in ASP.NET Core apps, see [Dependency injection with the Azure SDK for .NET](#).

Key concepts

An Azure AI Search service contains one or more indexes that provide persistent storage of searchable data in the form of JSON documents. (*If you're brand new to search, you can make a very rough analogy between indexes and database tables.*) The `Azure.Search.Documents` client library exposes operations on these resources through three main client types.

- `SearchClient` helps with:
 - [Searching](#) your indexed documents using [vector queries](#), [keyword queries](#) and [hybrid queries](#)
 - [Vector query filters](#) and [Text query filters](#)
 - [Semantic ranking](#) and [scoring profiles](#) for boosting relevance
 - [Autocompleting](#) partially typed search terms based on documents in the index
 - [Suggesting](#) the most likely matching text in documents as a user types
 - [Adding, Updating or Deleting Documents](#) documents from an index
- `SearchIndexClient` allows you to:
 - [Create, delete, update, or configure a search index](#)
 - [Declare custom synonym maps to expand or rewrite queries](#)
- `SearchIndexerClient` allows you to:

- Create indexers to automatically crawl data sources
- Define AI powered Skillsets to transform and enrich your data

Azure AI Search provides two powerful features:

Semantic ranking

Semantic ranking enhances the quality of search results for text-based queries. By enabling semantic ranking on your search service, you can improve the relevance of search results in two ways:

- It applies secondary ranking to the initial result set, promoting the most semantically relevant results to the top.
- It extracts and returns captions and answers in the response, which can be displayed on a search page to enhance the user's search experience.

To learn more about semantic ranking, you can refer to the [sample ↗](#).

Additionally, for more comprehensive information about semantic ranking, including its concepts and usage, you can refer to the [documentation](#). The documentation provides in-depth explanations and guidance on leveraging the power of semantic ranking in Azure AI Search.

Vector search

Vector search is an information retrieval technique that uses numeric representations of searchable documents and query strings. By searching for numeric representations of content that are most similar to the numeric query, vector search can find relevant matches, even if the exact terms of the query are not present in the index. Moreover, vector search can be applied to various types of content, including images and videos and translated text, not just same-language text.

To learn how to index vector fields and perform vector search, you can refer to the [sample ↗](#). This sample provides detailed guidance on indexing vector fields and demonstrates how to perform vector search.

Additionally, for more comprehensive information about vector search, including its concepts and usage, you can refer to the [documentation](#). The documentation provides in-depth explanations and guidance on leveraging the power of vector search in Azure AI Search.

The `Azure.Search.Documents` client library (v11) provides APIs for data plane operations. The previous `Microsoft.Azure.Search` client library (v10) is now retired. It has many similar looking APIs, so please be careful to avoid confusion when exploring online resources. A good rule of

thumb is to check for the namespace `using Azure.Search.Documents`; when you're looking for API reference.

Thread safety

We guarantee that all client instance methods are thread-safe and independent of each other ([guideline ↗](#)). This ensures that the recommendation of reusing client instances is always safe, even across threads.

Additional concepts

[Client options ↗](#) | [Accessing the response ↗](#) | [Long-running operations ↗](#) | [Handling failures ↗](#) | [Diagnostics ↗](#) | [Mocking](#) | [Client lifetime ↗](#)

Examples

The following examples all use a simple [Hotel data set ↗](#) that you can [import into your own index from the Azure portal](#). These are just a few of the basics - please [check out our Samples ↗](#) for much more.

- [Querying](#)
 - [Use C# types for search results](#)
 - [Use SearchDocument like a dictionary for search results](#)
 - [SearchOptions](#)
- [Creating an index](#)
- [Adding documents to your index](#)
- [Retrieving a specific document from your index](#)
- [Async APIs](#)

Advanced authentication

- [Create a client that can authenticate in a national cloud](#)

Querying

Let's start by importing our namespaces.

C#

```
using Azure.Search.Documents;
using Azure.Search.Documents.Indexes;
```

```
using Azure.Core.GeoJson;
```

We'll then create a `SearchClient` to access our hotels search index.

C#

```
// Get the service endpoint and API key from the environment
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
string key = Environment.GetEnvironmentVariable("SEARCH_API_KEY");
string indexName = "hotels";

// Create a client
AzureKeyCredential credential = new AzureKeyCredential(key);
SearchClient client = new SearchClient(endpoint, indexName, credential);
```

There are two ways to interact with the data returned from a search query. Let's explore them with a search for a "luxury" hotel.

Use C# types for search results

We can decorate our own C# types with [attributes from System.Text.Json](#):

C#

```
public class Hotel
{
    [JsonPropertyName("HotelId")]
    [SimpleField(IsKey = true, IsFilterable = true, IsSortable = true)]
    public string Id { get; set; }

    [JsonPropertyName("HotelName")]
    [SearchableField(IsFilterable = true, IsSortable = true)]
    public string Name { get; set; }

    [SimpleField(IsFilterable = true, IsSortable = true)]
    public GeoPoint GeoLocation { get; set; }

    // Complex fields are included automatically in an index if not ignored.
    public HotelAddress Address { get; set; }
}

public class HotelAddress
{
    public string StreetAddress { get; set; }

    [SimpleField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
    public string City { get; set; }

    [SimpleField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
    public string StateProvince { get; set; }
```

```
[SimpleField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
public string Country { get; set; }

[SimpleField(IsFilterable = true, IsSortable = true, IsFacetable = true)]
public string PostalCode { get; set; }
}
```

Then we use them as the type parameter when querying to return strongly-typed search results:

C#

```
SearchResults<Hotel> response = client.Search<Hotel>("luxury");
foreach (SearchResult<Hotel> result in response.GetResults())
{
    Hotel doc = result.Document;
    Console.WriteLine($"{doc.Id}: {doc.Name}");
}
```

If you're working with a search index and know the schema, creating C# types is recommended.

Use `SearchDocument` like a dictionary for search results

If you don't have your own type for search results, `SearchDocument` can be used instead. Here we perform the search, enumerate over the results, and extract data using `SearchDocument`'s dictionary indexer.

C#

```
SearchResults<SearchDocument> response = client.Search<SearchDocument>("luxury");
foreach (SearchResult<SearchDocument> result in response.GetResults())
{
    SearchDocument doc = result.Document;
    string id = (string)doc["HotelId"];
    string name = (string)doc["HotelName"];
    Console.WriteLine($"{id}: {name}");
}
```

SearchOptions

The `SearchOptions` provide powerful control over the behavior of our queries. Let's search for the top 5 luxury hotels with a good rating.

C#

```
int stars = 4;
SearchOptions options = new SearchOptions
{
    // Filter to only Rating greater than or equal our preference
    Filter = SearchFilter.Create($"Rating ge {stars}"),
    Size = 5, // Take only 5 results
    OrderBy = { "Rating desc" } // Sort by Rating from high to low
};
SearchResults<Hotel> response = client.Search<Hotel>("luxury", options);
// ...
```

Creating an index

You can use the `SearchIndexClient` to create a search index. Fields can be defined from a model class using `FieldBuilder`. Indexes can also define suggesters, lexical analyzers, and more.

Using the [Hotel sample](#) above, which defines both simple and complex fields:

C#

```
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
string key = Environment.GetEnvironmentVariable("SEARCH_API_KEY");

// Create a service client
AzureKeyCredential credential = new AzureKeyCredential(key);
SearchIndexClient client = new SearchIndexClient(endpoint, credential);

// Create the index using FieldBuilder.
SearchIndex index = new SearchIndex("hotels")
{
    Fields = new FieldBuilder().Build(typeof(Hotel)),
    Suggesters =
    {
        // Suggest query terms from the HotelName field.
        new SearchSuggester("sg", "HotelName")
    }
};

client.CreateIndex(index);
```

In scenarios when the model is not known or cannot be modified, you can also create fields explicitly using convenient `SimpleField`, `SearchableField`, or `ComplexField` classes:

C#

```
// Create the index using field definitions.
SearchIndex index = new SearchIndex("hotels")
{
```

```

Fields =
{
    new SimpleField("HotelId", SearchFieldDataType.String) { IsKey = true,
IsFilterable = true, IsSortable = true },
    new SearchableField("HotelName") { IsFilterable = true, IsSortable = true },
    new SearchableField("Description") { AnalyzerName =
LexicalAnalyzerName.EnLucene },
    new SearchableField("Tags", collection: true) { IsFilterable = true,
IsFacetable = true },
    new ComplexField("Address")
{
    Fields =
{
        new SearchableField("StreetAddress"),
        new SearchableField("City") { IsFilterable = true, IsSortable =
true, IsFacetable = true },
        new SearchableField("StateProvince") { IsFilterable = true,
IsSortable = true, IsFacetable = true },
        new SearchableField("Country") { IsFilterable = true, IsSortable =
true, IsFacetable = true },
        new SearchableField("PostalCode") { IsFilterable = true, IsSortable =
true, IsFacetable = true }
    }
},
Suggesters =
{
    // Suggest query terms from the hotelName field.
    new SearchSuggester("sg", "HotelName")
}
};

client.CreateIndex(index);

```

Adding documents to your index

You can `Upload`, `Merge`, `MergeOrUpload`, and `Delete` multiple documents from an index in a single batched request. There are [a few special rules for merging](#) to be aware of.

C#

```

IndexDocumentsBatch<Hotel> batch = IndexDocumentsBatch.Create(
    IndexDocumentsAction.Upload(new Hotel { Id = "783", Name = "Upload Inn" }),
    IndexDocumentsAction.Merge(new Hotel { Id = "12", Name = "Renovated Ranch" }));

IndexDocumentsOptions options = new IndexDocumentsOptions { ThrowOnAnyError = true
};
client.IndexDocuments(batch, options);

```

The request will succeed even if any of the individual actions fail and return an `IndexDocumentsResult` for inspection. There's also a `ThrowOnAnyError` option if you only care

about success or failure of the whole batch.

Retrieving a specific document from your index

In addition to querying for documents using keywords and optional filters, you can retrieve a specific document from your index if you already know the key. You could get the key from a query, for example, and want to show more information about it or navigate your customer to that document.

```
C#
```

```
Hotel doc = client.GetDocument<Hotel>("1");
Console.WriteLine($"{doc.Id}: {doc.Name}");
```

Async APIs

All of the examples so far have been using synchronous APIs, but we provide full support for async APIs as well. You'll generally just add an `Async` suffix to the name of the method and `await` it.

```
C#
```

```
SearchResults<Hotel> searchResponse = await client.SearchAsync<Hotel>("luxury");
await foreach (SearchResult<Hotel> result in searchResponse.GetResultsAsync())
{
    Hotel doc = result.Document;
    Console.WriteLine($"{doc.Id}: {doc.Name}");
}
```

Authenticate in a National Cloud

To authenticate in a [National Cloud](#), you will need to make the following additions to your client configuration:

- Set the `AuthorityHost` in the credential options or via the `AZURE_AUTHORITY_HOST` environment variable
- Set the `Audience` in `SearchClientOptions`

```
C#
```

```
// Create a SearchClient that will authenticate through AAD in the China national
cloud
string indexName = "nycjobs";
Uri endpoint = new Uri(Environment.GetEnvironmentVariable("SEARCH_ENDPOINT"));
```

```
SearchClient client = new SearchClient(endpoint, indexName,
    new DefaultAzureCredential(
        new DefaultAzureCredentialOptions()
    {
        AuthorityHost = AzureAuthorityHosts.AzureChina
    }),
    new SearchClientOptions()
{
    Audience = SearchAudience.AzureChina
});
```

Troubleshooting

Any `Azure.Search.Documents` operation that fails will throw a [RequestFailedException](#) with helpful [Status codes](#). Many of these errors are recoverable.

C#

```
try
{
    return client.GetDocument<Hotel>("12345");
}
catch (RequestFailedException ex) when (ex.Status == 404)
{
    Console.WriteLine("We couldn't find the hotel you are looking for!");
    Console.WriteLine("Please try selecting another.");
    return null;
}
```

You can also easily [enable console logging](#) if you want to dig deeper into the requests you're making against the service.

See our [troubleshooting guide](#) for details on how to diagnose various failure scenarios.

Next steps

- Go further with `Azure.Search.Documents` and our [samples](#)
- Read more about the [Azure AI Search service](#)

Contributing

See our [Search CONTRIBUTING.md](#) for details on building, testing, and contributing to this library.

This project welcomes contributions and suggestions. Most contributions require you to agree to a Contributor License Agreement (CLA) declaring that you have the right to, and actually do, grant us the rights to use your contribution. For details, visit cla.microsoft.com.

Microsoft Azure AI Search management client library for .NET

07/29/2025

Azure AI Search (formerly known as "Azure Cognitive Search") is an AI-powered information retrieval platform that helps developers build rich search experiences and generative AI apps that combine large language models with enterprise data.

This library supports managing Microsoft Azure AI Search resources. Use this library to create, configure, and manage your search resources.

This library follows the [new Azure SDK guidelines](#), and provides many core capabilities:

- Support MSAL.NET, Azure.Identity is out of box for supporting MSAL.NET.
- Support [OpenTelemetry](<https://opentelemetry.io/>) for distributed tracing.
- HTTP pipeline with custom policies.
- Better error-handling.
- Support uniform telemetry across all languages.

Getting started

Install the package

Install the Microsoft Azure AI Search management library for .NET with [NuGet](#):

.NET CLI

```
dotnet add package Azure.ResourceManager.Search
```

Prerequisites

- You must have an [Microsoft Azure subscription](#).

Authenticate the Client

To create an authenticated client and start interacting with Microsoft Azure resources, see the [quickstart guide here](#).

Key concepts

Key concepts of the Microsoft Azure SDK for .NET can be found [here](#).

Documentation

Documentation is available to help you learn how to use this package:

- [Quickstart](#).
- [API References](#).
- [Authentication](#).

Examples

Code samples for using the management library for .NET can be found in the following locations

- [.NET Management Library Code Samples](#)

Troubleshooting

- File an issue via [GitHub Issues](#).
- Check [previous questions](#) or ask new ones on Stack Overflow using Azure and .NET tags.

Next steps

For more information about Microsoft Azure SDK, see [this website](#).

Contributing

For details on contributing to this repository, see the [contributing guide](#).

This project welcomes contributions and suggestions. Most contributions require you to agree to a Contributor License Agreement (CLA) declaring that you have the right to, and actually do, grant us the rights to use your contribution. For details, visit <https://cla.microsoft.com>.

When you submit a pull request, a CLA-bot will automatically determine whether you need to provide a CLA and decorate the PR appropriately (for example, label, comment). Follow the

instructions provided by the bot. You'll only need to do this action once across all repositories using our CLA.

This project has adopted the [Microsoft Open Source Code of Conduct](#). For more information, see the [Code of Conduct FAQ](#) or contact opencode@microsoft.com with any other questions or comments.

Azure AI Search client library for Java - version 11.8.0

This is the Java client library for [Azure AI Search](#) (formerly known as "Azure Cognitive Search"). Azure AI Search service is an AI-powered information retrieval platform that helps developers build rich search experiences and generative AI apps that combine large language models with enterprise data.

Azure AI Search is well suited for the following application scenarios:

- Consolidate varied content types into a single searchable index. To populate an index, you can push JSON documents that contain your content, or if your data is already in Azure, create an indexer to pull in data automatically.
- Attach skillsets to an indexer to create searchable content from images and unstructured documents. A skillset leverages APIs from Azure AI Services for built-in OCR, entity recognition, key phrase extraction, language detection, text translation, and sentiment analysis. You can also add custom skills to integrate external processing of your content during data ingestion.
- In a search client application, implement query logic and user experiences similar to commercial web search engines and chat-style apps.

Use the Azure AI Search client library to:

- Submit queries using vector, keyword, and hybrid query forms.
- Implement filtered queries for metadata, geospatial search, faceted navigation, or to narrow results based on filter criteria.
- Create and manage search indexes.
- Upload and update documents in the search index.
- Create and manage indexers that pull data from Azure into an index.
- Create and manage skillsets that add AI enrichment to data ingestion.
- Create and manage analyzers for advanced text analysis or multi-lingual content.
- Optimize results through semantic ranking and scoring profiles to factor in business logic or freshness.

[Source code ↗](#) | [Package \(Maven\) ↗](#) | [API reference documentation ↗](#) | [Product documentation](#) | [Samples ↗](#)

Getting started

Include the package

Include the BOM file

Please include the azure-sdk-bom to your project to take dependency on the General Availability (GA) version of the library. In the following snippet, replace the {bom_version_to_target} placeholder with the version number. To learn more about the BOM, see the [AZURE SDK BOM README](#).

XML

```
<dependencyManagement>
  <dependencies>
    <dependency>
      <groupId>com.azure</groupId>
      <artifactId>azure-sdk-bom</artifactId>
      <version>{bom_version_to_target}</version>
      <type>pom</type>
      <scope>import</scope>
    </dependency>
  </dependencies>
</dependencyManagement>
```

and then include the direct dependency in the dependencies section without the version tag.

XML

```
<dependencies>
  <dependency>
    <groupId>com.azure</groupId>
    <artifactId>azure-search-documents</artifactId>
  </dependency>
</dependencies>
```

Include direct dependency

If you want to take dependency on a particular version of the library that is not present in the BOM, add the direct dependency to your project as follows.

XML

```
<dependency>
  <groupId>com.azure</groupId>
  <artifactId>azure-search-documents</artifactId>
  <version>11.8.0</version>
</dependency>
```

Prerequisites

- Java Development Kit (JDK) with version 8 or above
 - Here are details about Java 8 client compatibility with Azure Certificate Authority.
- Azure subscription ↗
- Azure AI Search service ↗
- To create a new search service, you can use the [Azure portal](#), [Azure PowerShell](#), or the [Azure CLI](#). Here's an example using the Azure CLI to create a free instance for getting started:

Bash

```
az search service create --name <mysearch> --resource-group <mysearch-rg> --sku free  
--location westus
```

See [choosing a pricing tier](#) for more information about available options.

Authenticate the client

To interact with the Search service, you'll need to create an instance of the appropriate client class: `SearchClient` for searching indexed documents, `SearchIndexClient` for managing indexes, or `SearchIndexerClient` for crawling data sources and loading search documents into an index. To instantiate a client object, you'll need an [endpoint](#) and [Azure roles](#) or an [API key](#). You can refer to the documentation for more information on [supported authenticating approaches](#) with the Search service.

Get an API Key

An API key can be an easier approach to start with because it doesn't require pre-existing role assignments.

You can get the [endpoint](#) and an [API key](#) from the search service in the [Azure Portal](#) ↗. Please refer the [documentation](#) for instructions on how to get an API key.

Alternatively, you can use the following [Azure CLI](#) command to retrieve the API key from the search service:

Bash

```
az search admin-key show --service-name <mysearch> --resource-group <mysearch-rg>
```

Note:

- The example Azure CLI snippet above retrieves an admin key. This allows for easier access when exploring APIs, but it should be managed carefully.

- There are two types of keys used to access your search service: **admin** (*read-write*) and **query** (*read-only*) keys. Restricting access and operations in client apps is essential to safeguarding the search assets on your service. Always use a query key rather than an admin key for any query originating from a client app.

The SDK provides three clients.

- `SearchIndexClient` for CRUD operations on indexes and synonym maps.
- `SearchIndexerClient` for CRUD operations on indexers, data sources, and skillsets.
- `SearchClient` for all document operations.

Create a SearchIndexClient

To create a `SearchIndexClient/SearchIndexAsyncClient`, you will need the values of the Azure AI Search service URL endpoint and admin key.

Java

```
SearchIndexClient searchIndexClient = new SearchIndexClientBuilder()  
    .endpoint(ENDPOINT)  
    .credential(new AzureKeyCredential(API_KEY))  
    .buildClient();
```

or

Java

```
SearchIndexAsyncClient searchIndexAsyncClient = new SearchIndexClientBuilder()  
    .endpoint(ENDPOINT)  
    .credential(new AzureKeyCredential(API_KEY))  
    .buildAsyncClient();
```

Create a SearchIndexerClient

To create a `SearchIndexerClient/SearchIndexerAsyncClient`, you will need the values of the Azure AI Search service URL endpoint and admin key.

Java

```
SearchIndexerClient searchIndexerClient = new SearchIndexerClientBuilder()  
    .endpoint(ENDPOINT)  
    .credential(new AzureKeyCredential(API_KEY))  
    .buildClient();
```

or

Java

```
SearchIndexerAsyncClient searchIndexerAsyncClient = new SearchIndexerClientBuilder()
    .endpoint(ENDPOINT)
    .credential(new AzureKeyCredential(API_KEY))
    .buildAsyncClient();
```

Create a SearchClient

Once you have the values of the Azure AI Search service URL endpoint and admin key, you can create the `SearchClient/SearchAsyncClient` with an existing index name:

Java

```
SearchClient searchClient = new SearchClientBuilder()
    .endpoint(ENDPOINT)
    .credential(new AzureKeyCredential(ADMIN_KEY))
    .indexName(INDEX_NAME)
    .buildClient();
```

or

Java

```
SearchAsyncClient searchAsyncClient = new SearchClientBuilder()
    .endpoint(ENDPOINT)
    .credential(new AzureKeyCredential(ADMIN_KEY))
    .indexName(INDEX_NAME)
    .buildAsyncClient();
```

Create a client using Microsoft Entra ID authentication

You can also create a `SearchClient`, `SearchIndexClient`, or `SearchIndexerClient` using Microsoft Entra ID authentication. Your user or service principal must be assigned the "Search Index Data Reader" role. Using the [DefaultAzureCredential](#) you can authenticate a service using Managed Identity or a service principal, authenticate as a developer working on an application, and more all without changing code. Please refer the [documentation](#) for instructions on how to connect to Azure AI Search using Azure role-based access control (Azure RBAC).

Before you can use the `DefaultAzureCredential`, or any credential type from [Azure.Identity](#), you'll first need to [install the Azure.Identity package](#).

To use `DefaultAzureCredential` with a client ID and secret, you'll need to set the `AZURE_TENANT_ID`, `AZURE_CLIENT_ID`, and `AZURE_CLIENT_SECRET` environment variables;

alternatively, you can pass those values to the `ClientSecretCredential` also in `azure-identity`.

Make sure you use the right namespace for `DefaultAzureCredential` at the top of your source file:

Java

```
import com.azure.identity.DefaultAzureCredential;
import com.azure.identity.DefaultAzureCredentialBuilder;
```

Then you can create an instance of `DefaultAzureCredential` and pass it to a new instance of your client:

Java

```
String indexName = "nycjobs";

// Get the service endpoint from the environment
String endpoint = Configuration.getGlobalConfiguration().get("SEARCH_ENDPOINT");
DefaultAzureCredential credential = new DefaultAzureCredentialBuilder().build();

// Create a client
SearchClient client = new SearchClientBuilder()
    .endpoint(endpoint)
    .indexName(indexName)
    .credential(credential)
    .buildClient();
```

Send your first search query

To get running with Azure AI Search first create an index following this [guide](#). With an index created you can use the following samples to begin using the SDK.

Key concepts

An Azure AI Search service contains one or more indexes that provide persistent storage of searchable data in the form of JSON documents. (*If you're new to search, you can make a very rough analogy between indexes and database tables.*) The `azure-search-documents` client library exposes operations on these resources through two main client types.

- `SearchClient` helps with:
 - [Searching](#) your indexed documents using [vector queries](#), [keyword queries](#) and [hybrid queries](#)
 - [Vector query filters](#) and [Text query filters](#)
 - [Semantic ranking](#) and [scoring profiles](#) for boosting relevance

- Autocompleting partially typed search terms based on documents in the index
- Suggesting the most likely matching text in documents as a user types
- Adding, Updating or Deleting Documents documents from an index
- `SearchIndexClient` allows you to:
 - Create, delete, update, or configure a search index
 - Declare custom synonym maps to expand or rewrite queries
- `SearchIndexerClient` allows you to:
 - Start indexers to automatically crawl data sources
 - Define AI powered Skillsets to transform and enrich your data

Azure AI Search provides two powerful features:

Semantic ranking

Semantic ranking enhances the quality of search results for text-based queries. By enabling semantic ranking on your search service, you can improve the relevance of search results in two ways:

- It applies secondary ranking to the initial result set, promoting the most semantically relevant results to the top.
- It extracts and returns captions and answers in the response, which can be displayed on a search page to enhance the user's search experience.

To learn more about semantic ranking, you can refer to the [documentation](#).

Vector Search

Vector search is an information retrieval technique that uses numeric representations of searchable documents and query strings. By searching for numeric representations of content that are most similar to the numeric query, vector search can find relevant matches, even if the exact terms of the query are not present in the index. Moreover, vector search can be applied to various types of content, including images and videos and translated text, not just same-language text.

To learn how to index vector fields and perform vector search, you can refer to the [sample ↗](#). This sample provides detailed guidance on indexing vector fields and demonstrates how to perform vector search.

Additionally, for more comprehensive information about vector search, including its concepts and usage, you can refer to the [documentation](#). The documentation provides in-depth explanations and guidance on leveraging the power of vector search in Azure AI Search.

Examples

The following examples all use a simple [Hotel data set](#) that you can import into your own index from the [Azure portal](#). These are just a few of the basics - please check out our [Samples](#) for much more.

- [Querying](#)
 - Use `SearchDocument` like a dictionary for search results
 - Use Java model for search results
 - Search Options
- [Creating an index](#)
- [Adding documents to your index](#)
- [Retrieving a specific document from your index](#)
- [Async APIs](#)
- [Create a client that can authenticate in a national cloud](#)

Querying

There are two ways to interact with the data returned from a search query.

Let's explore them with a search for a "luxury" hotel.

Use `SearchDocument` like a dictionary for search results

`SearchDocument` is the default type returned from queries when you don't provide your own. Here we perform the search, enumerate over the results, and extract data using `SearchDocument`'s dictionary indexer.

Java

```
for (SearchResult searchResult : SEARCH_CLIENT.search("luxury")) {  
    SearchDocument doc = searchResult.getDocument(SearchDocument.class);  
    String id = (String) doc.get("hotelId");  
    String name = (String) doc.get("hotelName");  
    System.out.printf("This is hotelId %s, and this is hotel name %s.%n", id, name);  
}
```

Use Java model class for search results

Define a `Hotel` class.

Java

```
public static class Hotel {
    @SimpleField(isKey = true, isFilterable = true, isSortable = true)
    private String id;
    @SearchableField(isFilterable = true, isSortable = true)
    private String name;

    public String getId() {
        return id;
    }

    public Hotel setId(String id) {
        this.id = id;
        return this;
    }

    public String getName() {
        return name;
    }

    public Hotel setName(String name) {
        this.name = name;
        return this;
    }
}
```

Use it in place of `SearchDocument` when querying.

Java

```
for (SearchResult searchResult : SEARCH_CLIENT.search("luxury")) {
    Hotel doc = searchResult.getDocument(Hotel.class);
    String id = doc.getId();
    String name = doc.getName();
    System.out.printf("This is hotelId %s, and this is hotel name %s.%n", id, name);
}
```

It is recommended, when you know the schema of the search index, to create a Java model class.

Search Options

The `SearchOptions` provide powerful control over the behavior of our queries.

Let's search for the top 5 luxury hotels with a good rating.

Java

```
SearchOptions options = new SearchOptions()
    .setFilter("rating ge 4")
    .setOrderBy("rating desc")
```

```
.setTop(5);
SearchPagedIterable searchResultsIterable = SEARCH_CLIENT.search("luxury", options,
Context.NONE);
// ...
```

Creating an index

You can use the [SearchIndexClient](#) to create a search index. Indexes can also define suggesters, lexical analyzers, and more.

There are multiple ways of preparing search fields for a search index. For basic needs, we provide a static helper method `buildSearchFields` in `SearchIndexClient` and `SearchIndexAsyncClient`, which can convert Java POJO class into `List<SearchField>`. There are three annotations `SimpleFieldProperty`, `SearchFieldProperty` and `FieldBuilderIgnore` to configure the field of model class.

Java

```
List<SearchField> searchFields = SearchIndexClient.buildSearchFields(Hotel.class,
null);
SEARCH_INDEX_CLIENT.createIndex(new SearchIndex("index", searchFields));
```

For advanced scenarios, we can build search fields using `SearchField` directly.

Java

```
List<SearchField> searchFieldList = new ArrayList<>();
searchFieldList.add(new SearchField("hotelId", SearchFieldDataType.STRING)
    .setKey(true)
    .setFilterable(true)
    .setSortable(true));

searchFieldList.add(new SearchField("hotelName", SearchFieldDataType.STRING)
    .setSearchable(true)
    .setFilterable(true)
    .setSortable(true));
searchFieldList.add(new SearchField("description", SearchFieldDataType.STRING)
    .setSearchable(true)
    .setAnalyzerName(LexicalAnalyzerName.EU_LUCENE));
searchFieldList.add(new SearchField("tags",
    SearchFieldDataType.collection(SearchFieldDataType.STRING))
    .setSearchable(true)
    .setFilterable(true)
    .setFacetable(true));
searchFieldList.add(new SearchField("address", SearchFieldDataType.COMPLEX)
    .setFields(new SearchField("streetAddress",
        SearchFieldDataType.STRING).setSearchable(true),
        new SearchField("city", SearchFieldDataType.STRING)
        .setSearchable(true))
```

```

.setFilterable(true)
.setFacetable(true)
.setSortable(true),
new SearchField("stateProvince", SearchFieldType.STRING)
.setSearchable(true)
.setFilterable(true)
.setFacetable(true)
.setSortable(true),
new SearchField("country", SearchFieldType.STRING)
.setSearchable(true)
.setFilterable(true)
.setFacetable(true)
.setSortable(true),
new SearchField("postalCode", SearchFieldType.STRING)
.setSearchable(true)
.setFilterable(true)
.setFacetable(true)
.setSortable(true)
));
// Prepare suggester.
SearchSuggester suggester = new SearchSuggester("sg",
Collections.singletonList("hotelName"));
// Prepare SearchIndex with index name and search fields.
SearchIndex index = new
SearchIndex("hotels").setFields(searchFieldList).setSuggesters(suggester);
// Create an index
SEARCH_INDEX_CLIENT.createIndex(index);

```

Retrieving a specific document from your index

In addition to querying for documents using keywords and optional filters, you can retrieve a specific document from your index if you already know the key. You could get the key from a query, for example, and want to show more information about it or navigate your customer to that document.

Java

```

Hotel hotel = SEARCH_CLIENT.getDocument("1", Hotel.class);
System.out.printf("This is hotelId %s, and this is hotel name %s.%n", hotel.getId(),
hotel.getName());

```

Adding documents to your index

You can `Upload`, `Merge`, `MergeOrUpload`, and `Delete` multiple documents from an index in a single batched request. There are [a few special rules for merging](#) to be aware of.

Java

```
IndexDocumentsBatch<Hotel> batch = new IndexDocumentsBatch<>();
batch.addUploadActions(Collections.singletonList(new
Hotel().setId("783").setName("Upload Inn")));
batch.addMergeActions(Collections.singletonList(new
Hotel().setId("12").setName("Renovated Ranch")));
SEARCH_CLIENT.indexDocuments(batch);
```

The request will throw `IndexBatchException` by default if any of the individual actions fail, and you can use `findFailedActionsToRetry` to retry on failed documents. There's also a `throwOnAnyError` option, and you can set it to `false` to get a successful response with an `IndexDocumentsResult` for inspection.

Async APIs

The examples so far have been using synchronous APIs, but we provide full support for async APIs as well. You'll need to use [SearchAsyncClient](#).

Java

```
SEARCH_ASYNC_CLIENT.search("luxury")
    .subscribe(result -> {
        Hotel hotel = result.getDocument(Hotel.class);
        System.out.printf("This is hotelId %s, and this is hotel name %s.%n",
            hotel.getId(), hotel.getName());
    });
}
```

Authenticate in a National Cloud

To authenticate in a [National Cloud](#), you will need to make the following additions to your client configuration:

- Set the `AuthorityHost` in the credential options or via the `AZURE_AUTHORITY_HOST` environment variable
- Set the `audience` in `SearchClientBuilder`, `SearchIndexClientBuilder`, or `SearchIndexerClientBuilder`

Java

```
// Create a SearchClient that will authenticate through AAD in the China national
cloud.
SearchClient searchClient = new SearchClientBuilder()
    .endpoint(ENDPOINT)
    .indexName(INDEX_NAME)
    .credential(new DefaultAzureCredentialBuilder()
        .authorityHost(AzureAuthorityHosts.AZURE_CHINA)
```

```
.build()
. audience(SearchAudience.AZURE_CHINA)
.buildClient();
```

Troubleshooting

See our [troubleshooting guide](#) for details on how to diagnose various failure scenarios.

General

When you interact with Azure AI Search using this Java client library, errors returned by the service correspond to the same HTTP status codes returned for [REST API](#) requests. For example, the service will return a `404` error if you try to retrieve a document that doesn't exist in your index.

Handling Search Error Response

Any Search API operation that fails will throw an [HttpResponseException](#) with helpful [Status codes](#). Many of these errors are recoverable.

Java

```
try {
    Iterable<SearchResult> results = SEARCH_CLIENT.search("hotel");
} catch (HttpResponseException ex) {
    // The exception contains the HTTP status code and the detailed message
    // returned from the search service
    HttpResponse response = ex.getResponse();
    System.out.println("Status Code: " + response.getStatusCode());
    System.out.println("Message: " + ex.getMessage());
}
```

You can also easily [enable console logging](#) if you want to dig deeper into the requests you're making against the service.

Enabling Logging

Azure SDKs for Java provide a consistent logging story to help aid in troubleshooting application errors and expedite their resolution. The logs produced will capture the flow of an application before reaching the terminal state to help locate the root issue. View the [logging](#) wiki for guidance about enabling logging.

Default HTTP Client

By default, a Netty based HTTP client will be used. The [HTTP clients wiki](#) provides more information on configuring or changing the HTTP client.

Next steps

- Samples are explained in detail [here](#).
- Read more about the [Azure AI Search service](#)

Contributing

This project welcomes contributions and suggestions. Most contributions require you to agree to a [Contributor License Agreement \(CLA\)](#) declaring that you have the right to, and actually do, grant us the rights to use your contribution.

When you submit a pull request, a CLA-bot will automatically determine whether you need to provide a CLA and decorate the PR appropriately (e.g., label, comment). Simply follow the instructions provided by the bot. You will only need to do this once across all repos using our CLA.

This project has adopted the [Microsoft Open Source Code of Conduct](#). For more information see the [Code of Conduct FAQ](#) or contact opencode@microsoft.com with any additional questions or comments.

Azure AI Search client library for JavaScript - version 12.2.0

[Azure AI Search](#) (formerly known as "Azure Cognitive Search") is an AI-powered information retrieval platform that helps developers build rich search experiences and generative AI apps that combine large language models with enterprise data.

The Azure AI Search service is well suited for the following application scenarios:

- Consolidate varied content types into a single searchable index. To populate an index, you can push JSON documents that contain your content, or if your data is already in Azure, create an indexer to pull in data automatically.
- Attach skillsets to an indexer to create searchable content from images and unstructured documents. A skillset leverages APIs from Azure AI Services for built-in OCR, entity recognition, key phrase extraction, language detection, text translation, and sentiment analysis. You can also add custom skills to integrate external processing of your content during data ingestion.
- In a search client application, implement query logic and user experiences similar to commercial web search engines and chat-style apps.

Use the `@azure/search-documents` client library to:

- Submit queries using vector, keyword, and hybrid query forms.
- Implement filtered queries for metadata, geospatial search, faceted navigation, or to narrow results based on filter criteria.
- Create and manage search indexes.
- Upload and update documents in the search index.
- Create and manage indexers that pull data from Azure into an index.
- Create and manage skillsets that add AI enrichment to data ingestion.
- Create and manage analyzers for advanced text analysis or multi-lingual content.
- Optimize results through semantic ranking and scoring profiles to factor in business logic or freshness.

- [API reference documentation](#)
- [REST API documentation](#)
- [Product documentation](#)
- [Samples ↗](#)

Getting started

Install the `@azure/search-documents` package

Bash

```
npm install @azure/search-documents
```

Currently supported environments

- [LTS versions of Node.js](#)
- Latest versions of Safari, Chrome, Microsoft Edge, and Firefox.

See our [support policy](#) for more details.

Prerequisites

- An [Azure subscription](#)
- A [Search service](#)

To create a new search service, you can use the [Azure portal](#), [Azure PowerShell](#), or the [Azure CLI](#). Here's an example using the Azure CLI to create a free instance for getting started:

Powershell

```
az search service create --name <mysearch> --resource-group <mysearch-rg> --sku free  
--location westus
```

See [choosing a pricing tier](#) for more information about available options.

Authenticate the client

To interact with the search service, you'll need to create an instance of the appropriate client class: `SearchClient` for searching indexed documents, `SearchIndexClient` for managing indexes, or `SearchIndexerClient` for crawling data sources and loading search documents into an index. To instantiate a client object, you'll need an [endpoint](#) and [Azure roles](#) or an [API key](#). You can refer to the documentation for more information on [supported authenticating approaches](#) with the search service.

Get an API Key

An API key can be an easier approach to start with because it doesn't require pre-existing role assignments.

You can get the **endpoint** and an **API key** from the search service in the [Azure portal](#). Please refer the [documentation](#) for instructions on how to get an API key.

Alternatively, you can use the following [Azure CLI](#) command to retrieve the API key from the search service:

Powershell

```
az search admin-key show --resource-group <your-resource-group-name> --service-name <your-resource-name>
```

There are two types of keys used to access your search service: **admin (read-write)** and **query (read-only)** keys. Restricting access and operations in client apps is essential to safeguarding the search assets on your service. Always use a query key rather than an admin key for any query originating from a client app.

Note: The example Azure CLI snippet above retrieves an admin key so it's easier to get started exploring APIs, but it should be managed carefully.

Once you have an api-key, you can use it as follows:

ts

```
import {  
  SearchClient,  
  AzureKeyCredential,  
  SearchIndexClient,  
  SearchIndexerClient,  
} from "@azure/search-documents";  
  
// To query and manipulate documents  
const searchClient = new SearchClient(  
  "<endpoint>",  
  "<indexName>",  
  new AzureKeyCredential("<apiKey>"),  
);  
  
// To manage indexes and synonymmaps  
const indexClient = new SearchIndexClient("<endpoint>", new AzureKeyCredential(""  
  <apiKey>"));  
  
// To manage indexers, datasources and skillsets  
const indexerClient = new SearchIndexerClient("<endpoint>", new AzureKeyCredential(""  
  <apiKey>));
```

Authenticate in a National Cloud

To authenticate in a [National Cloud](#), you will need to make the following additions to your client configuration:

- Set the `Audience` in `SearchClientOptions`

```
ts
```

```
import {
  SearchClient,
  AzureKeyCredential,
  KnownSearchAudience,
  SearchIndexClient,
  SearchIndexerClient,
} from "@azure/search-documents";

// To query and manipulate documents
const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",
  new AzureKeyCredential("<apiKey>"),
  {
    audience: KnownSearchAudience.AzureChina,
  },
);

// To manage indexes and synonymmaps
const indexClient = new SearchIndexClient("<endpoint>", new AzureKeyCredential("",
<apiKey>"), {
  audience: KnownSearchAudience.AzureChina,
});

// To manage indexers, datasources and skillsets
const indexerClient = new SearchIndexerClient("<endpoint>", new AzureKeyCredential("",
<apiKey>"), {
  audience: KnownSearchAudience.AzureChina,
});
```

Key concepts

An Azure AI Search service contains one or more indexes that provide persistent storage of searchable data in the form of JSON documents. (*If you're brand new to search, you can make a very rough analogy between indexes and database tables.*) The @azure/search-documents client library exposes operations on these resources through three main client types.

- `SearchClient` helps with:

- [Searching](#) your indexed documents using [vector queries](#), [keyword queries](#) and [hybrid queries](#)
- [Vector query filters](#) and [Text query filters](#)
- [Semantic ranking](#) and [scoring profiles](#) for boosting relevance
- [Autocompleting](#) partially typed search terms based on documents in the index
- [Suggesting](#) the most likely matching text in documents as a user types
- [Adding, Updating or Deleting Documents](#) documents from an index
- `SearchIndexClient` allows you to:
 - [Create, delete, update, or configure a search index](#)
 - [Declare custom synonym maps to expand or rewrite queries](#)
- `SearchIndexerClient` allows you to:
 - [Start indexers to automatically crawl data sources](#)
 - [Define AI powered Skillsets to transform and enrich your data](#)

Note: These clients cannot function in the browser because the APIs it calls do not have support for Cross-Origin Resource Sharing (CORS).

TypeScript/JavaScript specific concepts

Documents

An item stored inside a search index. The shape of this document is described in the index using the `fields` property. Each `SearchField` has a name, a datatype, and additional metadata such as if it is searchable or filterable.

Pagination

Typically you will only wish to [show a subset of search results](#) to a user at one time. To support this, you can use the `top`, `skip` and `includeTotalCount` parameters to provide a paged experience on top of search results.

Document field encoding

[Supported data types](#) in an index are mapped to JSON types in API requests/responses. The JS client library keeps these mostly the same, with some exceptions:

- `Edm.DateTimeOffset` is converted to a JS `Date`.
- `Edm.GeographyPoint` is converted to a `GeographyPoint` type exported by the client library.

- Special values of the `number` type (NaN, Infinity, -Infinity) are serialized as strings in the REST API, but are converted back to `number` by the client library.

Note: Data types are converted based on value, not the field type in the index schema. This means that if you have an ISO8601 Date string (e.g. "2020-03-06T18:48:27.896Z") as the value of a field, it will be converted to a Date regardless of how you stored it in your schema.

Examples

The following examples demonstrate the basics - please [check out our samples](#) for much more.

- [Creating an index](#)
- [Retrieving a specific document from your index](#)
- [Adding documents to your index](#)
- [Perform a search on documents](#)
 - [Querying with TypeScript](#)
 - [Querying with OData filters](#)
 - [Querying with facets](#)

Create an Index

```
ts

import { SearchIndexClient, AzureKeyCredential } from "@azure/search-documents";

const indexClient = new SearchIndexClient("<endpoint>", new AzureKeyCredential(""
<apiKey>"));

const result = await indexClient.createIndex({
  name: "example-index",
  fields: [
    {
      type: "Edm.String",
      name: "id",
      key: true,
    },
    {
      type: "Edm.Double",
      name: "awesomenessLevel",
      sortable: true,
      filterable: true,
      facetable: true,
    },
    {
      type: "Edm.String",
      name: "description",
    }
  ]
});
```

```

    searchable: true,
  },
{
  type: "Edm.ComplexType",
  name: "details",
  fields: [
    {
      type: "Collection(Edm.String)",
      name: "tags",
      searchable: true,
    },
  ],
},
{
  type: "Edm.Int32",
  name: "hiddenWeight",
  hidden: true,
},
],
});
console.log(`Index created with name ${result.name}`);

```

Retrieve a specific document from an index

A specific document can be retrieved by its primary key value:

```

ts

import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",
  new AzureKeyCredential("<apiKey>"),
);

const result = await searchClient.getDocument("1234");

```

Adding documents into an index

You can upload multiple documents into index inside a batch:

```

ts

import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",

```

```
new AzureKeyCredential("<apiKey>"),
);

const uploadResult = await searchClient.uploadDocuments([
// JSON objects matching the shape of the client's index
{},
{},
{},
],
);
for (const result of uploadResult.results) {
  console.log(`Uploaded ${result.key}; succeeded? ${result.succeeded}`);
}
```

Perform a search on documents

To list all results of a particular query, you can use `search` with a search string that uses [simple query syntax](#):

```
ts

import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",
  new AzureKeyCredential("<apiKey>"),
);

const searchResults = await searchClient.search("wifi -luxury");
for await (const result of searchResults.results) {
  console.log(result);
}
```

For a more advanced search that uses [Lucene syntax](#), specify `queryType` to be `full`:

```
ts

import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",
  new AzureKeyCredential("<apiKey>"),
);

const searchResults = await searchClient.search('Category:budget AND "recently
renovated"^3', {
  queryType: "full",
  searchMode: "all",
});
for await (const result of searchResults.results) {
```

```
    console.log(result);
}
```

Querying with TypeScript

In TypeScript, `SearchClient` takes a generic parameter that is the model shape of your index documents. This allows you to perform strongly typed lookup of fields returned in results. TypeScript is also able to check for fields returned when specifying a `select` parameter.

ts

```
import { SearchClient, AzureKeyCredential, SelectFields } from "@azure/search-documents";

// An example schema for documents in the index
interface Hotel {
    hotelId?: string;
    hotelName?: string | null;
    description?: string | null;
    descriptionVector?: Array<number>;
    parkingIncluded?: boolean | null;
    lastRenovationDate?: Date | null;
    rating?: number | null;
    rooms?: Array<{
        beds?: number | null;
        description?: string | null;
    }>;
}

const searchClient = new SearchClient<Hotel>(
    "<endpoint>",
    "<indexName>",
    new AzureKeyCredential("<apiKey>"),
);

const searchResults = await searchClient.search("wifi -luxury", {
    // Only fields in Hotel can be added to this array.
    // TS will complain if one is misspelled.
    select: ["hotelId", "hotelName", "rooms/beds"],
});

// These are other ways to declare the correct type for `select`.
const select = ["hotelId", "hotelName", "rooms/beds"] as const;
// This declaration lets you opt out of narrowing the TypeScript type of your
// documents,
// though the AI Search service will still only return these fields.
const selectWide: SelectFields<Hotel>[] = ["hotelId", "hotelName", "rooms/beds"];
// This is an invalid declaration. Passing this to `select` will result in a
// compiler error
// unless you opt out of including the model in the client constructor.
const selectInvalid = ["hotelId", "hotelName", "rooms/beds"];
```

```
for await (const result of searchResults.results) {
    // result.document has hotelId, hotelName, and rating.
    // Trying to access result.document.description would emit a TS error.
    console.log(result.document.hotelName);
}
```

Querying with OData filters

Using the `filter` query parameter allows you to query an index using the syntax of an [OData \\$filter expression](#).

ts

```
import { SearchClient, AzureKeyCredential, odata } from "@azure/search-documents";

const searchClient = new SearchClient(
    "<endpoint>",
    "<indexName>",
    new AzureKeyCredential("<apiKey>"),
);

const baseRateMax = 200;
const ratingMin = 4;
const searchResults = await searchClient.search("WiFi", {
    filter: odata`Rooms/any(room: room/BaseRate lt ${baseRateMax}) and Rating ge ${ratingMin}`,
    orderBy: ["Rating desc"],
    select: ["hotelId", "hotelName", "Rating"],
});
for await (const result of searchResults.results) {
    // Each result will have "HotelId", "HotelName", and "Rating"
    // in addition to the standard search result property "score"
    console.log(result);
}
```

Querying with vectors

Text embeddings can be queried using the `vector` search parameter. See [Query vectors](#) and [Filter vector queries](#) for more information.

ts

```
import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
    "<endpoint>",
    "<indexName>",
    new AzureKeyCredential("<apiKey>"),
```

```

);
const queryVector: number[] = [
  // Embedding of the query "What are the most luxurious hotels?"
];
const searchResults = await searchClient.search("*", {
  vectorSearchOptions: {
    queries: [
      {
        kind: "vector",
        vector: queryVector,
        fields: ["descriptionVector"],
        kNearestNeighborsCount: 3,
      },
    ],
  },
});
for await (const result of searchResults.results) {
  // These results are the nearest neighbors to the query vector
  console.log(result);
}

```

Querying with facets

Facets are used to help a user of your application refine a search along pre-configured dimensions. [Facet syntax](#) provides the options to sort and bucket facet values.

ts

```

import { SearchClient, AzureKeyCredential } from "@azure/search-documents";

const searchClient = new SearchClient(
  "<endpoint>",
  "<indexName>",
  new AzureKeyCredential("<apiKey>"),
);

const searchResults = await searchClient.search("WiFi", {
  facets: ["category,count:3,sort:count", "rooms/baseRate,interval:100"],
});
console.log(searchResults.facets);

```

When retrieving results, a `facets` property will be available that will indicate the number of results that fall into each facet bucket. This can be used to drive refinement (e.g. issuing a follow-up search that filters on the `Rating` being greater than or equal to 3 and less than 4.)

Troubleshooting

Logging

Enabling logging can help uncover useful information about failures. In order to see a log of HTTP requests and responses, set the `AZURE_LOG_LEVEL` environment variable to `info`.

Alternatively, logging can be enabled at runtime by calling `setLogLevel` in the `@azure/logger`:

ts

```
import { setLogLevel } from "@azure/logger";  
  
setLogLevel("info");
```

For more detailed instructions on how to enable logs, you can look at the [@azure/logger package docs](#).

Next steps

Classes

[+] [Expand table](#)

SearchManagementClient

Interfaces

[+] [Expand table](#)

AccessRule	Access rule in a network security perimeter configuration profile
AccessRuleProperties	Properties of Access Rule
AccessRuleProperties SubscriptionsItem	Subscription identifiers
AdminKeyResult	Response containing the primary and secondary admin API keys for a given Azure AI Search service.
AdminKeys	Interface representing a AdminKeys.
AdminKeysGet OptionalParams	Optional parameters.
AdminKeys RegenerateOptional Params	Optional parameters.
AsyncOperation Result	The details of a long running asynchronous shared private link resource operation.
CheckName AvailabilityInput	Input of check name availability API.
CheckName AvailabilityOutput	Output of check name availability API.
CloudError	Contains information about an API error.
CloudErrorBody	Describes a particular API error with an error code and a message.
DataPlaneAadOrApiKeyAuthOption	Indicates that either the API key or an access token from a Microsoft Entra ID tenant can be used for authentication.

DataPlaneAuthOptions	Defines the options for how the search service authenticates a data plane request. This cannot be set if 'disableLocalAuth' is set to true.
EncryptionWithCmk	Describes a policy that determines how resources within the search service are to be encrypted with customer managed keys.
Identity	Details about the search service identity. A null value indicates that the search service has no identity assigned.
IpRule	The IP restriction rule of the Azure AI Search service.
ListQueryKeysResult	Response containing the query API keys for a given Azure AI Search service.
NetworkRuleSet	Network specific rules that determine how the Azure AI Search service may be reached.
NetworkSecurityPerimeter	Information about a network security perimeter (NSP)
NetworkSecurityPerimeterConfiguration	Network security perimeter (NSP) configuration resource
NetworkSecurityPerimeterConfigurationListResult	Result of a list NSP (network security perimeter) configurations request.
NetworkSecurityPerimeterConfigurationProperties	Network security configuration properties.
NetworkSecurityPerimeterConfigurations	Interface representing a NetworkSecurityPerimeterConfigurations.
NetworkSecurityPerimeterConfigurationsGetOptionalParams	Optional parameters.
NetworkSecurityPerimeterConfigurationsListByServiceNextOptionalParams	Optional parameters.
NetworkSecurityPerimeterConfigurationsList	Optional parameters.

ByServiceOptionalParams	
NetworkSecurityPerimeterConfigurations_ReconcileHeaders	Defines headers for NetworkSecurityPerimeterConfigurations_reconcile operation.
NetworkSecurityPerimeterConfigurations_ReconcileOptionalParams	Optional parameters.
NetworkSecurityProfile	Network security perimeter configuration profile
Operation	Details of a REST API operation, returned from the Resource Provider Operations API
OperationDisplay	Localized display information for this particular operation.
OperationListResult	The result of the request to list REST API operations. It contains a list of operations and a URL to get the next set of results.
Operations	Interface representing a Operations.
OperationsListOptionalParams	Optional parameters.
PrivateEndpointConnection	Describes an existing private endpoint connection to the Azure AI Search service.
PrivateEndpointConnectionListResult	Response containing a list of private endpoint connections.
PrivateEndpointConnectionProperties	Describes the properties of an existing private endpoint connection to the search service.
PrivateEndpointConnectionPropertiesPrivateEndpoint	The private endpoint resource from Microsoft.Network provider.
PrivateEndpointConnectionPropertiesPrivateLinkService ConnectionState	Describes the current state of an existing Azure Private Link service connection to the private endpoint.
PrivateEndpointConnections	Interface representing a PrivateEndpointConnections.

PrivateEndpoint	Optional parameters.
ConnectionsDelete	
OptionalParams	
PrivateEndpoint	Optional parameters.
ConnectionsGet	
OptionalParams	
PrivateEndpoint	Optional parameters.
ConnectionsList	
ByServiceNext	
OptionalParams	
PrivateEndpoint	Optional parameters.
ConnectionsList	
ByServiceOptional	
Params	
PrivateEndpoint	Optional parameters.
ConnectionsUpdate	
OptionalParams	
PrivateLinkResource	Describes a supported private link resource for the Azure AI Search service.
PrivateLinkResourceProperties	Describes the properties of a supported private link resource for the Azure AI Search service. For a given API version, this represents the 'supported' groupIds when creating a shared private link resource.
PrivateLinkResources	Interface representing a PrivateLinkResources.
PrivateLinkResourcesListSupported	Optional parameters.
OptionalParams	
PrivateLinkResourcesResult	Response containing a list of supported Private Link Resources.
ProvisioningIssue	Describes a provisioning issue for a network security perimeter configuration
ProvisioningIssueProperties	Details of a provisioning issue for a network security perimeter (NSP) configuration. Resource providers should generate separate provisioning issue elements for each separate issue detected, and include a meaningful and distinctive description, as well as any appropriate suggestedResourceIds and suggestedAccessRules
ProxyResource	The resource model definition for a Azure Resource Manager proxy resource. It will not have tags and a location
QueryKey	Describes an API key for a given Azure AI Search service that conveys read-only permissions on the docs collection of an index.

QueryKeys	Interface representing a QueryKeys.
QueryKeysCreate OptionalParams	Optional parameters.
QueryKeysDelete OptionalParams	Optional parameters.
QueryKeysList BySearchServiceNext OptionalParams	Optional parameters.
QueryKeysList BySearchService OptionalParams	Optional parameters.
QuotaUsageResult	Describes the quota usage for a particular SKU.
QuotaUsageResult Name	The name of the SKU supported by Azure AI Search.
QuotaUsagesList Result	Response containing the quota usage information for all the supported SKUs of Azure AI Search.
Resource	Common fields that are returned in the response for all Azure Resource Manager resources
ResourceAssociation	Information about resource association
SearchManagement ClientOptionalParams	Optional parameters.
SearchManagement RequestOptions	Parameter group
SearchService	Describes an Azure AI Search service and its current state.
SearchServiceList Result	Response containing a list of Azure AI Search services.
SearchServiceUpdate	The parameters used to update an Azure AI Search service.
Services	Interface representing a Services.
ServicesCheckName AvailabilityOptionalParams	Optional parameters.
ServicesCreate OrUpdateOptionalParams	Optional parameters.

ServicesDeleteOptionalParams	Optional parameters.
ServicesGetOptionalParams	Optional parameters.
ServicesListByResourceGroupNextOptionalParams	Optional parameters.
ServicesListByResourceGroupOptionalParams	Optional parameters.
ServicesListBySubscriptionNextOptionalParams	Optional parameters.
ServicesListBySubscriptionOptionalParams	Optional parameters.
ServicesUpdateOptionalParams	Optional parameters.
ServicesUpgradeHeaders	Defines headers for Services_upgrade operation.
ServicesUpgradeOptionalParams	Optional parameters.
ShareablePrivateLinkResourceProperties	Describes the properties of a resource type that has been onboarded to private link service, supported by Azure AI Search.
ShareablePrivateLinkResourceType	Describes an resource type that has been onboarded to private link service, supported by Azure AI Search.
SharedPrivateLinkResource	Describes a shared private link resource managed by the Azure AI Search service.
SharedPrivateLinkResourceListResult	Response containing a list of shared private link resources.
SharedPrivateLinkResourceProperties	Describes the properties of an existing shared private link resource managed by the Azure AI Search service.
SharedPrivateLinkResources	Interface representing a SharedPrivateLinkResources.
SharedPrivateLinkResourcesCreate	Optional parameters.

OrUpdateOptionalParams	
SharedPrivateLinkResourcesDeleteOptionalParams	Optional parameters.
SharedPrivateLinkResourcesGetOptionalParams	Optional parameters.
SharedPrivateLinkResourcesListByServiceNextOptionalParams	Optional parameters.
SharedPrivateLinkResourcesListByServiceOptionalParams	Optional parameters.
Sku	Defines the SKU of a search service, which determines billing rate and capacity limits.
SystemData	Metadata pertaining to creation and last modification of the resource.
TrackedResource	The resource model definition for an Azure Resource Manager tracked top level resource which has 'tags' and a 'location'
UsageBySubscriptionSkuOptionalParams	Optional parameters.
Usages	Interface representing a Usages.
UsagesListBySubscriptionNextOptionalParams	Optional parameters.
UsagesListBySubscriptionOptionalParams	Optional parameters.
UserAssignedIdentity	User assigned identity properties

AadAuthFailure	Defines values for AadAuthFailureMode.
--------------------------------	--

Mode	
AccessRuleDirection	Defines values for AccessRuleDirection. KnownAccessRuleDirection can be used interchangeably with AccessRuleDirection, this enum contains the known values that the service supports.
ActionType	Defines values for ActionType. KnownActionType can be used interchangeably with ActionType, this enum contains the known values that the service supports.
AdminKeyKind	Defines values for AdminKeyKind.
AdminKeysGetResponse	Contains response data for the get operation.
AdminKeysRegenerateResponse	Contains response data for the regenerate operation.
ComputeType	Defines values for ComputeType. KnownComputeType can be used interchangeably with ComputeType, this enum contains the known values that the service supports.
CreatedByType	Defines values for CreatedByType. KnownCreatedByType can be used interchangeably with CreatedByType, this enum contains the known values that the service supports.

HostingMode	Defines values for HostingMode.
IdentityType	<p>Defines values for IdentityType.</p> <p>KnownIdentityType can be used interchangeably with IdentityType, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>None: Indicates that any identity associated with the search service needs to be removed.</p> <p>SystemAssigned: Indicates that system-assigned identity for the search service will be enabled.</p> <p>UserAssigned: Indicates that one or more user assigned identities will be assigned to the search service.</p> <p>SystemAssigned, UserAssigned: Indicates that system-assigned identity for the search service will be enabled along with the assignment of one or more user assigned identities.</p>
IssueType	<p>Defines values for IssueType.</p> <p>KnownIssueType can be used interchangeably with IssueType, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>Unknown: Unknown issue type</p> <p>ConfigurationPropagationFailure: An error occurred while applying the network security perimeter (NSP) configuration.</p> <p>MissingPerimeterConfiguration: A network connectivity issue is happening on the resource which could be addressed either by adding new resources to the network security perimeter (NSP) or by modifying access rules.</p> <p>MissingIdentityConfiguration: A managed identity hasn't been associated with the resource. The resource will still be able to validate inbound traffic from the network security perimeter (NSP) or matching inbound access rules, but it won't be able to perform outbound access as a member of the NSP.</p>
NetworkSecurityPerimeterConfigurationProvisioningState	<p>Defines values for NetworkSecurityPerimeterConfigurationProvisioningState.</p> <p>KnownNetworkSecurityPerimeterConfigurationProvisioningState can be used interchangeably with NetworkSecurityPerimeterConfigurationProvisioningState, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>Succeeded</p> <p>Creating</p> <p>Updating</p> <p>Deleting</p> <p>Accepted</p>

	Failed Canceled
NetworkSecurityPerimeterConfigurationsGetResponse	Contains response data for the get operation.
NetworkSecurityPerimeterConfigurationsListByServiceNextResponse	Contains response data for the listByServiceNext operation.
NetworkSecurityPerimeterConfigurationsListByServiceResponse	Contains response data for the listByService operation.
NetworkSecurityPerimeterConfigurationsReconcileResponse	Contains response data for the reconcile operation.
OperationsListResponse	Contains response data for the list operation.
Origin	Defines values for Origin. KnownOrigin can be used interchangeably with Origin, this enum contains the known values that the service supports.
Known values supported by the service	
	user system user,system
PrivateEndpointConnectionsDeleteResponse	Contains response data for the delete operation.
PrivateEndpointConnectionsGetResponse	Contains response data for the get operation.
PrivateEndpointConnectionsListByServiceNextResponse	Contains response data for the listByServiceNext operation.

PrivateEndpointConnectionsListByServiceResponse	Contains response data for the listByService operation.
PrivateEndpointConnectionsUpdateResponse	Contains response data for the update operation.
PrivateLinkResourcesListSupportedResponse	Contains response data for the listSupported operation.
PrivateLinkServiceConnectionProvisioningState	Defines values for PrivateLinkServiceConnectionProvisioningState. KnownPrivateLinkServiceConnectionProvisioningState can be used interchangeably with PrivateLinkServiceConnectionProvisioningState, this enum contains the known values that the service supports.
PrivateLinkServiceConnectionStatus	Defines values for PrivateLinkServiceConnectionStatus.
ProvisioningState	Defines values for ProvisioningState.
PublicNetworkAccess	Defines values for PublicNetworkAccess. KnownPublicNetworkAccess can be used interchangeably with PublicNetworkAccess, this enum contains the known values that the service supports.
Known values supported by the service	
Updating: The private link service connection is in the process of being created along with other resources for it to be fully functional.	
Deleting: The private link service connection is in the process of being deleted.	
Failed: The private link service connection has failed to be provisioned or deleted.	
Succeeded: The private link service connection has finished provisioning and is ready for approval.	
Incomplete: Provisioning request for the private link service connection resource has been accepted but the process of creation has not commenced yet.	
Canceled: Provisioning request for the private link service connection resource has been canceled.	
Known values supported by the service	
enabled: The search service is accessible from traffic originating from the public internet.	
disabled: The search service is not accessible from traffic originating from the public internet. Access is only permitted over approved private endpoint connections.	
securedByPerimeter: The network security perimeter configuration rules allow or	

	disallow public network access to the resource. Requires an associated network security perimeter.
QueryKeysCreate Response	Contains response data for the create operation.
QueryKeysList BySearchService NextResponse	Contains response data for the listBySearchServiceNext operation.
QueryKeysList BySearchService Response	Contains response data for the listBySearchService operation.
Resource AssociationAccess Mode	Defines values for ResourceAssociationAccessMode. KnownResourceAssociationAccessMode can be used interchangeably with ResourceAssociationAccessMode, this enum contains the known values that the service supports.
<h2>Known values supported by the service</h2>	
	<p>Enforced: Enforced access mode - traffic to the resource that failed access checks is blocked</p> <p>Learning: Learning access mode - traffic to the resource is enabled for analysis but not blocked</p> <p>Audit: Audit access mode - traffic to the resource that fails access checks is logged but not blocked</p>
SearchBypass	Defines values for SearchBypass. KnownSearchBypass can be used interchangeably with SearchBypass, this enum contains the known values that the service supports.
<h2>Known values supported by the service</h2>	
	<p>None: Indicates that no origin can bypass the rules defined in the 'ipRules' section. This is the default.</p> <p>AzureServices: Indicates that requests originating from Azure trusted services can bypass the rules defined in the 'ipRules' section.</p>
SearchData Exfiltration Protection	Defines values for searchDataExfiltrationProtection. KnownSearchDataExfiltrationProtection can be used interchangeably with searchDataExfiltrationProtection, this enum contains the known values that the service supports.
<h2>Known values supported by the service</h2>	
	BlockAll: Indicates that all data exfiltration scenarios are disabled.

SearchEncryptionComplianceStatus	Defines values for SearchEncryptionComplianceStatus.
SearchEncryptionWithCmk	Defines values for SearchEncryptionWithCmk.
SearchSemanticSearch	Defines values for SearchSemanticSearch. KnownSearchSemanticSearch can be used interchangeably with SearchSemanticSearch, this enum contains the known values that the service supports.
<h2>Known values supported by the service</h2>	
	<p>disabled: Indicates that semantic reranker is disabled for the search service. This is the default.</p> <p>free: Enables semantic reranker on a search service and indicates that it is to be used within the limits of the free plan. The free plan would cap the volume of semantic ranking requests and is offered at no extra charge. This is the default for newly provisioned search services.</p> <p>standard: Enables semantic reranker on a search service as a billable feature, with higher throughput and volume of semantically reranked queries.</p>
SearchServiceStatus	Defines values for SearchServiceStatus.
ServicesCheckNameAvailabilityResponse	Contains response data for the checkNameAvailability operation.
ServicesCreateOrUpdateResponse	Contains response data for the createOrUpdate operation.
ServicesGetResponse	Contains response data for the get operation.
ServicesListByResourceGroupNextResponse	Contains response data for the listByResourceGroupNext operation.
ServicesListByResourceGroupResponse	Contains response data for the listByResourceGroup operation.
ServicesListBySubscriptionNextResponse	Contains response data for the listBySubscriptionNext operation.
ServicesListBySubscriptionResponse	Contains response data for the listBySubscription operation.

Response	
ServicesUpdateResponse	Contains response data for the update operation.
ServicesUpgradeResponse	Contains response data for the upgrade operation.
Severity	<p>Defines values for Severity. KnownSeverity can be used interchangeably with Severity, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>Warning Error</p>
SharedPrivateLinkResourceAsyncResult	<p>Defines values for SharedPrivateLinkResourceAsyncResult. KnownSharedPrivateLinkResourceAsyncResult can be used interchangeably with SharedPrivateLinkResourceAsyncResult, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>Running Succeeded Failed</p>
SharedPrivateLinkResourceProvisioningState	<p>Defines values for SharedPrivateLinkResourceProvisioningState. KnownSharedPrivateLinkResourceProvisioningState can be used interchangeably with SharedPrivateLinkResourceProvisioningState, this enum contains the known values that the service supports.</p>
<h2>Known values supported by the service</h2>	
	<p>Updating: The shared private link resource is in the process of being created along with other resources for it to be fully functional. Deleting: The shared private link resource is in the process of being deleted. Failed: The shared private link resource has failed to be provisioned or deleted. Succeeded: The shared private link resource has finished provisioning and is ready for approval. Incomplete: Provisioning request for the shared private link resource has been accepted but the process of creation has not commenced yet.</p>
SharedPrivateLinkResourceStatus	<p>Defines values for SharedPrivateLinkResourceStatus. KnownSharedPrivateLinkResourceStatus can be used interchangeably with SharedPrivateLinkResourceStatus, this enum contains the known values that the service supports.</p>

Known values supported by the service

Pending: The shared private link resource has been created and is pending approval.

Approved: The shared private link resource is approved and is ready for use.

Rejected: The shared private link resource has been rejected and cannot be used.

Disconnected: The shared private link resource has been removed from the service.

SharedPrivateLinkResourcesCreateOrUpdateResponse	Contains response data for the createOrUpdate operation.
--	--

SharedPrivateLinkResourcesGetResponse	Contains response data for the get operation.
---	---

SharedPrivateLinkResourcesListByServiceNextResponse	Contains response data for the listByServiceNext operation.
---	---

SharedPrivateLinkResourcesListByServiceResponse	Contains response data for the listByService operation.
---	---

SkuName	Defines values for SkuName. KnownSkuName can be used interchangeably with SkuName, this enum contains the known values that the service supports.
-------------------------	--

Known values supported by the service

free: Free tier, with no SLA guarantees and a subset of the features offered on billable tiers.

basic: Billable tier for a dedicated service having up to 3 replicas.

standard: Billable tier for a dedicated service having up to 12 partitions and 12 replicas.

standard2: Similar to 'standard', but with more capacity per search unit.

standard3: The largest Standard offering with up to 12 partitions and 12 replicas (or up to 3 partitions with more indexes if you also set the hostingMode property to 'highDensity').

storage_optimized_I1: Billable tier for a dedicated service that supports 1TB per partition, up to 12 partitions.

storage_optimized_I2: Billable tier for a dedicated service that supports 2TB per partition, up to 12 partitions.

UnavailableNameReason	Defines values for UnavailableNameReason. KnownUnavailableNameReason can be used interchangeably with
---------------------------------------	--

`UnavailableNameReason`, this enum contains the known values that the service supports.

Known values supported by the service

Invalid: The search service name doesn't match naming requirements.

AlreadyExists: The search service name is already assigned to a different search service.

UpgradeAvailable	Defines values for <code>UpgradeAvailable</code> . <code>KnownUpgradeAvailable</code> can be used interchangeably with <code>UpgradeAvailable</code> , this enum contains the known values that the service supports.
----------------------------------	--

Known values supported by the service

notAvailable: An upgrade is currently not available for the service.

available: There is an upgrade available for the service.

UsageBySubscriptionSkuResponse	Contains response data for the <code>usageBySubscriptionSku</code> operation.
--	---

UsagesListBySubscriptionNextResponse	Contains response data for the <code>listBySubscriptionNext</code> operation.
--	---

UsagesListBySubscriptionResponse	Contains response data for the <code>listBySubscription</code> operation.
--	---

Enums

[] [Expand table](#)

KnownAccessRuleDirection	Known values of <code>AccessRuleDirection</code> that the service accepts.
KnownActionType	Known values of <code>ActionType</code> that the service accepts.
KnownComputeType	Known values of <code>ComputeType</code> that the service accepts.

KnownIdentityType	Known values of <code>IdentityType</code> that the service accepts.
KnownIssueType	Known values of <code>IssueType</code> that the service accepts.
KnownNetworkSecurityPerimeterConfiguration	Known values of <code>NetworkSecurityPerimeterConfigurationProvisioningState</code> that the service supports.

ProvisioningState	service accepts.
KnownOrigin	Known values of Origin that the service accepts.
KnownPrivateLinkServiceConnectionProvisioningState	Known values of PrivateLinkServiceConnectionProvisioningState that the service accepts.
KnownPublicNetworkAccess	Known values of PublicNetworkAccess that the service accepts.
KnownResourceAssociationAccessMode	Known values of ResourceAssociationAccessMode that the service accepts.
KnownSearchBypass	Known values of SearchBypass that the service accepts.
KnownSearchDataExfiltrationProtection	Known values of SearchDataExfiltrationProtection that the service accepts.
KnownSearchSemanticSearch	Known values of SearchSemanticSearch that the service accepts.
KnownSeverity	Known values of Severity that the service accepts.
KnownSharedPrivateLinkResourceAsyncResult	Known values of SharedPrivateLinkResourceAsyncResult that the service accepts.
KnownSharedPrivateLinkResourceProvisioningState	Known values of SharedPrivateLinkResourceProvisioningState that the service accepts.
KnownSharedPrivateLinkResourceStatus	Known values of SharedPrivateLinkResourceStatus that the service accepts.
KnownSkuName	Known values of SkuName that the service accepts.
KnownUnavailableNameReason	Known values of UnavailableNameReason that the service accepts.
KnownUpgradeAvailable	Known values of UpgradeAvailable that the service accepts.

Functions

[\[\]](#) [Expand table](#)

getContinuationToken(unknown)	Given the last <code>.value</code> produced by the <code>byPage</code> iterator, returns a continuation token that can be used to begin paging from that point later.
-------------------------------	---

Function Details

getContinuationToken(unknown)

Given the last `.value` produced by the `byPage` iterator, returns a continuation token that can be used to begin paging from that point later.

TypeScript

```
function getContinuationToken(page: unknown): string | undefined
```

Parameters

page `unknown`

An object from accessing `value` on the `IteratorResult` from a `byPage` iterator.

Returns

`string | undefined`

The continuation token that can be passed into `byPage()` during future calls.

Azure AI Search client library for Python - version 11.6.0

[Azure AI Search](#) (formerly known as "Azure Cognitive Search") is an AI-powered information retrieval platform that helps developers build rich search experiences and generative AI apps that combine large language models with enterprise data.

Azure AI Search is well suited for the following application scenarios:

- Consolidate varied content types into a single searchable index. To populate an index, you can push JSON documents that contain your content, or if your data is already in Azure, create an indexer to pull in data automatically.
- Attach skillsets to an indexer to create searchable content from images and unstructured documents. A skillset leverages APIs from Azure AI Services for built-in OCR, entity recognition, key phrase extraction, language detection, text translation, and sentiment analysis. You can also add custom skills to integrate external processing of your content during data ingestion.
- In a search client application, implement query logic and user experiences similar to commercial web search engines and chat-style apps.

Use the `Azure.Search.Documents` client library to:

- Submit queries using vector, keyword, and hybrid query forms.
- Implement filtered queries for metadata, geospatial search, faceted navigation, or to narrow results based on filter criteria.
- Create and manage search indexes.
- Upload and update documents in the search index.
- Create and manage indexers that pull data from Azure into an index.
- Create and manage skillsets that add AI enrichment to data ingestion.
- Create and manage analyzers for advanced text analysis or multi-lingual content.
- Optimize results through semantic ranking and scoring profiles to factor in business logic or freshness.

[Source code ↗](#) | [Package \(PyPI\) ↗](#) | [Package \(Conda\) ↗](#) | [API reference documentation ↗](#) |
[Product documentation](#) | [Samples ↗](#)

Getting started

Install the package

Install the Azure AI Search client library for Python with [pip ↗](#):

Bash

```
pip install azure-search-documents
```

Prerequisites

- Python 3.8 or later is required to use this package.
- You need an [Azure subscription](#) and an [Azure AI Search service](#) to use this package.

To create a new search service, you can use the [Azure portal](#), [Azure PowerShell](#), or the [Azure CLI](#).

Powershell

```
az search service create --name <mysearch> --resource-group <mysearch-rg> --sku free  
--location westus
```

See [choosing a pricing tier](#) for more information about available options.

Authenticate the client

To interact with the search service, you'll need to create an instance of the appropriate client class: `SearchClient` for searching indexed documents, `SearchIndexClient` for managing indexes, or `SearchIndexerClient` for crawling data sources and loading search documents into an index. To instantiate a client object, you'll need an `endpoint` and [Azure roles](#) or an [API key](#). You can refer to the documentation for more information on [supported authenticating approaches](#) with the search service.

Get an API Key

An API key can be an easier approach to start with because it doesn't require pre-existing role assignments.

You can get the `endpoint` and an `API key` from the Search service in the [Azure portal](#). Please refer the [documentation](#) for instructions on how to get an API key.

Alternatively, you can use the following [Azure CLI](#) command to retrieve the API key from the Search service:

Powershell

```
az search admin-key show --service-name <mysearch> --resource-group <mysearch-rg>
```

There are two types of keys used to access your search service: **admin** (*read-write*) and **query** (*read-only*) keys. Restricting access and operations in client apps is essential to safeguarding the search assets on your service. Always use a query key rather than an admin key for any query originating from a client app.

Note: The example Azure CLI snippet above retrieves an admin key so it's easier to get started exploring APIs, but it should be managed carefully.

Create a SearchClient

To instantiate the `SearchClient`, you'll need the **endpoint**, **API key** and **index name**:

Python

```
from azure.core.credentials import AzureKeyCredential
from azure.search.documents import SearchClient

service_endpoint = os.environ["AZURE_SEARCH_SERVICE_ENDPOINT"]
index_name = os.environ["AZURE_SEARCH_INDEX_NAME"]
key = os.environ["AZURE_SEARCH_API_KEY"]

search_client = SearchClient(service_endpoint, index_name, AzureKeyCredential(key))
```

Create a client using Microsoft Entra ID authentication

You can also create a `SearchClient`, `SearchIndexClient`, or `SearchIndexerClient` using Microsoft Entra ID authentication. Your user or service principal must be assigned the "Search Index Data Reader" role. Using the [DefaultAzureCredential](#) you can authenticate a service using Managed Identity or a service principal, authenticate as a developer working on an application, and more all without changing code. Please refer the [documentation](#) for instructions on how to connect to Azure AI Search using Azure role-based access control (Azure RBAC).

Before you can use the `DefaultAzureCredential`, or any credential type from [Azure.Identity](#), you'll first need to [install the Azure.Identity package](#).

To use `DefaultAzureCredential` with a client ID and secret, you'll need to set the `AZURE_TENANT_ID`, `AZURE_CLIENT_ID`, and `AZURE_CLIENT_SECRET` environment variables; alternatively, you can pass those values to the `ClientSecretCredential` also in `Azure.Identity`.

Make sure you use the right namespace for `DefaultAzureCredential` at the top of your source file:

Python

```
from azure.identity import DefaultAzureCredential
from azure.search.documents import SearchClient

service_endpoint = os.getenv("AZURE_SEARCH_SERVICE_ENDPOINT")
index_name = os.getenv("AZURE_SEARCH_INDEX_NAME")
credential = DefaultAzureCredential()

search_client = SearchClient(service_endpoint, index_name, credential)
```

Key concepts

An Azure AI Search service contains one or more indexes that provide persistent storage of searchable data in the form of JSON documents. (*If you're brand new to search, you can make a very rough analogy between indexes and database tables.*) The Azure.Search.Documents client library exposes operations on these resources through three main client types.

- `SearchClient` helps with:
 - [Searching](#) your indexed documents using [vector queries](#), [keyword queries](#) and [hybrid queries](#)
 - [Vector query filters](#) and [Text query filters](#)
 - [Semantic ranking](#) and [scoring profiles](#) for boosting relevance
 - [Autocompleting](#) partially typed search terms based on documents in the index
 - [Suggesting](#) the most likely matching text in documents as a user types
 - [Adding, Updating or Deleting Documents](#) documents from an index
- `SearchIndexClient` allows you to:
 - [Create, delete, update, or configure a search index](#)
 - [Declare custom synonym maps to expand or rewrite queries](#)
- `SearchIndexerClient` allows you to:
 - [Start indexers to automatically crawl data sources](#)
 - [Define AI powered Skillsets to transform and enrich your data](#)

Azure AI Search provides two powerful features: **semantic ranking** and **vector search**.

Semantic ranking enhances the quality of search results for text-based queries. By enabling semantic ranking on your search service, you can improve the relevance of search results in two ways:

- It applies secondary ranking to the initial result set, promoting the most semantically relevant results to the top.

- It extracts and returns captions and answers in the response, which can be displayed on a search page to enhance the user's search experience.

To learn more about semantic ranking, you can refer to the [documentation](#).

Vector search is an information retrieval technique that uses numeric representations of searchable documents and query strings. By searching for numeric representations of content that are most similar to the numeric query, vector search can find relevant matches, even if the exact terms of the query are not present in the index. Moreover, vector search can be applied to various types of content, including images and videos and translated text, not just same-language text.

To learn how to index vector fields and perform vector search, you can refer to the [sample](#). This sample provides detailed guidance on indexing vector fields and demonstrates how to perform vector search.

Additionally, for more comprehensive information about vector search, including its concepts and usage, you can refer to the [documentation](#). The documentation provides in-depth explanations and guidance on leveraging the power of vector search in Azure AI Search.

The `Azure.Search.Documents` client library (v1) provides APIs for data plane operations. The previous `Microsoft.Azure.Search` client library (v10) is now retired. It has many similar looking APIs, so please be careful to avoid confusion when exploring online resources. A good rule of thumb is to check for the namespace `Azure.Search.Documents`; when you're looking for API reference.

Examples

The following examples all use a simple [Hotel data set](#) that you can [import into your own index from the Azure portal](#). These are just a few of the basics - please [check out our Samples](#) for much more.

- [Querying](#)
- [Creating an index](#)
- [Adding documents to your index](#)
- [Retrieving a specific document from your index](#)
- [Async APIs](#)

Querying

Let's start by importing our namespaces.

Python

```
import os
from azure.core.credentials import AzureKeyCredential
from azure.search.documents import SearchClient
```

We'll then create a `SearchClient` to access our hotels search index.

Python

```
index_name = "hotels"
# Get the service endpoint and API key from the environment
endpoint = os.environ["SEARCH_ENDPOINT"]
key = os.environ["SEARCH_API_KEY"]

# Create a client
credential = AzureKeyCredential(key)
client = SearchClient(endpoint=endpoint,
                      index_name=index_name,
                      credential=credential)
```

Let's search for a "luxury" hotel.

Python

```
results = client.search(search_text="luxury")

for result in results:
    print("{}: {}".format(result["hotelId"], result["hotelName"]))
```

Creating an index

You can use the `SearchIndexClient` to create a search index. Fields can be defined using convenient `SimpleField`, `SearchableField`, or `ComplexField` models. Indexes can also define suggesters, lexical analyzers, and more.

Python

```
client = SearchIndexClient(service_endpoint, AzureKeyCredential(key))
name = "hotels"
fields = [
    SimpleField(name="hotelId", type=SearchFieldDataType.String, key=True),
    SimpleField(name="baseRate", type=SearchFieldDataType.Double),
    SearchableField(name="description", type=SearchFieldDataType.String,
collection=True),
    ComplexField(
        name="address",
        fields=[
            SimpleField(name="streetAddress", type=SearchFieldDataType.String),
```

```
        SimpleField(name="city", type=SearchFieldDataType.String),
    ],
    collection=True,
),
]
cors_options = CorsOptions(allowed_origins=[ "*"], max_age_in_seconds=60)
scoring_profiles: List[ScoringProfile] = []
index = SearchIndex(name=name, fields=fields, scoring_profiles=scoring_profiles,
cors_options=cors_options)

result = client.create_index(index)
```

Adding documents to your index

You can `Upload`, `Merge`, `MergeOrUpload`, and `Delete` multiple documents from an index in a single batched request. There are [a few special rules for merging](#) to be aware of.

Python

```
DOCUMENT = {
    "category": "Hotel",
    "hotelId": "1000",
    "rating": 4.0,
    "rooms": [],
    "hotelName": "Azure Inn",
}

result = search_client.upload_documents(documents=[DOCUMENT])

print("Upload of new document succeeded: {}".format(result[0].succeeded))
```

Authenticate in a National Cloud

To authenticate in a [National Cloud](#), you will need to make the following additions to your client configuration:

- Set the `AuthorityHost` in the credential options or via the `AZURE_AUTHORITY_HOST` environment variable
- Set the `audience` in `SearchClient`, `SearchIndexClient`, or `SearchIndexerClient`

Python

```
# Create a SearchClient that will authenticate through AAD in the China national
cloud.
import os
from azure.identity import DefaultAzureCredential, AzureAuthorityHosts
from azure.search.documents import SearchClient
```

```
index_name = "hotels"
endpoint = os.environ["SEARCH_ENDPOINT"]
key = os.environ["SEARCH_API_KEY"]
credential = DefaultAzureCredential(authority=AzureAuthorityHosts.AZURE_CHINA)

search_client = SearchClient(endpoint, index_name, credential=credential,
audience="https://search.azure.cn")
```

Retrieving a specific document from your index

In addition to querying for documents using keywords and optional filters, you can retrieve a specific document from your index if you already know the key. You could get the key from a query, for example, and want to show more information about it or navigate your customer to that document.

Python

```
from azure.core.credentials import AzureKeyCredential
from azure.search.documents import SearchClient

search_client = SearchClient(service_endpoint, index_name, AzureKeyCredential(key))

result = search_client.get_document(key="23")

print("Details for hotel '23' are:")
print("    Name: {}".format(result["hotelName"]))
print("    Rating: {}".format(result["rating"]))
print("    Category: {}".format(result["category"]))
```

Async APIs

This library includes a complete async API. To use it, you must first install an async transport, such as [aiohttp](#). See [azure-core documentation](#) for more information.

Python

```
from azure.core.credentials import AzureKeyCredential
from azure.search.documents.aio import SearchClient

search_client = SearchClient(service_endpoint, index_name, AzureKeyCredential(key))

async with search_client:
    results = await search_client.search(search_text="spa")

    print("Hotels containing 'spa' in the name (or other fields):")
    async for result in results:
        print("    Name: {} (rating {})".format(result["hotelName"],
result["rating"]))
```

Troubleshooting

General

The Azure AI Search client will raise exceptions defined in [Azure Core](#).

Logging

This library uses the standard [logging](#) library for logging. Basic information about HTTP sessions (URLs, headers, etc.) is logged at INFO level.

Detailed DEBUG level logging, including request/response bodies and unredacted headers, can be enabled on a client with the `logging_enable` keyword argument:

Python

```
import sys
import logging
from azure.core.credentials import AzureKeyCredential
from azure.search.documents import SearchClient

# Create a logger for the 'azure' SDK
logger = logging.getLogger('azure')
logger.setLevel(logging.DEBUG)

# Configure a console output
handler = logging.StreamHandler(stream=sys.stdout)
logger.addHandler(handler)

# This client will log detailed information about its HTTP sessions, at DEBUG level
client = SearchClient("<service endpoint>", "<index_name>", AzureKeyCredential("<api key>"), logging_enable=True)
```

Similarly, `logging_enable` can enable detailed logging for a single operation, even when it isn't enabled for the client:

Python

```
result = client.search(search_text="spa", logging_enable=True)
```

Supported data types (Azure AI Search)

10/08/2025

This article describes the data types supported by Azure AI Search. Fields and the values used in filter expressions are typed according to the [Entity Data Model \(EDM\)](#). Specifying an EDM data type is a requirement for field definition.

! Note

If you're using [indexers](#), see [Data type map for indexers in Azure AI Search](#) for more information about how indexers map source-specific data types to EDM data types in a search index.

EDM data types for vector fields

A [vector field](#) type must be valid for the output of your embedding model. For example, if you use text-embedding-ada-002, the output format is `Float32` or `Collection(Edm.Single)`. In this scenario, you can't assign an `Int8` data type because casting from `float` to `int` primitives is prohibited. However, you can cast from `Float32` to `Float16` or `(Collection(Edm.Half))`.

Vector fields are an array of embeddings. In EDM, an array is a collection.

[] [Expand table](#)

Data type	Vector type	Description	Recommended use
<code>Collection(Edm.Byte)</code>	Binary	1-bit unsigned binary. Generally available in Create or Update Index .	Supports integration with models that emit binary embeddings, such as Cohere's v3 binary embedding models or custom quantization logic that emits 1-bit unsigned binary output. For fields of type <code>Collection(Edm.Byte)</code> , see Index binary data for help with specifying the field definition and vector search algorithms for binary data.
<code>Collection(Edm.Single)</code>	<code>Float32</code>	32-bit floating point. Generally available in Create or Update Index .	Default data type in Microsoft tools that create vector fields on your behalf. Strikes a balance between precision and efficiency. Most embedding models emit vectors as <code>Float32</code> .

Data type	Vector type	Description	Recommended use
Collection(Edm.Half)	Float16	16-bit floating point with lower precision and range. Generally available in Create or Update Index .	Useful for scenarios where memory and computational efficiency are critical, and where sacrificing some precision is acceptable. Often leads to faster query times and reduced memory footprint compared to <code>Float32</code> , although with slightly reduced accuracy. You can assign a <code>Float16</code> type to index <code>Float32</code> embeddings as <code>Float16</code> . You can also use <code>Float16</code> for embedding models or custom quantization processes that emit <code>Float16</code> natively.
Collection(Edm.Int16)	Int16	16-bit signed integer. Generally available in Create or Update Index .	Offers reduced memory footprint compared to <code>Float32</code> and support for higher-precision quantization methods while still retaining sufficient precision for many applications. Suitable for cases where memory efficiency is important. Requires that you have custom quantization that outputs vectors as <code>Int16</code> .
Collection(Edm.SByte)	Int8	8-bit signed integer. Generally available in Create or Update Index .	Provides significant memory and computational efficiency gains compared to <code>Float32</code> or <code>Float16</code> . However, it likely requires supplemental techniques (like quantization and oversampling) to offset the reduction in precision and recall appropriately. Requires that you have custom quantization that outputs vectors as <code>Int8</code> .

EDM data types for nonvector fields

[] [Expand table](#)

Data type	Description
Edm.String	Text data.
Edm.Boolean	Contains true/false values.
Edm.Int32	32-bit integer values.
Edm.Int64	64-bit integer values.
Edm.Double	Double-precision IEEE 754 floating-point values.

Data type	Description
<code>Edm.DateTimeOffset</code>	Date and time values represented in the OData V4 format: <code>yyyy-MM-ddTHH:mm:ss.fffZ</code> or <code>yyyy-MM-ddTHH:mm:ss.fff[+ -]HH:mm</code> . Precision of <code>DateTimeOffset</code> fields is limited to milliseconds. If you upload <code>DateTimeOffset</code> values with submillisecond precision, the value returned is rounded up to milliseconds (for example, <code>2024-04-15T10:30:09.7552052Z</code> is returned as <code>2024-04-15T10:30:09.7550000Z</code>). When you upload <code>DateTimeOffset</code> values with time zone information to your index, Azure AI Search normalizes these values to UTC. For example, <code>2024-01-13T14:03:00-08:00</code> is stored as <code>2024-01-13T22:03:00Z</code> . If you need to store time zone information, add an extra field to your index.
<code>Edm.GeographyPoint</code>	A point representing a geographic location on the globe. For request and response bodies, the representation of values of this type follows the GeoJSON "Point" type format. For URLs, OData uses a literal form based on the WKT standard. A point literal is constructed as <code>geography'POINT(lon lat)'</code> .
<code>Edm.ComplexType</code>	Objects whose properties map to subfields that can be of any other supported data type. This type enables indexing of structured hierarchical data such as JSON. Objects in a field of type <code>Edm.ComplexType</code> can contain nested objects, but the level of nesting is limited. The limits are described in Service limits .
<code>Collection(Edm.String)</code>	A list of strings.
<code>Collection(Edm.Boolean)</code>	A list of boolean values.
<code>Collection(Edm.Int32)</code>	A list of 32-bit integer values.
<code>Collection(Edm.Int64)</code>	A list of 64-bit integer values.
<code>Collection(Edm.Double)</code>	A list of double-precision numeric values.
<code>Collection(Edm.DateTimeOffset)</code>	A list of date time values.
<code>Collection(Edm.GeographyPoint)</code>	A list of points representing geographic locations.
<code>Collection(Edm.ComplexType)</code>	A list of objects of type <code>Edm.ComplexType</code> . There's a limit on the maximum number of elements across all collections of type <code>Edm.ComplexType</code> in a document. See Service limits for details.

All of the above types are nullable, except for collections of primitive and complex types, for example, `Collection(Edm.String)`. Nullable fields can be explicitly set to null. They're automatically set to null when omitted from a document that is uploaded to an Azure AI Search index. Collection fields are automatically set to empty (`[]` in JSON) when they're omitted from a document. Also, it isn't possible to store a null value in a collection field.

Unlike complex collections, there's no upper limit specifically on the number of items in a collection of primitive types, but the [16-MB upper limit on payload size](#) applies to all parts of documents, including collections.

Geospatial data type used in filter expressions

In Azure AI Search, geospatial search is expressed as a filter.

Edm.GeographyPolygon is a polygon representing a geographic region on the globe. While this type can't be used in document fields, it can be used as an argument to the `geo.intersects` function. The literal form for URLs in OData is based on the [WKT \(Well-known text\)](#) and [OGC's simple feature access standards](#). A polygon literal is constructed as `geography'POLYGON((lon lat, lon lat, ...))'`.

Important

Points in a polygon *must* be in counterclockwise order. Points in a polygon are interpreted in counterclockwise order, relative to the inside of the polygon. For example, a 4-point closed polygon around London would be -0.3°W 51.6°N [top left] , -0.3°W 51.4°N [bottom left], 0.1°E 51.4°N [bottom right], 0.1°E 51.6°N [top right], -0.3°W 51.6°N [starting point].

Data type map for indexers (Azure AI Search)

10/08/2025

When you're building an index schema for indexer-based indexing, the data types in source data must map to an allowed data type for the fields in the target index.

This article provides data type comparisons between SQL Data Types, JSON data types, and Azure AI Search. It contains the following sections:

- [SQL Server Data Types to Azure AI Search Data Types](#)
- [JSON Data Types to Azure AI Search Data Types](#)

SQL Server Data Types to Azure AI Search Data Types

[Expand table](#)

SQL Server Data Type	Allowed target index field types	Notes
bit	Edm.Boolean, Edm.String	
int, smallint, tinyint	Edm.Int32, Edm.Int64, Edm.String	
bigint	Edm.Int64, Edm.String	
real, float	Edm.Double, Edm.String	
smallmoney, money	Edm.String	Azure AI Search doesn't support converting decimal types into Edm.Double because doing so would lose precision.
decimal		
numeric		
char, nchar, varchar, nvarchar	Edm.String	
		Collection(Edm.String). See Field Mapping Functions for details on how to transform a string column into a Collection(Edm.String)
smalldatetime, datetime,	Edm.DateTimeOffset, Edm.String	

SQL Server Data Type	Allowed target index field types	Notes
datetime2, date, datetimeoffset		
uniqueidentifier	Edm.String	
rowversion	N/A	Row-version columns can't be stored in the search index, but they can be used for change tracking.
geography	Edm.GeographyPoint, Edm.String	If using geography data types , only geography instances of type POINT with SRID 4326 (which is the default) are supported. If using strings, only GeoJSON points in the following format are supported: <code>{"type": "Point", "coordinates": [long, lat]}</code>
time, timespan	N/A	Not supported.
varbinary		
image		
xml		
geometry		
CLR types		

JSON Data Types to Azure AI Search Data Types

[Expand table](#)

JSON data type	Allowed target index field types
bool	Edm.Boolean, Edm.String
Integral numbers	Edm.Int32, Edm.Int64, Edm.String
Floating-point numbers	Edm.Double, Edm.String
string	Edm.String
arrays of primitive types, for example ["a", "b", "c"]	Collection(Edm.String)

JSON data type	Allowed target index field types
Strings that look like dates	Edm.DateTimeOffset, Edm.String
GeoJSON point objects	Edm.GeographyPoint GeoJSON points are JSON objects in the following format : <code>{"type": "Point", "coordinates": [long, lat]}</code>
JSON objects	Edm.ComplexType Azure AI Search maps JSON objects to corresponding complex type schemas

Stopwords reference (Microsoft analyzers)

Article • 08/28/2024

When text is indexed into Azure AI Search, it's processed by analyzers so it can be efficiently stored in a search index. During this [lexical analysis](#) process, [language analyzers](#) will remove stopwords specific to that language. Stopwords are non-essential words such as "the" or "an" that can be removed without compromising the lexical integrity of your content.

Stopword removal applies to all supported [Lucene and Microsoft analyzers](#) used in Azure AI Search.

This article lists the stopwords used by the Microsoft analyzer for each language.

For the stopword list for Lucene analyzers, see the [Apache Lucene source code on GitHub](#).

Tip

To view the output of any given analyzer, call the [Analyze Text REST API](#). This API is often helpful for debugging unexpected search results.

Simple query syntax in Azure AI Search

Article • 12/10/2024

For full text search scenarios, Azure AI Search implements two Lucene-based query languages, each one aligned to a query parser. The [Simple Query Parser](#) is the default. It covers common use cases and attempts to interpret a request even if it's not perfectly composed. The other parser is [Lucene Query Parser](#) and it supports more advanced query constructions.

This article is the query syntax reference for the simple query parser.

Query syntax for both parsers applies to query expressions passed in the `search` parameter of a [query request](#), not to be confused with the [OData syntax](#), with its own syntax and rules for `filter` and `orderby` expressions in the same request.

Although the simple parser is based on the [Apache Lucene Simple Query Parser](#) class, its implementation in Azure AI Search excludes fuzzy search. If you need [fuzzy search](#), consider the alternative [full Lucene query syntax](#) instead.

Example (simple syntax)

This example shows a simple query, distinguished by `"queryType": "simple"` and valid syntax. Although query type is set below, it's the default and can be omitted unless you're reverting from an alternative type. The following example is a search over independent terms, with a requirement that all matching documents include "pool".

HTTP

```
POST https://{{service-name}}.search.windows.net/indexes/hotel-rooms-sample/docs/search?api-version=2024-07-01
{
  "queryType": "simple",
  "search": "budget hotel +pool",
  "searchMode": "all"
}
```

The `searchMode` parameter is relevant in this example. Whenever boolean operators are on the query, you should generally set `searchMode=all` to ensure that *all* of the criteria are matched. Otherwise, you can use the default `searchMode=any` that favors recall over precision.

For more examples, see [Simple query syntax examples](#). For details about the query request and parameters, see [Search Documents \(REST API\)](#).

Keyword search on terms and phrases

Strings passed to the `search` parameter can include terms or phrases in any supported language, boolean operators, precedence operators, wildcard or prefix characters for "starts with" queries, escape characters, and URL encoding characters. The `search` parameter is optional. Unspecified, `search` (`search=*` or `search=" "`) returns the top 50 documents in arbitrary (unranked) order.

- A *term search* is a query of one or more terms, where any of the terms are considered a match.
- A *phrase search* is an exact phrase enclosed in quotation marks `" "`. For example, while `Roach Motel` (without quotes) would search for documents containing `Roach` and/or `Motel` anywhere in any order, `"Roach Motel"` (with quotes) will only match documents that contain that whole phrase together and in that order (lexical analysis still applies).

Depending on your search client, you might need to escape the quotation marks in a phrase search. For example, in a POST request, a phrase search on `"Roach Motel"` in the request body might be specified as `"\"Roach Motel\""`. If you're using the Azure SDKs, the search client escapes the quotation marks when it serializes the search text. Your search phrase can be sent be as "Roach Motel".

By default, all strings passed in the `search` parameter undergo lexical analysis. Make sure you understand the tokenization behavior of the analyzer you're using. Often, when query results are unexpected, the reason can be traced to how terms are tokenized at query time. You can [test tokenization on specific strings](#) to confirm the output.

Any text input with one or more terms is considered a valid starting point for query execution. Azure AI Search will match documents containing any or all of the terms, including any variations found during analysis of the text.

As straightforward as this sounds, there's one aspect of query execution in Azure AI Search that *might* produce unexpected results, increasing rather than decreasing search results as more terms and operators are added to the input string. Whether this expansion actually occurs depends on the inclusion of a NOT operator, combined with a `searchMode` parameter setting that determines how NOT is interpreted in terms of `AND` or `OR` behaviors. For more information, see the `NOT` operator under [Boolean operators](#).

Boolean operators

You can embed Boolean operators in a query string to improve the precision of a match. In the simple syntax, boolean operators are character-based. Text operators, such as the word AND, aren't supported.

[Expand table

Character	Example	Usage
+	pool + ocean	An <code>AND</code> operation. For example, <code>pool + ocean</code> stipulates that a document must contain both terms.
	pool ocean	An <code>OR</code> operation finds a match when either term is found. In the example, the query engine will return a match on documents containing either <code>pool</code> or <code>ocean</code> or both. Because <code>OR</code> is the default conjunction operator, you could also leave it out, such that <code>pool ocean</code> is the equivalent of <code>pool ocean</code> .
-	pool - ocean	A <code>NOT</code> operation returns matches on documents that exclude the term. The <code>searchMode</code> parameter on a query request controls whether a term with the <code>NOT</code> operator is <code>ANDed</code> or <code>ORed</code> with other terms in the query (assuming there's no boolean operators on the other terms). Valid values include <code>any</code> or <code>all</code> . <code>searchMode=any</code> increases the recall of queries by including more results, and by default <code>-</code> will be interpreted as "OR NOT". For example, <code>pool - ocean</code> will match documents that either contain the term <code>pool</code> or those that don't contain the term <code>ocean</code> . <code>searchMode=all</code> increases the precision of queries by including fewer results, and by default <code>-</code> will be interpreted as "AND NOT". For example, with <code>searchMode=any</code> , the query <code>pool - ocean</code> will match documents that contain the term "pool" and all documents that don't contain the term "ocean". This is arguably a more intuitive behavior for the <code>-</code> operator. Therefore, you should consider using <code>searchMode=all</code> instead of <code>searchMode=any</code> if you want to optimize searches for precision instead of recall, and Your users frequently use the <code>-</code> operator in searches. When deciding on a <code>searchMode</code> setting, consider the user interaction patterns for queries in various applications. Users who are searching for information are more likely to include an operator in a query, as opposed to e-commerce sites that have more built-in navigation structures.

Prefix queries

For "starts with" queries, add a suffix operator (*) as the placeholder for the remainder of a term. A prefix query must begin with at least one plain text character before you can add the suffix operator.

[Expand table](#)

Character	Example	Usage
*	<code>lingui*</code> will match on "linguistic" or "linguini"	The asterisk (*) represents one or more characters of arbitrary length, ignoring case.

Similar to filters, a prefix query looks for an exact match. As such, there's no relevance scoring (all results receive a search score of 1.0). Be aware that prefix queries can be slow, especially if the index is large and the prefix consists of a small number of characters. An alternative methodology, such as edge n-gram tokenization, might perform faster. Terms using prefix search can't be longer than 1000 characters.

Simple syntax supports prefix matching only. For suffix or infix matching against the end or middle of a term, use the [full Lucene syntax for wildcard search](#).

Escaping search operators

In the simple syntax, search operators include these characters: + | " () ' \

If any of these characters are part of a token in the index, escape it by prefixing it with a single backslash (\) in the query. For example, suppose you used a custom analyzer for whole term tokenization, and your index contains the string "Luxury+Hotel". To get an exact match on this token, insert an escape character: `search=luxury\+hotel`.

To make things simple for the more typical cases, there are two exceptions to this rule where escaping isn't needed:

- The NOT operator - only needs to be escaped if it's the first character after a whitespace. If the - appears in the middle (for example, in `3352CDD0-EF30-4A2E-A512-3B30AF40F3FD`), you can skip escaping.
- The suffix operator * only needs to be escaped if it's the last character before a whitespace. If the * appears in the middle (for example, in `4*4=16`), no escaping is needed.

① Note

By default, the standard analyzer will delete and break words on hyphens, whitespace, ampersands, and other characters during [lexical analysis](#). If you require special characters to remain in the query string, you might need an analyzer that preserves them in the index. Some choices include Microsoft natural [language analyzers](#), which preserves hyphenated words, or a custom analyzer for more complex patterns. For more information, see [Partial terms, patterns, and special characters](#).

Encoding unsafe and reserved characters in URLs

Ensure all unsafe and reserved characters are encoded in a URL. For example, '#' is an unsafe character because it's a fragment/anchor identifier in a URL. The character must be encoded to `%23` if used in a URL. '&' and '=' are examples of reserved characters as they delimit parameters and specify values in Azure AI Search. For more information, see [RFC1738: Uniform Resource Locators \(URL\)](#).

Unsafe characters are `" ` < > # % { } | \ ^ ~ []`. Reserved characters are `; / ? : @ = + &`.

Special characters

Special characters can range from currency symbols like '\$' or '€', to emojis. Many analyzers, including the default standard analyzer, will exclude special characters during indexing, which means they won't be represented in your index.

If you need special character representation, you can assign an analyzer that preserves them:

- The whitespace analyzer considers any character sequence separated by white spaces as tokens (so the '♥' emoji would be considered a token).
- A [language analyzer](#), such as the Microsoft English analyzer (`en.microsoft`), would take the '\$' or '€' string as a token.

For confirmation, you can [test an analyzer](#) to see what tokens are generated for a given string. As you might expect, you might not get full tokenization from a single analyzer. A workaround is to create multiple fields that contain the same content, but with different analyzer assignments (for example, `description_en`, `description_fr`, and so forth for language analyzers).

When using Unicode characters, make sure symbols are properly escaped in the query url (for instance for '♥' would use the escape sequence `%E2%9D%A4+`). Some web clients do this translation automatically.

Precedence (grouping)

You can use parentheses to create subqueries, including operators within the parenthetical statement. For example, `motel+(wifi|luxury)` will search for documents containing the "motel" term and either "wifi" or "luxury" (or both).

Query size limits

If your application generates search queries programmatically, we recommend designing it in such a way that it doesn't generate queries of unbounded size.

- For GET, the length of the URL can't exceed 8 KB.
- For POST (and any other request), where the body of the request includes `search` and other parameters such as `filter` and `orderby`, the maximum size is 16 MB.
Additional limits include:
 - The maximum length of the search clause is 100,000 characters.
 - The maximum number of clauses in `search` (expressions separated by AND or OR) is 1024.
 - The maximum search term size is 1000 characters for [prefix search](#).
 - There's also a limit of approximately 32 KB on the size of any individual term in a query.

For more information on query limits, see [API request limits](#).

Next steps

If you'll be constructing queries programmatically, review [Full text search in Azure AI Search](#) to understand the stages of query processing and the implications of text analysis.

You can also review the following articles to learn more about query construction:

Lucene query syntax in Azure AI Search

Article • 12/11/2024

When creating queries in Azure AI Search, you can opt for the full [Lucene Query Parser](#) syntax for specialized query forms: wildcard, fuzzy search, proximity search, regular expressions. Much of the Lucene Query Parser syntax is [implemented intact in Azure AI Search](#), except for *range searches*, which are constructed through `$filter` expressions.

To use full Lucene syntax, set the `queryType` to `full` and pass in a query expression patterned for wildcard, fuzzy search, or one of the other query forms supported by the full syntax. In REST, query expressions are provided in the `search` parameter of a [Search Documents \(REST API\)](#) request.

Example (full syntax)

The following example is a search request constructed using the full syntax. This particular example shows in-field search and term boosting. It looks for hotels where the category field contains the term `budget`. Any documents containing the phrase `"recently renovated"` are ranked higher as a result of the term boost value (3).

```
HTTP  
  
POST /indexes/hotels-sample-index/docs/search?api-version=2024-07-01  
{  
  "queryType": "full",  
  "search": "category:budget AND \"recently renovated\"^3",  
  "searchMode": "all"  
}
```

While not specific to any query type, the `searchMode` parameter is relevant in this example. Whenever operators are on the query, you should generally set `searchMode=all` to ensure that *all* of the criteria are matched.

For more examples, see [Lucene query syntax examples](#). For details about the query request and parameters, including `searchMode`, see [Search Documents \(REST API\)](#).

Syntax fundamentals

The following syntax fundamentals apply to all queries that use the Lucene syntax.

Operator evaluation in context

Placement determines whether a symbol is interpreted as an operator or just another character in a string.

For example, in Lucene full syntax, the tilde (~) is used for both fuzzy search and proximity search. When placed after a quoted phrase, ~ invokes proximity search. When placed at the end of a term, ~ invokes fuzzy search.

Within a term, such as `business~analyst`, the character isn't evaluated as an operator. In this case, assuming the query is a term or phrase query, [full text search](#) with [lexical analysis](#) strips out the ~ and breaks the term `business~analyst` in two: `business` OR `analyst`.

The example above is the tilde (~), but the same principle applies to every operator.

Escaping special characters

In order to use any of the search operators as part of the search text, escape the character by prefixing it with a single backslash (\). For example, for a wildcard search on `https://`, where `://` is part of the query string, you would specify `search=https\:**`. Similarly, an escaped phone number pattern might look like this `\+1 \(800\)-642\(-7676`.

Special characters that require escaping include the following:

+ - & | ! () { } [] ^ " ~ * ? : \ /

ⓘ Note

Although escaping keeps tokens together, [lexical analysis](#) during indexing may strip them out. For example, the standard Lucene analyzer will break words on hyphens, whitespace, and other characters. If you require special characters in the query string, you might need an analyzer that preserves them in the index. Some choices include Microsoft natural [language analyzers](#), which preserves hyphenated words, or a custom analyzer for more complex patterns. For more information, see [Partial terms, patterns, and special characters](#).

Encoding unsafe and reserved characters in URLs

Ensure all unsafe and reserved characters are encoded in a URL. For example, # is an unsafe character because it's a fragment/anchor identifier in a URL. The character must be encoded to %23 if used in a URL. & and = are examples of reserved characters as they delimit parameters and specify values in Azure AI Search. See [RFC1738: Uniform Resource Locators \(URL\)](#) for more details.

Unsafe characters are " ` < > # % { } | \ ^ ~ []. Reserved characters are ; / ? : @ = + &.

Boolean operators

You can embed Boolean operators in a query string to improve the precision of a match. The full syntax supports text operators in addition to character operators. Always specify text boolean operators (AND, OR, NOT) in all caps.

[Expand table](#)

Text operator	Character operator	Example	Usage
AND	+	wifi AND luxury	Specifies terms that a match must contain. In the example, the query engine looks for documents containing both wifi and luxury. The plus character (+) can also be used directly in front of a term to make it required. For example, +wifi +luxury stipulates that both terms must appear somewhere in the field of a single document.
OR	(none) ¹	wifi OR luxury	Finds a match when either term is found. In the example, the query engine returns match on documents containing either wifi or luxury or both. Because OR is the default conjunction operator, you could also leave it out, such that wifi luxury is the equivalent of wifi OR luxury.
NOT	!, -	wifi - luxury	Returns a match on documents that exclude the term. For example, wifi -luxury searches for documents that have the wifi term but not luxury.

¹ The | character isn't supported for OR operations.

NOT Boolean operator

 **Important**

The NOT operator (`NOT`, `!`, or `-`) behaves differently in full syntax than it does in simple syntax.

- In simple syntax, queries with negation always have a wildcard automatically added. For example, the query `-luxury` is automatically expanded to `-luxury *`.
- In full syntax, queries with negation cannot be combined with a wildcard. For example, the queries `-luxury *` is not allowed.
- In full syntax, queries with a single negation are not allowed. For example, the query `-luxury` is not allowed.
- In full syntax, negations will behave as if they are always ANDed onto the query regardless of the search mode.
 - For example, the full syntax query `wifi -luxury` in full syntax only fetches documents that contain the term `wifi`, and then applies the negation `-luxury` to those documents.
- If you want to use negations to search over all documents in the index, simple syntax with the `any` search mode is recommended.
- If you want to use negations to search over a subset of documents in the index, full syntax or the simple syntax with the `all` search mode are recommended.

[\[+\] Expand table](#)

Query Type	Search Mode	Example Query	Behavior
Simple	any	<code>wifi -luxury</code>	Returns all documents in the index. Documents with the term "wifi" or documents missing the term "luxury" are ranked higher than other documents. The query is expanded to <code>wifi OR -luxury OR *</code> .
Simple	all	<code>wifi -luxury</code>	Returns only documents in the index that contain the term "wifi" and don't contain the term "luxury". The query is expanded to <code>wifi AND -luxury AND *</code> .
Full	any	<code>wifi -luxury</code>	Returns only documents in the index that contain the term "wifi", and then documents that contain the term "luxury" are removed from the results.
Full	all	<code>wifi -luxury</code>	Returns only documents in the index that contain the term "wifi", and then documents that contain the term "luxury" are removed from the results.

Fielded search

You can define a fielded search operation with the `fieldName:searchExpression` syntax, where the search expression can be a single word or a phrase, or a more complex expression in parentheses, optionally with Boolean operators. Some examples include the following:

- `genre:jazz NOT history`
- `artists:(“Miles Davis” “John Coltrane”)`

Be sure to put multiple strings within quotation marks if you want both strings to be evaluated as a single entity, in this case searching for two distinct artists in the `artists` field.

The field specified in `fieldName:searchExpression` must be a `searchable` field. See [Create Index](#) for details on how index attributes are used in field definitions.

ⓘ Note

When using fielded search expressions, you do not need to use the `searchFields` parameter because each fielded search expression has a field name explicitly specified. However, you can still use the `searchFields` parameter if you want to run a query where some parts are scoped to a specific field, and the rest could apply to several fields. For example, the query `search=genre:jazz NOT history&searchFields=description` would match `jazz` only to the `genre` field, while it would match `NOT history` with the `description` field. The field name provided in `fieldName:searchExpression` always takes precedence over the `searchFields` parameter, which is why in this example, we do not need to include `genre` in the `searchFields` parameter.

Fuzzy search

A fuzzy search finds matches in terms that have a similar construction, expanding a term up to the maximum of 50 terms that meet the distance criteria of two or less. For more information, see [Fuzzy search](#).

To do a fuzzy search, use the tilde `~` symbol at the end of a single word with an optional parameter, a number between 0 and 2 (default), that specifies the edit distance. For example, `blue~` or `blue~1` would return `blue`, `blues`, and `glue`.

Fuzzy search can only be applied to terms, not quotation-enclosed phrases, but you can append the tilde to each term individually in a multi-part name or phrase. For example,

Unviersty~ of~ Wshington~ would match on University of Washington.

Proximity search

Proximity searches are used to find terms that are near each other in a document. Insert a tilde ~ symbol at the end of a phrase followed by the number of words that create the proximity boundary. For example, "hotel airport"~5 finds the terms hotel and airport within five words of each other in a document.

Term boosting

Term boosting refers to ranking a document higher if it contains the boosted term, relative to documents that don't contain the term. This differs from scoring profiles in that scoring profiles boost certain fields, rather than specific terms.

The following example helps illustrate the differences. Suppose that there's a scoring profile that boosts matches in a certain field, say *genre* in the [musicstoreindex](#) example. Term boosting could be used to further boost certain search terms higher than others. For example, rock^2 electronic boosts documents that contain the search terms in the genre field higher than other searchable fields in the index. Further, documents that contain the search term *rock* are ranked higher than the other search term *electronic* as a result of the term boost value (2).

To boost a term, use the caret, ^, symbol with a boost factor (a number) at the end of the term you're searching. You can also boost phrases. The higher the boost factor, the more relevant the term is relative to other search terms. By default, the boost factor is 1. Although the boost factor must be positive, it can be less than 1 (for example, 0.20).

Regular expression search

A regular expression search finds a match based on patterns that are valid under Apache Lucene, as documented in the [RegExp class](#).

In Azure AI Search, a regular expression is:

- Enclosed between forward slashes /
- Lower-case only

For example, to find documents containing motel or hotel, specify /[mh]otel/. Regular expression searches are matched against single words.

Some tools and languages impose extra escape character requirements beyond the [escape rules](#) imposed by Azure AI Search. For JSON, strings that include a forward slash are escaped with a backward slash: `microsoft.com/azure/` becomes `search=/.*microsoft.com\azure\/.*/` where `search=/.* <string-placeholder>.*/` sets up the regular expression, and `microsoft.com\azure\/` is the string with an escaped forward slash.

Two common symbols in regex queries are `.` and `*`. A `.` matches any one character and a `*` matches the previous character zero or more times. For example, `/be./` matches the terms `bee` and `bet` while `/be*/` would match `be`, `bee`, and `beee` but not `bet`. Together, `.*` allow you to match any series of characters so `/be.*/` would match any term that starts with `be` such as `better`.

If you get syntax errors in your regular expression, review the [escape rules](#) for special characters. You might also try a different client to confirm whether the problem is tool-specific.

Wildcard search

You can use generally recognized syntax for multiple (*) or single (?) character wildcard searches. Full Lucene syntax supports prefix and infix matching. Use [regular expression](#) syntax for suffix matching.

Note the Lucene query parser supports the use of these symbols with a single term, and not a phrase.

[] Expand table

Affix type	Description and examples
prefix	Term fragment comes before <code>*</code> or <code>?</code> . For example, a query expression of <code>search=alpha*</code> returns <code>alphanumeric</code> or <code>alphabetical</code> . Prefix matching is supported in both simple and full syntax.
suffix	Term fragment comes after <code>*</code> or <code>?</code> , with a forward slash to delimit the construct. For example, <code>search=/.*numeric/</code> returns <code>alphanumeric</code> .
infix	Term fragments enclose <code>*</code> or <code>?</code> . For example, <code>search=non*al</code> returns <code>non-numerical</code> and <code>nonsensical</code> .

You can combine operators in one expression. For example, `980?2*` matches on `98072-1222` and `98052-1234`, where `?` matches on a single (required) character, and `*` matches

on characters of an arbitrary length that follow.

Suffix matching requires the regular expression forward slash / delimiters. Generally, you can't use a * or ? symbol as the first character of a term, without the /. It's also important to note that the * behaves differently when used outside of regex queries. Outside of the regex forward slash / delimiter, the * is a wildcard character and matches any series of characters much like .* in regex. As an example, `search=/non.*a1/` produces the same result set as `search=non*a1`.

ⓘ Note

As a rule, pattern matching is slow so you might want to explore alternative methods, such as edge n-gram tokenization that creates tokens for sequences of characters in a term. With n-gram tokenization, the index will be larger, but queries might execute faster, depending on the pattern construction and the length of strings you are indexing. For more information, see [Partial term search and patterns with special characters](#).

Effect of an analyzer on wildcard queries

During query parsing, queries that are formulated as prefix, suffix, wildcard, or regular expressions are passed as-is to the query tree, bypassing [lexical analysis](#). Matches will only be found if the index contains the strings in the format your query specifies. In most cases, you need an analyzer during indexing that preserves string integrity so that partial term and pattern matching succeeds. For more information, see [Partial term search in Azure AI Search queries](#).

Consider a situation where you might want the search query `terminal*` to return results that contain terms such as `terminate`, `termination`, and `terminates`.

If you were to use the en.lucene (English Lucene) analyzer, it would apply aggressive stemming of each term. For example, `terminate`, `termination`, `terminates` will all be tokenized down to the token `termi` in your index. On the other side, terms in queries using wildcards or fuzzy search aren't analyzed at all, so there would be no results that would match the `terminat*` query.

On the other side, the Microsoft analyzers (in this case, the en.microsoft analyzer) are a bit more advanced and use lemmatization instead of stemming. This means that all generated tokens should be valid English words. For example, `terminate`, `terminates`,

and `termination` will mostly stay whole in the index, and would be a preferable choice for scenarios that depend a lot on wildcards and fuzzy search.

Scoring wildcard and regex queries

Azure AI Search uses frequency-based scoring ([BM25 ↗](#)) for text queries. However, for wildcard and regex queries where scope of terms can potentially be broad, the frequency factor is ignored to prevent the ranking from biasing towards matches from rarer terms. All matches are treated equally for wildcard and regex searches.

Special characters

In some circumstances, you might want to search for a special character, like an '♥' emoji or the '€' sign. In such cases, make sure that the analyzer you use doesn't filter those characters out. The standard analyzer bypasses many special characters, excluding them from your index.

Analyzers that tokenize special characters include the whitespace analyzer, which takes into consideration any character sequences separated by whitespaces as tokens (so the ❤ string would be considered a token). Also, a language analyzer like the Microsoft English analyzer ("en.microsoft"), would take the "€" string as a token. You can [test an analyzer](#) to see what tokens it generates for a given query.

When using Unicode characters, make sure symbols are properly escaped in the query url (for instance for ❤ would use the escape sequence `%E2%9D%A4+`). Some REST clients do this translation automatically.

Precedence (grouping)

You can use parentheses to create subqueries, including operators within the parenthetical statement. For example, `motel+(wifi|luxury)` searches for documents containing the `motel` term and either `wifi` or `luxury` (or both).

Field grouping is similar but scopes the grouping to a single field. For example, `hotelAmenities:(gym+(wifi|pool))` searches the field `hotelAmenities` for `gym` and `wifi`, or `gym` and `pool`.

Query size limits

Azure AI Search imposes limits on query size and composition because unbounded queries can destabilize your search service. There are limits on query size and composition (the number of clauses). Limits also exist for the length of prefix search and for the complexity of regex search and wildcard search. If your application generates search queries programmatically, we recommend designing it in such a way that it doesn't generate queries of unbounded size.

For more information on query limits, see [API request limits](#).

moreLikeThis (preview) in Azure AI Search

Article • 02/20/2025

ⓘ Important

This feature is in public preview under [Supplemental Terms of Use](#). The [preview REST API](#) supports this feature.

`moreLikeThis=[key]` is a query parameter in the [Search Documents API](#) that finds documents similar to the document specified by the document key. When a search request is made with `moreLikeThis`, a query is generated with search terms extracted from the given document that describe that document best. The generated query is then used to make the search request. The `moreLikeThis` parameter can't be used with the search parameter, `search=[string]`.

By default, the contents of all top-level searchable fields are considered. If you want to specify particular fields instead, you can use the `searchFields` parameter.

The `moreLikeThis` parameter isn't supported for [complex types](#) and the presence of complex types will impact your query logic. If your index is a complex type, you must set `searchFields` to the top-level searchable fields over which `moreLikeThis` iterates. For example, if the index has a searchable `field1` of type `Edm.String`, and `field2` that's a complex type with searchable subfields, the value of `searchFields` must be set to `field1` to exclude `field2`.

Examples

All following examples use the hotels sample from [Quickstart: Create a search index in the Azure portal](#).

Simple query

The following query finds documents whose description fields are most similar to the field of the source document as specified by the `moreLikeThis` parameter:

HTTP

```
GET /indexes/hotels-sample-index/docs?  
moreLikeThis=29&searchFields=Description&api-version=2024-05-01-preview
```

In this example, the request searches for hotels similar to the one with `HotelId` 29. Rather than using HTTP GET, you can also invoke `MoreLikeThis` using HTTP POST:

HTTP

```
POST /indexes/hotels-sample-index/docs/search?api-version=2024-05-01-preview  
{  
  "moreLikeThis": "29",  
  "searchFields": "Description"  
}
```

Apply filters

`MoreLikeThis` can be combined with other common query parameters like `$filter`. For instance, the query can be restricted to only hotels whose category is 'Budget' and where the rating is higher than 3.5:

HTTP

```
GET /indexes/hotels-sample-index/docs?  
moreLikeThis=20&searchFields=Description&$filter=(Category eq 'Budget' and  
Rating gt 3.5)&api-version=2024-05-01-preview
```

Select fields and limit results

The `$top` selector can be used to limit how many results should be returned in a `MoreLikeThis` query. Also, fields can be selected with `$select`. Here the top three hotels are selected along with their ID, Name, and Rating:

HTTP

```
GET /indexes/hotels-sample-index/docs?  
moreLikeThis=20&searchFields=Description&$filter=(Category eq 'Budget' and  
Rating gt 3.5)&$top=3&$select=HotelId,HotelName,Rating&api-version=2024-05-  
01-preview
```

Next steps

You can use any REST client for this exercise.

OData language overview for `$filter`, `$orderby`, and `$select` in Azure AI Search

Article • 12/10/2024

This article provides an overview of the OData expression language used in `$filter`, `$order-by`, and `$select` expressions for keyword search in Azure AI Search over numeric and string (nonvector) fields.

The language is presented "bottom-up" starting with the most basic elements. The OData expressions that you can construct in a query request range from simple to highly complex, but they all share common elements. Shared elements include:

- **Field paths**, which refer to specific fields of your index.
- **Constants**, which are literal values of a certain data type.

Once you understand these common concepts, you can continue with the top-level syntax for each expression:

- **`$filter`** expressions are evaluated during query parsing, constraining search to specific fields or adding match criteria used during index scans.
- **`$orderby`** expressions are applied as a post-processing step over a result set to sort the documents that are returned.
- **`$select`** expressions determine which document fields are included in the result set.

The syntax of these expressions is distinct from the [simple](#) or [full](#) query syntax used in the `search` parameter, although there's some overlap in the syntax for referencing fields.

For examples in other languages such as Python or C#, see the examples in the [azure-search-vector-samples](#) repository.

ⓘ Note

Terminology in Azure AI Search differs from the [OData standard](#) in a few ways. What we call a **field** in Azure AI Search is called a **property** in OData, and similarly for **field path** versus **property path**. An **index** containing **documents** in Azure AI Search is referred to more generally in OData as an **entity set** containing **entities**. The Azure AI Search terminology is used throughout this reference.

Field paths

The following EBNF (Extended Backus-Naur Form [↗](#)) defines the grammar of field paths.

```
OData  
field_path ::= identifier('/'identifier)*  
identifier ::= [a-zA-Z_][a-zA-Z_0-9]*
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

 **Note**

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

A field path is composed of one or more **identifiers** separated by slashes. Each identifier is a sequence of characters that must start with an ASCII letter or underscore, and contain only ASCII letters, digits, or underscores. The letters can be upper- or lowercase.

An identifier can refer either to the name of a field, or to a **range variable** in the context of a [collection expression](#) (`any` or `all`) in a filter. A range variable is like a loop variable that represents the current element of the collection. For complex collections, that variable represents an object, which is why you can use field paths to refer to subfields of the variable. This is analogous to dot notation in many programming languages.

Examples of field paths are shown in the following table:

 [Expand table](#)

Field path	Description
<code>HotelName</code>	Refers to a top-level field of the index
<code>Address/City</code>	Refers to the <code>City</code> subfield of a complex field in the index; <code>Address</code> is of type <code>Edm.ComplexType</code> in this example
<code>Rooms/Type</code>	Refers to the <code>Type</code> subfield of a complex collection field in the index; <code>Rooms</code> is of type <code>Collection(Edm.ComplexType)</code> in this example

Field path	Description
Stores/Address/Country	Refers to the <code>Country</code> subfield of the <code>Address</code> subfield of a complex collection field in the index; <code>Stores</code> is of type <code>Collection(Edm.ComplexType)</code> and <code>Address</code> is of type <code>Edm.ComplexType</code> in this example
room/Type	Refers to the <code>Type</code> subfield of the <code>room</code> range variable, for example in the filter expression <code>Rooms/any(room: room/Type eq 'deluxe')</code>
store/Address/Country	Refers to the <code>Country</code> subfield of the <code>Address</code> subfield of the <code>store</code> range variable, for example in the filter expression <code>Stores/any(store: store/Address/Country eq 'Canada')</code>

The meaning of a field path differs depending on the context. In filters, a field path refers to the value of a *single instance* of a field in the current document. In other contexts, such as `$orderby`, `$select`, or in [fielded search in the full Lucene syntax](#), a field path refers to the field itself. This difference has some consequences for how you use field paths in filters.

Consider the field path `Address/City`. In a filter, this refers to a single city for the current document, like "San Francisco". In contrast, `Rooms/Type` refers to the `Type` subfield for many rooms (like "standard" for the first room, "deluxe" for the second room, and so on). Since `Rooms/Type` doesn't refer to a *single instance* of the subfield `Type`, it can't be used directly in a filter. Instead, to filter on room type, you would use a [lambda expression](#) with a range variable, like this:

OData
<code>Rooms/any(room: room/Type eq 'deluxe')</code>

In this example, the range variable `room` appears in the `room/Type` field path. That way, `room/Type` refers to the type of the current room in the current document. This is a single instance of the `Type` subfield, so it can be used directly in the filter.

Using field paths

Field paths are used in many parameters of the [Azure AI Search REST APIs](#). The following table lists all the places where they can be used, plus any restrictions on their usage:

[Expand table](#)

API	Parameter name	Restrictions
Create or Update Index	suggesters/sourceFields	None
Create or Update Index	scoringProfiles/text/weights	Can only refer to searchable fields
Create or Update Index	scoringProfiles/functions/fieldName	Can only refer to filterable fields
Search	search when queryType is full	Can only refer to searchable fields
Search	facet	Can only refer to facetable fields
Search	highlight	Can only refer to searchable fields
Search	searchFields	Can only refer to searchable fields
Suggest and Autocomplete	searchFields	Can only refer to fields that are part of a suggester
Search, Suggest, and Autocomplete	\$filter	Can only refer to filterable fields
Search and Suggest	\$orderby	Can only refer to sortable fields
Search, Suggest, and Lookup	\$select	Can only refer to retrievable fields

Constants

Constants in OData are literal values of a given [Entity Data Model \(EDM\)](#) type. See [Supported data types](#) for a list of supported types in Azure AI Search. Constants of collection types aren't supported.

The following table shows examples of constants for each of the nonvector data types that support OData expressions:

[] [Expand table](#)

Data type	Example constants
Edm.Boolean	true, false

Data type	Example constants
Edm.DateTimeOffset	2019-05-06T12:30:05.451Z
Edm.Double	3.14159, -1.2e7, NaN, INF, -INF
Edm.GeographyPoint	geography 'POINT(-122.131577 47.678581)'
Edm.GeographyPolygon	geography 'POLYGON((-122.031577 47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581))'
Edm.Int32	123, -456
Edm.Int64	283032927235
Edm.String	'hello'

Escaping special characters in string constants

String constants in OData are delimited by single quotes. If you need to construct a query with a string constant that might itself contain single quotes, you can escape the embedded quotes by doubling them.

For example, a phrase with an unformatted apostrophe like "Alice's car" would be represented in OData as the string constant '`Alice''s car`'.

ⓘ Important

When constructing filters programmatically, it's important to remember to escape string constants that come from user input. This is to mitigate the possibility of [injection attacks](#), especially when using filters to implement [security trimming](#).

Constants syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar for most of the constants shown in the above table. The grammar for geo-spatial types can be found in [OData geo-spatial functions in Azure AI Search](#).

OData

```
constant ::=  
    string_literal  
    | date_time_offset_literal  
    | integer_literal  
    | float_literal
```

```

| boolean_literal
| 'null'

string_literal ::= '"'([^\"] | \"")*"""

date_time_offset_literal ::= date_part'T' time_part time_zone

date_part ::= year'-'month'-'day

time_part ::= hour':'minute(':'second('.'fractional_seconds)?)?

zero_to_fifty_nine ::= [0-5]digit

digit ::= [0-9]

year ::= digit digit digit digit

month ::= '0'[1-9] | '1'[0-2]

day ::= '0'[1-9] | [1-2]digit | '3'[0-1]

hour ::= [0-1]digit | '2'[0-3]

minute ::= zero_to_fifty_nine

second ::= zero_to_fifty_nine

fractional_seconds ::= integer_literal

time_zone ::= 'Z' | sign hour':'minute

sign ::= '+' | '-'

/* In practice integer literals are limited in length to the precision of
the corresponding EDM data type. */
integer_literal ::= digit+

float_literal ::=
    sign? whole_part fractional_part? exponent?
    | 'NaN'
    | '-INF'
    | 'INF'

whole_part ::= integer_literal

fractional_part ::= '.'integer_literal

exponent ::= 'e' sign? integer_literal

boolean_literal ::= 'true' | 'false'

```

An interactive syntax diagram is also available:

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

Building expressions from field paths and constants

Field paths and constants are the most basic part of an OData expression, but they're already full expressions themselves. In fact, the `$select` parameter in Azure AI Search is nothing but a comma-separated list of field paths, and `$orderby` isn't much more complicated than `$select`. If you happen to have a field of type `Edm.Boolean` in your index, you can even write a filter that is nothing but the path of that field. The constants `true` and `false` are likewise valid filters.

However, it's more common to have complex expressions that refer to more than one field and constant. These expressions are built in different ways depending on the parameter.

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar for the `$filter`, `$orderby`, and `$select` parameters. These are built up from simpler expressions that refer to field paths and constants:

OData

```
filter_expression ::= boolean_expression  
  
order_by_expression ::= order_by_clause(' ',' order_by_clause)*  
  
select_expression ::= '*' | field_path(' ', field_path)*
```

An interactive syntax diagram is also available:

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

Next steps

The `$orderby` and `$select` parameters are both comma-separated lists of simpler expressions. The `$filter` parameter is a Boolean expression that is composed of simpler subexpressions. These subexpressions are combined using logical operators such as [and](#), [or](#), [and not](#), comparison operators such as [eq](#), [lt](#), [gt](#), and so on, and collection operators such as [any](#) and [all](#).

The `$filter`, `$orderby`, and `$select` parameters are explored in more detail in the following articles:

- [OData \\$filter syntax in Azure AI Search](#)
- [OData \\$orderby syntax in Azure AI Search](#)
- [OData \\$select syntax in Azure AI Search](#)

OData \$filter syntax in Azure AI Search

Article • 08/28/2024

In Azure AI Search, the `$filter` parameter specifies inclusion or exclusion criteria for returning matches in search results. This article describes the OData syntax of `$filter` and provides examples.

Field path construction and constants are described in the [OData language overview in Azure AI Search](#). For more information about filter scenarios, see [Filters in Azure AI Search](#).

Syntax

A filter in the OData language is a Boolean expression, which in turn can be one of several types of expression, as shown by the following EBNF ([Extended Backus-Naur Form](#)):

```
boolean_expression ::=  
    collection_filter_expression  
    | logical_expression  
    | comparison_expression  
    | boolean_literal  
    | boolean_function_call  
    | '(' boolean_expression ')'  
    | variable  
  
/* This can be a range variable in the case of a lambda, or a field path. */  
variable ::= identifier | field_path
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

The types of Boolean expressions include:

- Collection filter expressions using `any` or `all`. These apply filter criteria to collection fields. For more information, see [OData collection operators in Azure AI Search](#).
- Logical expressions that combine other Boolean expressions using the operators `and`, `or`, and `not`. For more information, see [OData logical operators in Azure AI Search](#).
- Comparison expressions, which compare fields or range variables to constant values using the operators `eq`, `ne`, `gt`, `lt`, `ge`, and `le`. For more information, see [OData comparison operators in Azure AI Search](#). Comparison expressions are also used to compare distances between geo-spatial coordinates using the `geo.distance` function. For more information, see [OData geo-spatial functions in Azure AI Search](#).
- The Boolean literals `true` and `false`. These constants can be useful sometimes when programmatically generating filters, but otherwise don't tend to be used in practice.
- Calls to Boolean functions, including:
 - `geo.intersects`, which tests whether a given point is within a given polygon. For more information, see [OData geo-spatial functions in Azure AI Search](#).
 - `search.in`, which compares a field or range variable with each value in a list of values. For more information, see [OData search.in function in Azure AI Search](#).
 - `search.ismatch` and `search.ismatchscoring`, which execute full-text search operations in a filter context. For more information, see [OData full-text search functions in Azure AI Search](#).
- Field paths or range variables of type `Edm.Boolean`. For example, if your index has a Boolean field called `.IsEnabled` and you want to return all documents where this field is `true`, your filter expression can just be the name `.IsEnabled`.
- Boolean expressions in parentheses. Using parentheses can help to explicitly determine the order of operations in a filter. For more information on the default precedence of the OData operators, see the next section.

Operator precedence in filters

If you write a filter expression with no parentheses around its sub-expressions, Azure AI Search will evaluate it according to a set of operator precedence rules. These rules are based on which operators are used to combine sub-expressions. The following table lists groups of operators in order from highest to lowest precedence:

[\[\] Expand table](#)

Group	Operator(s)
Logical operators	not
Comparison operators	eq, ne, gt, lt, ge, le
Logical operators	and
Logical operators	or

An operator that is higher in the above table will "bind more tightly" to its operands than other operators. For example, `and` is of higher precedence than `or`, and comparison operators are of higher precedence than either of them, so the following two expressions are equivalent:

odata-filter Expr

```
Rating gt 0 and Rating lt 3 or Rating gt 7 and Rating lt 10
((Rating gt 0) and (Rating lt 3)) or ((Rating gt 7) and (Rating lt 10))
```

The `not` operator has the highest precedence of all -- even higher than the comparison operators. That's why if you try to write a filter like this:

odata-filter Expr

```
not Rating gt 5
```

You'll get this error message:

text

```
Invalid expression: A unary operator with an incompatible type was
detected. Found operand type 'Edm.Int32' for operator kind 'Not'.
```

This error happens because the operator is associated with just the `Rating` field, which is of type `Edm.Int32`, and not with the entire comparison expression. The fix is to put the operand of `not` in parentheses:

odata-filter Expr

```
not (Rating gt 5)
```

Filter size limitations

There are limits to the size and complexity of filter expressions that you can send to Azure AI Search. The limits are based roughly on the number of clauses in your filter expression. A good guideline is that if you have hundreds of clauses, you are at risk of exceeding the limit. We recommend designing your application in such a way that it doesn't generate filters of unbounded size.

💡 Tip

Using [the search.in function](#) instead of long disjunctions of equality comparisons can help avoid the filter clause limit, since a function call counts as a single clause.

Examples

Find all hotels with at least one room with a base rate less than \$200 that are rated at or above 4:

odata-filter-expr

```
$filter=Rooms/any(room: room/BaseRate lt 200.0) and Rating ge 4
```

Find all hotels other than "Sea View Motel" that have been renovated since 2010:

odata-filter-expr

```
$filter=HotelName ne 'Sea View Motel' and LastRenovationDate ge 2010-01-01T00:00:00Z
```

Find all hotels that were renovated in 2010 or later. The datetime literal includes time zone information for Pacific Standard Time:

odata-filter-expr

```
$filter=LastRenovationDate ge 2010-01-01T00:00:00-08:00
```

Find all hotels that have parking included and where all rooms are non-smoking:

odata-filter-expr

```
$filter=ParkingIncluded and Rooms/all(room: not room/SmokingAllowed)
```

- OR -

odata-filter-expr

```
$filter=ParkingIncluded eq true and Rooms/all(room: room/SmokingAllowed eq false)
```

Find all hotels that are Luxury or include parking and have a rating of 5:

odata-filter-expr

```
$filter=(Category eq 'Luxury' or ParkingIncluded eq true) and Rating eq 5
```

Find all hotels with the tag "wifi" in at least one room (where each room has tags stored in a `Collection(Edm.String)` field):

odata-filter-expr

```
$filter=Rooms/any(room: room/Tags/any(tag: tag eq 'wifi'))
```

Find all hotels with any rooms:

odata-filter-expr

```
$filter=Rooms/any()
```

Find all hotels that don't have rooms:

odata-filter-expr

```
$filter=not Rooms/any()
```

Find all hotels within 10 kilometers of a given reference point (where `Location` is a field of type `Edm.GeographyPoint`):

odata-filter-expr

```
$filter=geo.distance(Location, geography'POINT(-122.131577 47.678581)') le 10
```

Find all hotels within a given viewport described as a polygon (where `Location` is a field of type `Edm.GeographyPoint`). The polygon must be closed, meaning the first and last point sets must be the same. Also, [the points must be listed in counterclockwise order](#).

odata-filter-expr

```
$filter=geo.intersects(Location, geography'POLYGON((-122.031577  
47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577  
47.578581)))')
```

Find all hotels where the "Description" field is null. The field will be null if it was never set, or if it was explicitly set to null:

odata-filter-expr

```
$filter=Description eq null
```

Find all hotels with name equal to either 'Sea View motel' or 'Budget hotel'). These phrases contain spaces, and space is a default delimiter. You can specify an alternative delimiter in single quotes as the third string parameter:

odata-filter-expr

```
$filter=search.in(HotelName, 'Sea View motel,Budget hotel', ',')
```

Find all hotels with name equal to either 'Sea View motel' or 'Budget hotel' separated by '|':

odata-filter-expr

```
$filter=search.in(HotelName, 'Sea View motel|Budget hotel', '|')
```

Find all hotels where all rooms have the tag 'wifi' or 'tub':

odata-filter-expr

```
$filter=Rooms/any(room: room/Tags/any(tag: search.in(tag, 'wifi, tub')))
```

Find a match on phrases within a collection, such as 'heated towel racks' or 'hairdryer included' in tags.

odata-filter-expr

```
$filter=Rooms/any(room: room/Tags/any(tag: search.in(tag, 'heated towel  
racks,hairdryer included', ',')))
```

Find documents with the word "waterfront". This filter query is identical to a [search request](#) with `search=waterfront`.

```
odata-filter-expr
```

```
$filter=search.ismatchscoring('waterfront')
```

Find documents with the word "hostel" and rating greater or equal to 4, or documents with the word "motel" and rating equal to 5. This request couldn't be expressed without the `search.ismatchscoring` function since it combines full-text search with filter operations using `or`.

```
odata-filter-expr
```

```
$filter=search.ismatchscoring('hostel') and rating ge 4 or  
search.ismatchscoring('motel') and rating eq 5
```

Find documents without the word "luxury".

```
odata-filter-expr
```

```
$filter=not search.ismatch('luxury')
```

Find documents with the phrase "ocean view" or rating equal to 5. The `search.ismatchscoring` query will be executed only against fields `HotelName` and `Description`. Documents that matched only the second clause of the disjunction will be returned too -- hotels with `Rating` equal to 5. Those documents will be returned with score equal to zero to make it clear that they didn't match any of the scored parts of the expression.

```
odata-filter-expr
```

```
$filter=search.ismatchscoring('"ocean view"', 'Description,HotelName')  
or Rating eq 5
```

Find hotels where the terms "hotel" and "airport" are no more than five words apart in the description, and where all rooms are non-smoking. This query uses the [full Lucene query language](#).

```
odata-filter-expr
```

```
$filter=search.ismatch('"hotel airport"~5', 'Description', 'full',
```

```
'any') and not Rooms/any(room: room/SmokingAllowed)
```

Find documents that have a word that starts with the letters "lux" in the Description field. This query uses [prefix search](#) in combination with `search.ismatch`.

odata-filter-expr

```
$filter=search.ismatch('lux*', 'Description')
```

OData \$orderby syntax in Azure AI Search

Article • 08/28/2024

In Azure AI Search, the `$orderby` parameter specifies a custom sort order for search results. This article describes the OData syntax of `$orderby` and provides examples.

Field path construction and constants are described in the [OData language overview in Azure AI Search](#). For more information about sorting behaviors, see [Ordering results](#).

Syntax

The `$orderby` parameter accepts a comma-separated list of up to 32 **order-by clauses**. The syntax of an order-by clause is described by the following EBNF ([Extended Backus-Naur Form ↗](#)):

```
order_by_clause ::= (field_path | sortable_function) ('asc' | 'desc')?  
sortable_function ::= geo_distance_call | 'search.score()'
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

Each clause has sort criteria, optionally followed by a sort direction (`asc` for ascending or `desc` for descending). If you don't specify a direction, the default is ascending. If there are null values in the field, null values appear first if the sort is `asc` and last if the sort is `desc`.

The sort criteria can either be the path of a `sortable` field or a call to either the `geo.distance` or the `search.score` functions.

For string fields, the default [ASCII sort order](#) and default [Unicode sort order](#) will be used. By default, sorting is case sensitive but you can use a [normalizer](#) to preprocess the text before sorting to change this behavior. You can also use an `asciifolding` normalizer to convert non-ASCII characters to their ASCII equivalent, if one exists.

If multiple documents have the same sort criteria and the `search.score` function isn't used (for example, if you sort by a numeric `Rating` field and three documents all have a rating of 4), ties will be broken by document score in descending order. When document scores are the same (for example, when there's no full-text search query specified in the request), then the relative ordering of the tied documents is indeterminate.

You can specify multiple sort criteria. The order of expressions determines the final sort order. For example, to sort descending by score, followed by Rating, the syntax would be `$orderby=search.score() desc,Rating desc`.

The syntax for `geo.distance` in `$orderby` is the same as it is in `$filter`. When using `geo.distance` in `$orderby`, the field to which it applies must be of type `Edm.GeographyPoint` and it must also be `sortable`.

The syntax for `search.score` in `$orderby` is `search.score()`. The function `search.score` doesn't take any parameters.

Examples

Sort hotels ascending by base rate:

```
odata-filter-expr  
$orderby=BaseRate asc
```

Sort hotels descending by rating, then ascending by base rate (remember that ascending is the default):

```
odata-filter-expr  
$orderby=Rating desc,BaseRate
```

Sort hotels descending by rating, then ascending by distance from the given coordinates:

```
odata-filter-expr
```

```
$orderby=Rating desc,geo.distance(Location, geography'POINT(-122.131577  
47.678581)') asc
```

Sort hotels in descending order by search.score and rating, and then in ascending order by distance from the given coordinates. Between two hotels with identical relevance scores and ratings, the closest one is listed first:

odata-filter-expr

```
$orderby=search.score() desc,Rating desc,geo.distance(Location,  
geography'POINT(-122.131577 47.678581)') asc
```

OData \$select syntax in Azure AI Search

Article • 08/28/2024

In Azure AI Search, the **\$select** parameter specifies which fields to include in search results. This article describes the OData syntax of **\$select** and provides examples.

Field path construction and constants are described in the [OData language overview in Azure AI Search](#). For more information about search result composition, see [How to work with search results in Azure AI Search](#).

Syntax

The **\$select** parameter determines which fields for each document are returned in the query result set. The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar for the **\$select** parameter:

```
select_expression ::= '*' | field_path(',') field_path)*  
field_path ::= identifier('/'identifier)*
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

The **\$select** parameter comes in two forms:

1. A single star (*), indicating that all retrievable fields should be returned, or
2. A comma-separated list of field paths, identifying which fields should be returned.

When using the second form, you may only specify retrievable fields in the list.

If you list a complex field without specifying its subfields explicitly, all retrievable subfields will be included in the query result set. For example, assume your index has an

`Address` field with `Street`, `City`, and `Country` subfields that are all retrievable. If you specify `Address` in `$select`, the query results will include all three subfields.

Examples

Include the `HotelId`, `HotelName`, and `Rating` top-level fields in the results, and include the `City` subfield of `Address`:

odata-filter-expr

```
$select=HotelId, HotelName, Rating, Address/City
```

An example result might look like this:

JSON

```
{
  "HotelId": "1",
  "HotelName": "Stay-Kay City Hotel",
  "Rating": 4,
  "Address": {
    "City": "New York"
  }
}
```

Include the `HotelName` top-level field in the results. Include all subfields of `Address`.

Include the `Type` and `BaseRate` subfields of each object in the `Rooms` collection:

odata-filter-expr

```
$select=HotelName, Address, Rooms/Type, Rooms/BaseRate
```

An example result might look like this:

JSON

```
{
  "HotelName": "Stay-Kay City Hotel",
  "Rating": 4,
  "Address": {
    "StreetAddress": "677 5th Ave",
    "City": "New York",
    "StateProvince": "NY",
    "Country": "USA",
    "PostalCode": "10022"
  },
}
```

```
"Rooms": [
  {
    "Type": "Budget Room",
    "BaseRate": 9.69
  },
  {
    "Type": "Budget Room",
    "BaseRate": 8.09
  }
]
```

OData collection operators in Azure AI Search - `any` and `all`

Article • 08/28/2024

When writing an [OData filter expression](#) to use with Azure AI Search, it's often useful to filter on collection fields. You can achieve this using the `any` and `all` operators.

Syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar of an OData expression that uses `any` or `all`.

```
collection_filter_expression ::=  
    field_path'/all(' lambda_expression ')'  
  | field_path'/any(' lambda_expression ')'  
  | field_path'/any()'  
  
lambda_expression ::= identifier ':' boolean_expression
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

There are three forms of expression that filter collections.

- The first two iterate over a collection field, applying a predicate given in the form of a lambda expression to each element of the collection.
 - An expression using `all` returns `true` if the predicate is true for every element of the collection.
 - An expression using `any` returns `true` if the predicate is true for at least one element of the collection.
- The third form of collection filter uses `any` without a lambda expression to test whether a collection field is empty. If the collection has any elements, it returns

`true`. If the collection is empty, it returns `false`.

A **lambda expression** in a collection filter is like the body of a loop in a programming language. It defines a variable, called the **range variable**, that holds the current element of the collection during iteration. It also defines another boolean expression that is the filter criteria to apply to the range variable for each element of the collection.

Examples

Match documents whose `tags` field contains exactly the string "wifi":

```
text  
tags/any(t: t eq 'wifi')
```

Match documents where every element of the `ratings` field falls between 3 and 5, inclusive:

```
text  
ratings/all(r: r ge 3 and r le 5)
```

Match documents where any of the geo coordinates in the `locations` field is within the given polygon:

```
text  
locations/any(loc: geo.intersects(loc, geography'POLYGON((-122.031577  
47.578581, -122.031577 47.678581, -122.131577 47.678581, -122.031577  
47.578581)))')
```

Match documents where the `rooms` field is empty:

```
text  
not rooms/any()
```

Match documents where (for all rooms) the `rooms/amenities` field contains "tv", and `rooms/baseRate` is less than 100:

```
text
```

```
rooms/all(room: room/amenities/any(a: a eq 'tv') and room/baseRate lt 100.0)
```

Limitations

Not every feature of filter expressions is available inside the body of a lambda expression. The limitations differ depending on the data type of the collection field that you want to filter. The following table summarizes the limitations.

[Expand table](#)

Data type	Features allowed in lambda expressions with <code>any</code>	Features allowed in lambda expressions with <code>all</code>
<code>Collection(Edm.ComplexType)</code>	Everything except <code>search.ismatch</code> and <code>search.ismatchscoring</code>	Same
<code>Collection(Edm.String)</code>	Comparisons with <code>eq</code> or <code>search.in</code>	Comparisons with <code>ne</code> or <code>not search.in()</code>
	Combining sub-expressions with <code>or</code>	Combining sub-expressions with <code>and</code>
<code>Collection(Edm.Boolean)</code>	Comparisons with <code>eq</code> or <code>ne</code>	Same
<code>Collection(Edm.GeographyPoint)</code>	Using <code>geo.distance</code> with <code>lt</code> or <code>le</code> <code>geo.intersects</code>	Using <code>geo.distance</code> with <code>gt</code> or <code>ge</code> <code>not geo.intersects(...)</code>
	Combining sub-expressions with <code>or</code>	Combining sub-expressions with <code>and</code>
<code>Collection(Edm.DateTimeOffset)</code> , <code>Collection(Edm.Double)</code> , <code>Collection(Edm.Int32)</code> , <code>Collection(Edm.Int64)</code>	Comparisons using <code>eq</code> , <code>ne</code> , <code>lt</code> , <code>gt</code> , <code>le</code> , or <code>ge</code>	Comparisons using <code>eq</code> , <code>ne</code> , <code>lt</code> , <code>gt</code> , <code>le</code> , or <code>ge</code>
	Combining comparisons with other sub-expressions using <code>or</code>	Combining comparisons with other sub-expressions using <code>and</code>
	Combining comparisons except <code>ne</code> with other sub-expressions using <code>and</code>	Combining comparisons except <code>eq</code> with other sub-expressions using <code>or</code>
	Expressions using	Expressions using

Data type	Features allowed in lambda expressions with <code>any</code>	Features allowed in lambda expressions with <code>all</code>
	combinations of <code>and</code> and <code>or</code> in Disjunctive Normal Form (DNF) ↗	combinations of <code>and</code> and <code>or</code> in Conjunctive Normal Form (CNF) ↗

For more details on these limitations as well as examples, see [Troubleshooting collection filters in Azure AI Search](#). For more in-depth information on why these limitations exist, see [Understanding collection filters in Azure AI Search](#).

OData comparison operators in Azure AI Search - `eq`, `ne`, `gt`, `lt`, `ge`, and `le`

Article • 08/28/2024

The most basic operation in an [OData filter expression](#) in Azure AI Search is to compare a field to a given value. Two types of comparison are possible -- equality comparison, and range comparison. You can use the following operators to compare a field to a constant value:

Equality operators:

- `eq`: Test whether a field is **equal to** a constant value
- `ne`: Test whether a field is **not equal to** a constant value

Range operators:

- `gt`: Test whether a field is **greater than** a constant value
- `lt`: Test whether a field is **less than** a constant value
- `ge`: Test whether a field is **greater than or equal to** a constant value
- `le`: Test whether a field is **less than or equal to** a constant value

You can use the range operators in combination with the [logical operators](#) to test whether a field is within a certain range of values. See the [examples](#) later in this article.

ⓘ Note

If you prefer, you can put the constant value on the left side of the operator and the field name on the right side. For range operators, the meaning of the comparison is reversed. For example, if the constant value is on the left, `gt` would test whether the constant value is greater than the field. You can also use the comparison operators to compare the result of a function, such as `geo.distance`, with a value. For Boolean functions such as `search.ismatch`, comparing the result to `true` or `false` is optional.

Syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar of an OData expression that uses the comparison operators.

```
comparison_expression ::=  
    variable_or_function comparison_operator constant |  
    constant comparison_operator variable_or_function  
  
variable_or_function ::= variable | function_call  
  
comparison_operator ::= 'gt' | 'lt' | 'ge' | 'le' | 'eq' | 'ne'
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

 Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

There are two forms of comparison expressions. The only difference between them is whether the constant appears on the left- or right-hand-side of the operator. The expression on the other side of the operator must be a **variable** or a function call. A variable can be either a field name, or a range variable in the case of a [lambda expression](#).

Data types for comparisons

The data types on both sides of a comparison operator must be compatible. For example, if the left side is a field of type `Edm.DateTimeOffset`, then the right side must be a date-time constant. Numeric data types are more flexible. You can compare variables and functions of any numeric type with constants of any other numeric type, with a few limitations, as described in the following table.

 Expand table

Variable or function type	Constant value type	Limitations
<code>Edm.Double</code>	<code>Edm.Double</code>	Comparison is subject to special rules for NaN
<code>Edm.Double</code>	<code>Edm.Int64</code>	Constant is converted to <code>Edm.Double</code> , resulting in a loss of precision for values of large magnitude
<code>Edm.Double</code>	<code>Edm.Int32</code>	n/a

Variable or function type	Constant value type	Limitations
Edm.Int64	Edm.Double	Comparisons to <code>NaN</code> , <code>-INF</code> , or <code>INF</code> are not allowed
Edm.Int64	Edm.Int64	n/a
Edm.Int64	Edm.Int32	Constant is converted to <code>Edm.Int64</code> before comparison
Edm.Int32	Edm.Double	Comparisons to <code>NaN</code> , <code>-INF</code> , or <code>INF</code> are not allowed
Edm.Int32	Edm.Int64	n/a
Edm.Int32	Edm.Int32	n/a

For comparisons that are not allowed, such as comparing a field of type `Edm.Int64` to `NaN`, the Azure AI Search REST API will return an "HTTP 400: Bad Request" error.

ⓘ Important

Even though numeric type comparisons are flexible, we highly recommend writing comparisons in filters so that the constant value is of the same data type as the variable or function to which it is being compared. This is especially important when mixing floating-point and integer values, where implicit conversions that lose precision are possible.

Special cases for `null` and `NaN`

When using comparison operators, it's important to remember that all non-collection fields in Azure AI Search can potentially be `null`. The following table shows all the possible outcomes for a comparison expression where either side can be `null`:

[\[+\] Expand table](#)

Operator	Result when only the field or variable is <code>null</code>	Result when only the constant is <code>null</code>	Result when both the field or variable and the constant are <code>null</code>
<code>gt</code>	<code>false</code>	HTTP 400: Bad Request error	HTTP 400: Bad Request error
<code>lt</code>	<code>false</code>	HTTP 400: Bad Request error	HTTP 400: Bad Request error

Operator	Result when only the field or variable is <code>null</code>	Result when only the constant is <code>null</code>	Result when both the field or variable and the constant are <code>null</code>
<code>ge</code>	<code>false</code>	HTTP 400: Bad Request error	HTTP 400: Bad Request error
<code>le</code>	<code>false</code>	HTTP 400: Bad Request error	HTTP 400: Bad Request error
<code>eq</code>	<code>false</code>	<code>false</code>	<code>true</code>
<code>ne</code>	<code>true</code>	<code>true</code>	<code>false</code>

In summary, `null` is equal only to itself, and is not less or greater than any other value.

If your index has fields of type `Edm.Double` and you upload `NaN` values to those fields, you will need to account for that when writing filters. Azure AI Search implements the IEEE 754 standard for handling `NaN` values, and comparisons with such values produce non-obvious results, as shown in the following table.

[\[+\] Expand table](#)

Operator	Result when at least one operand is <code>NaN</code>
<code>gt</code>	<code>false</code>
<code>lt</code>	<code>false</code>
<code>ge</code>	<code>false</code>
<code>le</code>	<code>false</code>
<code>eq</code>	<code>false</code>
<code>ne</code>	<code>true</code>

In summary, `NaN` is not equal to any value, including itself.

Comparing geo-spatial data

You can't directly compare a field of type `Edm.GeographyPoint` with a constant value, but you can use the `geo.distance` function. This function returns a value of type `Edm.Double`, so you can compare it with a numeric constant to filter based on the distance from constant geo-spatial coordinates. See the [examples](#) below.

Comparing string data

Strings can be compared in filters for exact matches using the `eq` and `ne` operators. These comparisons are case-sensitive.

Examples

Match documents where the `Rating` field is between 3 and 5, inclusive:

```
text  
Rating ge 3 and Rating le 5
```

Match documents where the `Location` field is less than 2 kilometers from the given latitude and longitude:

```
text  
geo.distance(Location, geography'POINT(-122.031577 47.578581)') lt 2.0
```

Match documents where the `LastRenovationDate` field is greater than or equal to January 1st, 2015, midnight UTC:

```
text  
LastRenovationDate ge 2015-01-01T00:00:00.000Z
```

Match documents where the `Details/Sku` field is not `null`:

```
text  
Details/Sku ne null
```

Match documents for hotels where at least one room has type "Deluxe Room", where the string of the `Rooms/Type` field matches the filter exactly:

```
text  
Rooms/any(room: room/Type eq 'Deluxe Room')
```

OData full-text search functions in Azure AI Search - `search.ismatch` and `search.ismatchscoring`

07/10/2025

Azure AI Search supports full-text search in the context of [OData filter expressions](#) via the `search.ismatch` and `search.ismatchscoring` functions. These functions allow you to combine full-text search with strict Boolean filtering in ways that aren't possible just by using the top-level `search` parameter of the [Search API](#).

! Note

The `search.ismatch` and `search.ismatchscoring` functions are only supported in filters in the [Search API](#). They aren't supported in the [Suggest](#) or [Autocomplete](#) APIs.

Syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar of the `search.ismatch` and `search.ismatchscoring` functions:

```
search_is_match_call ::=  
    'search.ismatch'('scoring')? '(' search_is_match_parameters ')'  
  
search_is_match_parameters ::=  
    string_literal(',') string_literal(',', 'query_type', 'search_mode')?  
  
query_type ::= "'full'" | "'simple'"  
  
search_mode ::= "'any'" | "'all'"
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

! Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

search.ismatch

The `search.ismatch` function evaluates a full-text search query as a part of a filter expression. Matching documents are returned in the result set. The following overloads of this function are available:

- `search.ismatch(search)`
- `search.ismatch(search, searchFields)`
- `search.ismatch(search, searchFields, queryType, searchMode)`

The parameters are defined in the following table:

[] [Expand table](#)

Parameter	Type	Description
name		
<code>search</code>	<code>Edm.String</code>	The search query (in either simple or full Lucene query syntax).
<code>searchFields</code>	<code>Edm.String</code>	Comma-separated list of searchable fields to search in; defaults to all searchable fields in the index. When you use fielded search in the <code>search</code> parameter, the field specifiers in the Lucene query override any fields specified in this parameter.
<code>queryType</code>	<code>Edm.String</code>	' <code>simple</code> ' or ' <code>full</code> '; defaults to ' <code>simple</code> '. Specifies what query language was used in the <code>search</code> parameter.
<code>searchMode</code>	<code>Edm.String</code>	' <code>any</code> ' or ' <code>all</code> ', defaults to ' <code>any</code> '. Indicates whether any or all of the search terms in the <code>search</code> parameter must be matched in order to count the document as a match. When you use the Lucene Boolean operators in the <code>search</code> parameter, they take precedence over this parameter.

All the above parameters are equivalent to the corresponding [search request parameters in the Search API](#).

The `search.ismatch` function returns a value of type `Edm.Boolean`, which allows you to compose it with other filter subexpressions using the Boolean [logical operators](#).

! Note

Azure AI Search doesn't support using `search.ismatch` or `search.ismatchscoring` inside lambda expressions. This means it isn't possible to write filters over collections of objects that can correlate full-text search matches with strict filter matches on the same object. For more information on this limitation as well as examples, see [Troubleshooting](#)

[collection filters in Azure AI Search](#). For more in-depth information on why this limitation exists, see [Understanding collection filters in Azure AI Search](#).

search.ismatchscoring

The `search.ismatchscoring` function, like the `search.ismatch` function, returns `true` for documents that match the full-text search query passed as a parameter. The difference between them is that the relevance score of documents matching the `search.ismatchscoring` query contributes to the overall document score, whereas for `search.ismatch`, the document score doesn't change. The following overloads of this function are available with parameters identical to those of `search.ismatch`:

- `search.ismatchscoring(search)`
- `search.ismatchscoring(search, searchFields)`
- `search.ismatchscoring(search, searchFields, queryType, searchMode)`

Both the `search.ismatch` and `search.ismatchscoring` functions can be used in the same filter expression.

Examples

Find documents with the word "waterfront". This filter query is identical to a [search request](#) with `search=waterfront`.

odata-filter-expr

```
search.ismatchscoring('waterfront')
```

Here's the full query syntax for this request, which you can run in Search Explorer in the Azure portal. Output consists of matches on `waterfront`, `water`, and `front`.

JSON

```
{
  "search": "*",
  "select": "HotelId, HotelName, Description",
  "searchMode": "all",
  "queryType": "simple",
  "count": true,
  "filter": "search.ismatchscoring('waterfront')"
}
```

Find documents with the word "pool" and rating greater or equal to 4, or documents with the word "motel" and equal to 3.2. Note, this request couldn't be expressed without the `search.ismatchscoring` function.

odata-filter-expr

```
search.ismatchscoring('pool') and Rating ge 4 or  
search.ismatchscoring('motel') and Rating eq 3.2
```

Here's the full query syntax for this request for Search Explorer. Output consists of matches on hotels with pools having a rating greater than 4, or motels with a rating equal to 3.2.

JSON

```
{  
  "search": "*",
  "select": "HotelId, HotelName, Description, Tags, Rating",
  "searchMode": "all",
  "queryType": "simple",
  "count": true,
  "filter": "search.ismatchscoring('pool') and Rating ge 4 or
            search.ismatchscoring('motel') and Rating eq 3.2"
}
```

Find documents without the word "luxury".

odata-filter-expr

```
not search.ismatch('luxury')
```

Here's the full query syntax for this request. Output consists of matches on the term luxury.

JSON

```
{  
  "search": "*",
  "select": "HotelId, HotelName, Description, Tags, Rating",
  "searchMode": "all",
  "queryType": "simple",
  "count": true,
  "filter": "not search.ismatch('luxury')"
}
```

Find documents with the phrase "ocean" or rating equal to 3.2. The `search.ismatchscoring` query is executed only against fields `HotelName` and `Description`.

Here's the full query syntax for this request. Documents that match only the second clause of the disjunction are returned too (specifically, hotels with `Rating` equal to `3.2`). To make it clear that those documents didn't match any of the scored parts of the expression, they're returned with score equal to zero.

JSON

```
{  
  "search": "*",  
  "select": "HotelId, HotelName, Description, Rating",  
  "searchMode": "all",  
  "queryType": "full",  
  "count": true,  
  "filter": "search.ismatchscoring('ocean', 'Description,HotelName') or Rating eq  
3.2"  
}
```

Output consists of 4 matches: hotels that mention "ocean" in the Description or Hotel Name, or hotels with a rating of 3.2. Notice the search score of zero for matches on the second clause.

JSON

```
{  
  "@odata.count": 4,  
  "value": [  
    {  
      "@search.score": 1.6076145,

    "Description": "Extend Your Stay. Affordable home away from home, with
amenities like free Wi-Fi, full kitchen, and convenient laundry service.",
    "Rating": 3.2
  }
]
}

```

Find documents where the terms "hotel" and "airport" are within 5 words from each other in the description of the hotel, and where smoking isn't allowed in at least some of the rooms.

odata-filter-expr

```

search.ismatch('"hotel airport"~5', 'Description', 'full', 'any') and
Rooms/any(room: not room/SmokingAllowed)

```

Here's the full query syntax. To run in Search Explorer, escape the interior quotation marks with a backslash character.

JSON

```
{
  "search": "*",
  "select": "HotelId, HotelName, Description, Tags, Rating",
  "searchMode": "all",
  "queryType": "simple",
  "count": true,
  "filter": "search.ismatch('\"hotel airport\"~5', 'Description', 'full', 'any')
and Rooms/any(room: not room/SmokingAllowed)"
}
```

Output consists of a single document where the terms "hotel" and "airport" are within 5 words distance. Smoking is allowed for several rooms in most hotels, including the one in this search result.

JSON

```
{
  "@odata.count": 1,
  "value": [
    {
      "@search.score": 1,
      "HotelId": "40",

OData geo-spatial functions in Azure AI Search - `geo.distance` and `geo.intersects`

Article • 08/28/2024

Azure AI Search supports geo-spatial queries in [OData filter expressions](#) via the `geo.distance` and `geo.intersects` functions. The `geo.distance` function returns the distance in kilometers between two points, one being a field or range variable, and one being a constant passed as part of the filter. The `geo.intersects` function returns `true` if a given point is within a given polygon, where the point is a field or range variable and the polygon is specified as a constant passed as part of the filter.

The `geo.distance` function can also be used in the [\\$orderby parameter](#) to sort search results by distance from a given point. The syntax for `geo.distance` in `$orderby` is the same as it is in `$filter`. When using `geo.distance` in `$orderby`, the field to which it applies must be of type `Edm.GeographyPoint` and it must also be **sortable**.

ⓘ Note

When using `geo.distance` in the `$orderby` parameter, the field you pass to the function must contain only a single geo-point. In other words, it must be of type `Edm.GeographyPoint` and not `Collection(Edm.GeographyPoint)`. It is not possible to sort on collection fields in Azure AI Search.

Syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar of the `geo.distance` and `geo.intersects` functions, as well as the geo-spatial values on which they operate:

```
geo_distance_call ::=  
    'geo.distance(' variable ',' geo_point ')'  
    | 'geo.distance(' geo_point ',' variable ')'  
  
geo_point ::= "geography'POINT(" lon_lat ")"  
  
lon_lat ::= float_literal ' ' float_literal
```

```
geo_intersects_call ::=  
    'geo.intersects(' variable ',' geo_polygon ')'  
  
/* You need at least four points to form a polygon, where the first and  
last points are the same. */  
geo_polygon ::=  
    "geography'POLYGON((" lon_lat ',' lon_lat ',' lon_lat ',' lon_lat_list  
"))'"  
  
lon_lat_list ::= lon_lat(',' lon_lat)*
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

 **Note**

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

geo.distance

The `geo.distance` function takes two parameters of type `Edm.GeographyPoint` and returns an `Edm.Double` value that is the distance between them in kilometers. This differs from other services that support OData geo-spatial operations, which typically return distances in meters.

One of the parameters to `geo.distance` must be a geography point constant, and the other must be a field path (or a range variable in the case of a filter iterating over a field of type `Collection(Edm.GeographyPoint)`). The order of these parameters doesn't matter.

The geography point constant is of the form `geography'POINT(<longitude><latitude>)'`, where the longitude and latitude are numeric constants.

 **Note**

When using `geo.distance` in a filter, you must compare the distance returned by the function with a constant using `lt`, `le`, `gt`, or `ge`. The operators `eq` and `ne` are not supported when comparing distances. For example, this is a correct usage of `geo.distance: $filter=geo.distance(location, geography'POINT(-122.131577 47.678581)') le 5.`

geo.intersects

The `geo.intersects` function takes a variable of type `Edm.GeographyPoint` and a constant `Edm.GeographyPolygon` and returns an `Edm.Boolean` -- `true` if the point is within the bounds of the polygon, `false` otherwise.

The polygon is a two-dimensional surface stored as a sequence of points defining a bounding ring (see the [examples](#) below). The polygon needs to be closed, meaning the first and last point sets must be the same. [Points in a polygon must be in counterclockwise order](#).

Geo-spatial queries and polygons spanning the 180th meridian

For many geo-spatial query libraries formulating a query that includes the 180th meridian (near the dateline) is either off-limits or requires a workaround, such as splitting the polygon into two, one on either side of the meridian.

In Azure AI Search, geo-spatial queries that include 180-degree longitude will work as expected if the query shape is rectangular and your coordinates align to a grid layout along longitude and latitude (for example, `geo.intersects(location, geography'POLYGON((179 65, 179 66, -179 66, -179 65, 179 65))')`). Otherwise, for non-rectangular or unaligned shapes, consider the split polygon approach.

Geo-spatial functions and `null`

Like all other non-collection fields in Azure AI Search, fields of type `Edm.GeographyPoint` can contain `null` values. When Azure AI Search evaluates `geo.intersects` for a field that is `null`, the result will always be `false`. The behavior of `geo.distance` in this case depends on the context:

- In filters, `geo.distance` of a `null` field results in `null`. This means the document will not match because `null` compared to any non-null value evaluates to `false`.
- When sorting results using `$orderby`, `geo.distance` of a `null` field results in the maximum possible distance. Documents with such a field will sort lower than all others when the sort direction `asc` is used (the default), and higher than all others when the direction is `desc`.

Examples

Filter examples

Find all hotels within 10 kilometers of a given reference point (where location is a field of type `Edm.GeographyPoint`):

odata-filter Expr

```
geo.distance(location, geography'POINT(-122.131577 47.678581)') le 10
```

Find all hotels within a given viewport described as a polygon (where location is a field of type `Edm.GeographyPoint`). Note that the polygon is closed (the first and last point sets must be the same) and [the points must be listed in counterclockwise order](#).

odata-filter Expr

```
geo.intersects(location, geography'POLYGON((-122.031577 47.578581,  
-122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581))')
```

Order-by examples

Sort hotels descending by `rating`, then ascending by distance from the given coordinates:

odata-filter Expr

```
rating desc,geo.distance(location, geography'POINT(-122.131577  
47.678581)') asc
```

Sort hotels in descending order by `search.score` and `rating`, and then in ascending order by distance from the given coordinates so that between two hotels with identical ratings, the closest one is listed first:

odata-filter Expr

```
search.score() desc,rating desc,geo.distance(location,  
geography'POINT(-122.131577 47.678581)') asc
```

OData logical operators in Azure AI Search - `and`, `or`, `not`

Article • 08/28/2024

OData filter expressions in Azure AI Search are Boolean expressions that evaluate to `true` or `false`. You can write a complex filter by writing a series of simpler filters and composing them using the logical operators from Boolean algebra ↗:

- `and`: A binary operator that evaluates to `true` if both its left and right sub-expressions evaluate to `true`.
- `or`: A binary operator that evaluates to `true` if either one of its left or right sub-expressions evaluates to `true`.
- `not`: A unary operator that evaluates to `true` if its sub-expression evaluates to `false`, and vice-versa.

These, together with the collection operators `any` and `all`, allow you to construct filters that can express very complex search criteria.

Syntax

The following EBNF (Extended Backus-Naur Form ↗) defines the grammar of an OData expression that uses the logical operators.

```
logical_expression ::=  
    boolean_expression ('and' | 'or') boolean_expression  
    | 'not' boolean_expression
```

An interactive syntax diagram is also available:

[OData syntax diagram for Azure AI Search](#)

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

There are two forms of logical expressions: binary (`and`/`or`), where there are two sub-expressions, and unary (`not`), where there is only one. The sub-expressions can be Boolean expressions of any kind:

- Fields or range variables of type `Edm.Boolean`
- Functions that return values of type `Edm.Boolean`, such as `geo.intersects` or `search.ismatch`
- [Comparison expressions](#), such as `rating gt 4`
- [Collection expressions](#), such as `Rooms/any(room: room/Type eq 'Deluxe Room')`
- The Boolean literals `true` or `false`.
- Other logical expressions constructed using `and`, `or`, and `not`.

Important

There are some situations where not all kinds of sub-expression can be used with `and`/`or`, particularly inside lambda expressions. See [OData collection operators in Azure AI Search](#) for details.

Logical operators and `null`

Most Boolean expressions such as functions and comparisons cannot produce `null` values, and the logical operators cannot be applied to the `null` literal directly (for example, `x and null` is not allowed). However, Boolean fields can be `null`, so you need to be aware of how the `and`, `or`, and `not` operators behave in the presence of null. This is summarized in the following table, where `b` is a field of type `Edm.Boolean`:

[\[\] Expand table](#)

Expression	Result when <code>b</code> is <code>null</code>
<code>b</code>	<code>false</code>
<code>not b</code>	<code>true</code>
<code>b eq true</code>	<code>false</code>
<code>b eq false</code>	<code>false</code>
<code>b eq null</code>	<code>true</code>
<code>b ne true</code>	<code>true</code>

Expression	Result when <code>b</code> is <code>null</code>
<code>b ne false</code>	<code>true</code>
<code>b ne null</code>	<code>false</code>
<code>b and true</code>	<code>false</code>
<code>b and false</code>	<code>false</code>
<code>b or true</code>	<code>true</code>
<code>b or false</code>	<code>false</code>

When a Boolean field `b` appears by itself in a filter expression, it behaves as if it had been written `b eq true`, so if `b` is `null`, the expression evaluates to `false`. Similarly, `not b` behaves like `not (b eq true)`, so it evaluates to `true`. In this way, `null` fields behave the same as `false`. This is consistent with how they behave when combined with other expressions using `and` and `or`, as shown in the table above. Despite this, a direct comparison to `false` (`b eq false`) will still evaluate to `false`. In other words, `null` is not equal to `false`, even though it behaves like it in Boolean expressions.

Examples

Match documents where the `rating` field is between 3 and 5, inclusive:

```
odata-filter-expr
rating ge 3 and rating le 5
```

Match documents where all elements of the `ratings` field are less than 3 or greater than 5:

```
odata-filter-expr
ratings/all(r: r lt 3 or r gt 5)
```

Match documents where the `location` field is within the given polygon, and the document does not contain the term "public".

```
odata-filter-expr
geo.intersects(location, geography'POLYGON((-122.031577 47.578581,
-122.031577 47.678581, -122.131577 47.678581, -122.031577 47.578581))') and
not contains(lowercase($t), 'public')
```

```
not search.ismatch('public')
```

Match documents for hotels in Vancouver, Canada where there is a deluxe room with a base rate less than 160:

odata-filter Expr

```
Address/City eq 'Vancouver' and Address/Country eq 'Canada' and  
Rooms/any(room: room/Type eq 'Deluxe Room' and room/BaseRate lt 160)
```

OData `search.in` function in Azure AI Search

Article • 08/28/2024

A common scenario in [OData filter expressions](#) is to check whether a single field in each document is equal to one of many possible values. For example, this is how some applications implement [security trimming](#) -- by checking a field containing one or more principal IDs against a list of principal IDs representing the user issuing the query. One way to write a query like this is to use the `eq` and `or` operators:

```
odata-filter-expr
```

```
group_ids/any(g: g eq '123' or g eq '456' or g eq '789')
```

However, there is a shorter way to write this, using the `search.in` function:

```
odata-filter-expr
```

```
group_ids/any(g: search.in(g, '123, 456, 789'))
```

ⓘ Important

Besides being shorter and easier to read, using `search.in` also provides [performance benefits](#) and avoids certain [size limitations of filters](#) when there are hundreds or even thousands of values to include in the filter. For this reason, we strongly recommend using `search.in` instead of a more complex disjunction of equality expressions.

ⓘ Note

Version 4.01 of the OData standard has recently introduced the [in operator](#), which has similar behavior as the `search.in` function in Azure AI Search. However, Azure AI Search does not support this operator, so you must use the `search.in` function instead.

Syntax

The following EBNF ([Extended Backus-Naur Form](#)) defines the grammar of the `search.in` function:

```
search_in_call ::=  
    'search.in(' variable ',' string_literal(',') string_literal)? ')'
```

An interactive syntax diagram is also available:

OData syntax diagram for Azure AI Search

ⓘ Note

See [OData expression syntax reference for Azure AI Search](#) for the complete EBNF.

The `search.in` function tests whether a given string field or range variable is equal to one of a given list of values. Equality between the variable and each value in the list is determined in a case-sensitive fashion, the same way as for the `eq` operator. Therefore an expression like `search.in(myfield, 'a, b, c')` is equivalent to `myfield eq 'a' or myfield eq 'b' or myfield eq 'c'`, except that `search.in` will yield much better performance.

There are two overloads of the `search.in` function:

- `search.in(variable, valueList)`
- `search.in(variable, valueList, delimiters)`

The parameters are defined in the following table:

[+] [Expand table](#)

Parameter	Type	Description
name		
<code>variable</code>	<code>Edm.String</code>	A string field reference (or a range variable over a string collection field in the case where <code>search.in</code> is used inside an <code>any</code> or <code>all</code> expression).
<code>valueList</code>	<code>Edm.String</code>	A string containing a delimited list of values to match against the <code>variable</code> parameter. If the <code>delimiters</code> parameter is not specified, the default delimiters are space and comma.

Parameter	Type	Description
name		

`delimiters` `Edm.String` A string where each character is treated as a separator when parsing the `valueList` parameter. The default value of this parameter is `' , '`, which means that any values with spaces and/or commas between them will be separated. If you need to use separators other than spaces and commas because your values include those characters, you can specify alternate delimiters such as `'|'` in this parameter.

Performance of `search.in`

If you use `search.in`, you can expect sub-second response time when the second parameter contains a list of hundreds or thousands of values. There is no explicit limit on the number of items you can pass to `search.in`, although you are still limited by the maximum request size. However, the latency will grow as the number of values grows.

Examples

Find all hotels with name equal to either 'Sea View motel' or 'Budget hotel'. Phrases contain spaces, which is a default delimiter. You can specify an alternative delimiter in single quotes as the third string parameter:

odata-filter Expr

```
search.in(HotelName, 'Sea View motel,Budget hotel', ',')
```

Find all hotels with name equal to either 'Sea View motel' or 'Budget hotel' separated by '|':

odata-filter Expr

```
search.in(HotelName, 'Sea View motel|Budget hotel', '|')
```

Find all hotels with rooms that have the tag 'wifi' or 'tub':

odata-filter Expr

```
Rooms/any(room: room/Tags/any(tag: search.in(tag, 'wifi, tub')))
```

Find a match on phrases within a collection, such as 'heated towel racks' or 'hairdryer included' in tags.

```
odata-filter-expr
```

```
Rooms/any(room: room/Tags/any(tag: search.in(tag, 'heated towel  
racks,hairdryer included', ',')))
```

Find all hotels without the tag 'motel' or 'cabin':

```
odata-filter-expr
```

```
Tags/all(tag: not search.in(tag, 'motel, cabin'))
```

OData `search.score` function in Azure AI Search

Article • 08/28/2024

When you send a query to Azure AI Search without the `$orderby` parameter, the results that come back will be sorted in descending order by relevance score. Even when you do use `$orderby`, the relevance score is used to break ties by default. However, sometimes it's useful to use the relevance score as an initial sort criteria, and some other criteria as the tie-breaker. The example in this article demonstrates using the `search.score` function for sorting.

ⓘ Note

The relevance score is computed by the relevance ranking algorithm, and the range varies depending on which algorithm you use. For more information, see [Relevance and scoring in Azure AI Search](#).

Syntax

The syntax for `search.score` in `$orderby` is `search.score()`. The function `search.score` doesn't take any parameters. It can be used with the `asc` or `desc` sort-order specifier, just like any other clause in the `$orderby` parameter. It can appear anywhere in the list of sort criteria.

Example

Sort hotels in descending order by `search.score` and `rating`, and then in ascending order by distance from the given coordinates so that between two hotels with identical ratings, the closest one is listed first:

odata-filter-expr

```
search.score() desc, rating desc, geo.distance(location,

OData expression syntax reference for Azure AI Search

Article • 08/28/2024

Azure AI Search uses [OData expressions](#) as parameters throughout the API. Most commonly, OData expressions are used for the `$orderby` and `$filter` parameters. These expressions can be complex, containing multiple clauses, functions, and operators. However, even simple OData expressions like property paths are used in many parts of the Azure AI Search REST API. For example, path expressions are used to refer to subfields of complex fields everywhere in the API, such as when listing subfields in a [suggester](#), a [scoring function](#), the `$select` parameter, or even [fielded search in Lucene queries](#).

This article describes all these forms of OData expressions using a formal grammar. There is also an [interactive diagram](#) to help visually explore the grammar.

Formal grammar

We can describe the subset of the OData language supported by Azure AI Search using an EBNF ([Extended Backus-Naur Form](#)) grammar. Rules are listed "top-down", starting with the most complex expressions, and breaking them down into more primitive expressions. At the top are the grammar rules that correspond to specific parameters of the Azure AI Search REST API:

- `$filter`, defined by the `filter_expression` rule.
- `$orderby`, defined by the `order_by_expression` rule.
- `$select`, defined by the `select_expression` rule.
- Field paths, defined by the `field_path` rule. Field paths are used throughout the API. They can refer to either top-level fields of an index, or subfields with one or more [complex field](#) ancestors.

After the EBNF is a browsable [syntax diagram](#) that allows you to interactively explore the grammar and the relationships between its rules.

```
/* Top-level rules */

filter_expression ::= boolean_expression

order_by_expression ::= order_by_clause( ',' order_by_clause )*
```

```
select_expression ::= '*' | field_path(',') field_path)*

field_path ::= identifier('/'identifier)*

/* Shared base rules */

identifier ::= [a-zA-Z_][a-zA-Z_0-9]/*

/* Rules for $orderby */

order_by_clause ::= (field_path | sortable_function) ('asc' | 'desc')?

sortable_function ::= geo_distance_call | 'search.score()'

/* Rules for $filter */

boolean_expression ::=
    collection_filter_expression
  | logical_expression
  | comparison_expression
  | boolean_literal
  | boolean_function_call
  | '(' boolean_expression ')'
  | variable

/* This can be a range variable in the case of a lambda, or a field path. */
variable ::= identifier | field_path

collection_filter_expression ::=
    field_path'/all(' lambda_expression ')
  | field_path'/any(' lambda_expression ')
  | field_path'/any()

lambda_expression ::= identifier ':' boolean_expression

logical_expression ::=
    boolean_expression ('and' | 'or') boolean_expression
  | 'not' boolean_expression

comparison_expression ::=
    variable_or_function comparison_operator constant |
    constant comparison_operator variable_or_function

variable_or_function ::= variable | function_call

comparison_operator ::= 'gt' | 'lt' | 'ge' | 'le' | 'eq' | 'ne'

/* Rules for constants and literals */

constant ::=
```

```

string_literal
| date_time_offset_literal
| integer_literal
| float_literal
| boolean_literal
| 'null'

string_literal ::= """([^\"] | '\"'')*"""

date_time_offset_literal ::= date_part'T'time_part time_zone

date_part ::= year'-'month'-'day

time_part ::= hour':'minute(':second('.fractional_seconds)?)？

zero_to_fifty_nine ::= [0-5]digit

digit ::= [0-9]

year ::= digit digit digit digit

month ::= '0'[1-9] | '1'[0-2]

day ::= '0'[1-9] | [1-2]digit | '3'[0-1]

hour ::= [0-1]digit | '2'[0-3]

minute ::= zero_to_fifty_nine

second ::= zero_to_fifty_nine

fractional_seconds ::= integer_literal

time_zone ::= 'Z' | sign hour':'minute

sign ::= '+' | '-'

/* In practice integer literals are limited in length to the precision of
the corresponding EDM data type. */
integer_literal ::= sign? digit+

float_literal :=
    sign? whole_part fractional_part? exponent?
    | 'NaN'
    | '-INF'
    | 'INF'

whole_part ::= integer_literal

fractional_part ::= '.'integer_literal

exponent ::= 'e' sign? integer_literal

boolean_literal ::= 'true' | 'false'

```

```

/* Rules for functions */

function_call ::= 
    geo_distance_call |
    boolean_function_call

geo_distance_call ::= 
    'geo.distance(' variable ',' geo_point ')'
    | 'geo.distance(' geo_point ',' variable ')'

geo_point ::= "geography'POINT(" lon_lat ")'"

lon_lat ::= float_literal ' ' float_literal

boolean_function_call ::= 
    geo_intersects_call |
    search_in_call |
    search_is_match_call

geo_intersects_call ::= 
    'geo.intersects(' variable ',' geo_polygon ')'

/* You need at least four points to form a polygon, where the first and
last points are the same. */
geo_polygon ::= 
    "geography'POLYGON((" lon_lat ',' lon_lat ',' lon_lat ',' lon_lat_list
    ")))'"

lon_lat_list ::= lon_lat(',') lon_lat)*

search_in_call ::= 
    'search.in(' variable ',' string_literal(',') string_literal)? ')'

/* Note that it is illegal to call search.ismatch or search.ismatchscoring
from inside a lambda expression. */
search_is_match_call ::= 
    'search.ismatch('scoring')?'(' search_is_match_parameters ')'

search_is_match_parameters ::= 
    string_literal(',') string_literal(',') query_type ',' search_mode)??)?

query_type ::= "'full'" | "'simple'"

search_mode ::= "'any'" | "'all'"

```

Syntax diagram

az search

Manage Search.

Commands

 Expand table

Name	Description	Type	Status
az search admin-key	Manage Azure Search admin keys.	Core	GA
az search admin-key renew	Regenerates either the primary or secondary admin API key.	Core	GA
az search admin-key show	Gets the primary and secondary admin API keys for the specified Azure Cognitive Search service.	Core	GA
az search private-endpoint-connection	Manage Azure Search private endpoint connections.	Core	GA
az search private-endpoint-connection delete	Disconnects the private endpoint connection and deletes it from the search service.	Core	GA
az search private-endpoint-connection list	Gets a list of all private endpoint connections in the given service.	Core	GA
az search private-endpoint-connection show	Gets the details of the private endpoint connection to the search service in the given resource group.	Core	GA
az search private-endpoint-connection update	Update an existing private endpoint connection in a Search service in the given resource group.	Core	GA
az search private-link-resource	Manage Azure Search private link resources.	Core	GA
az search private-link-resource list	Gets a list of all supported private link resource types for the given service.	Core	GA
az search query-key	Manage Azure Search query keys.	Core	GA
az search query-key create	Generates a new query key for the specified search service.	Core	GA

Name	Description	Type	Status
az search query-key delete	Deletes the specified query key.	Core	GA
az search query-key list	Returns the list of query API keys for the given Azure Cognitive Search service.	Core	GA
az search service	Manage Service.	Core	GA
az search service admin-key	Manage Admin Key.	Core	GA
az search service admin-key list	Gets the primary and secondary admin API keys for the specified Azure AI Search service.	Core	GA
az search service admin-key regenerate	Regenerates either the primary or secondary admin API key. You can only regenerate one key at a time.	Core	GA
az search service check-name-availability	Checks whether or not the given search service name is available for use. Search service names must be globally unique since they are part of the service URI (<a href="https://<name>.search.windows.net">https://<name>.search.windows.net).	Core	GA
az search service create	Creates or updates a search service in the given resource group. If the search service already exists, all properties will be updated with the given values.	Core	GA
az search service delete	Delete a search service in the given resource group, along with its associated resources.	Core	GA
az search service list	Gets a list of all Search services in the given resource group.	Core	GA
az search service network-security-perimeter-configuration	Manage Network Security Perimeter Configuration.	Core	GA
az search service network-security-perimeter-configuration list	List a list of network security perimeter configurations for a search service.	Core	GA
az search service network-security-perimeter-configuration reconcile	Reconcile network security perimeter configuration for the Azure AI Search resource provider. This triggers a manual resync with network security perimeter configurations by ensuring the search service carries the latest configuration.	Core	GA
az search service network-security-	Get a network security perimeter configuration.	Core	GA

Name	Description	Type	Status
perimeter-configuration show			
az search service private-endpoint-connection	Manage Private Endpoint Connection.	Core	GA
az search service private-endpoint-connection delete	Delete the private endpoint connection and deletes it from the search service.	Core	GA
az search service private-endpoint-connection list	List a list of all private endpoint connections in the given service.	Core	GA
az search service private-endpoint-connection show	Get the details of the private endpoint connection to the search service in the given resource group.	Core	GA
az search service private-endpoint-connection update	Update a private endpoint connection to the search service in the given resource group.	Core	GA
az search service private-link-resource	Manage Private Link Resource.	Core	GA
az search service private-link-resource list	List a list of all supported private link resource types for the given service.	Core	GA
az search service query-key	Manage Create Query Key.	Core	GA
az search service query-key create	Create a new query key for the specified search service. You can create up to 50 query keys per service.	Core	GA
az search service query-key delete	Delete the specified query key. Unlike admin keys, query keys are not regenerated. The process for regenerating a query key is to delete and then recreate it.	Core	GA
az search service query-key list	Returns the list of query API keys for the given Azure AI Search service.	Core	GA
az search service shared-private-link-resource	Manage Shared Private Link Resource.	Core	GA
az search service shared-private-link-resource create	Create the creation or update of a shared private link resource managed by the search service in the given resource group.	Core	GA

Name	Description	Type	Status
az search service shared-private-link-resource delete	Delete the deletion of the shared private link resource from the search service.	Core	GA
az search service shared-private-link-resource list	List a list of all shared private link resources managed by the given service.	Core	GA
az search service shared-private-link-resource show	Get the details of the shared private link resource managed by the search service in the given resource group.	Core	GA
az search service shared-private-link-resource update	Update the creation or update of a shared private link resource managed by the search service in the given resource group.	Core	GA
az search service shared-private-link-resource wait	Place the CLI in a waiting state until a condition is met.	Core	GA
az search service show	Get the search service with the given name in the given resource group.	Core	GA
az search service update	Update an existing search service in the given resource group.	Core	GA
az search service upgrade	Upgrades the Azure AI Search service to the latest version available.	Core	GA
az search service wait	Place the CLI in a waiting state until a condition is met.	Core	GA
az search shared-private-link-resource	Manage Azure Search shared private link resources.	Core	GA
az search shared-private-link-resource create	Create shared privatelink resources in a Search service in the given resource group.	Core	GA
az search shared-private-link-resource delete	Initiates the deletion of the shared private link resource from the search service.	Core	GA
az search shared-private-link-resource list	Gets a list of all shared private link resources managed by the given service.	Core	GA
az search shared-private-link-resource show	Gets the details of the shared private link resource managed by the search service in the given resource group.	Core	GA

Name	Description	Type	Status
az search shared-private-link-resource update	Update shared privatelink resources in a Search service in the given resource group.	Core	GA
az search shared-private-link-resource wait	Wait for async shared private link resource operations.	Core	GA
az search usage	Manage Usage.	Core	GA
az search usage list	List a list of all Azure AI Search quota usages across the subscription.	Core	GA
az search usage show	Get the quota usage for a search SKU in the given subscription.	Core	GA

Az.Search Module

Preview

This is a Preview module. Preview modules aren't recommended for use in production environments. For more information, see <https://aka.ms/azps-refstatus>.

This topic displays help topics for the Azure AI Search Cmdlets.

Networking

[] Expand table

Cmdlet	Description
Get-AzSearchNetworkSecurityPerimeterConfiguration	Gets an Azure AI Search service network security perimeter configuration.
Invoke-AzSearchNetworkSecurityPerimeterConfigurationReconcile	Reconciles network security perimeter configuration for an Azure AI Search service.

Search

[] Expand table

Cmdlet	Description
Get-AzSearchAdminKeyPair	Gets admin key pair of the Azure AI Search service.
Get-AzSearchPrivateEndpointConnection	Gets private endpoint connection(s) to the Azure AI Search service.
Get-AzSearchPrivateLinkResource	Gets private link resource details for the Azure AI Search service.
Get-AzSearchQueryKey	Gets query key(s) of the Azure AI Search service.
Get-AzSearchService	Gets an Azure AI Search service.
Get-AzSearchSharedPrivateLinkResource	Gets shared private link resources(s) of the Azure AI Search service.
New-AzSearchAdminKey	Regenerates an admin key of the Azure AI Search service.

Cmdlet	Description
New-AzSearchQueryKey	Create a new query key for the Azure AI Search service.
New-AzSearchService	Creates an Azure AI Search service.
New-AzSearchSharedPrivateLinkResource	Creates a shared private link resource for the Azure AI Search service.
Remove-AzSearchPrivateEndpointConnection	Remove the private endpoint connection from the Azure AI Search service.
Remove-AzSearchQueryKey	Remove the query key from the Azure AI Search service.
Remove-AzSearchService	Remove an Azure AI Search service.
Remove-AzSearchSharedPrivateLinkResource	Remove the shared private link resource from the Azure AI Search service.
Set-AzSearchPrivateEndpointConnection	Update the private endpoint connection to the Azure AI Search service.
Set-AzSearchService	Update an Azure AI Search service.
Set-AzSearchSharedPrivateLinkResource	Update the shared private link resource for the Azure AI Search service.

Microsoft.Search searchServices

Bicep resource definition

The searchServices resource type can be deployed with operations that target:

For a list of changed properties in each API version, see [change log](#).

Resource format

To create a Microsoft.Search/searchServices resource, add the following Bicep to your template.

Bicep

```
resource symbolicname 'Microsoft.Search/searchServices@2025-05-01' = {
  scope: resourceSymbolicName or scope
  identity: {
    type: 'string'
    userAssignedIdentities: {
      {customized property}: {}
    }
  }
  location: 'string'
  name: 'string'
  properties: {
    authOptions: {
      aadOrApiKey: {
        aadAuthFailureMode: 'string'
      }
      apiKeyOnly: any(...)
    }
    computeType: 'string'
    dataExfiltrationProtections: [
      'string'
    ]
    disableLocalAuth: bool
    encryptionWithCmk: {
      enforcement: 'string'
    }
    endpoint: 'string'
    hostingMode: 'string'
    networkRuleSet: {
      bypass: 'string'
      ipRules: [
        {
          value: 'string'
        }
      ]
    }
    partitionCount: int
    publicNetworkAccess: 'string'
    replicaCount: int
    semanticSearch: 'string'
    upgradeAvailable: 'string'
  }
  sku: {
    name: 'string'
  }
  tags: {
    {customized property}: 'string'
  }
}
```

Property Values

Microsoft.Search/searchServices

 Expand table

Name	Description	Value
identity	The identity of the resource.	Identity
location	The geo-location where the resource lives	string (required)
name	The resource name	string (required)
properties	Properties of the search service.	SearchServiceProperties
scope	Use when creating a resource at a scope that is different than the deployment scope.	Set this property to the symbolic name of a resource to apply the extension resource .
sku	The SKU of the search service, which determines price tier and capacity limits. This property is required when creating a new search service.	Sku
tags	Resource tags	Dictionary of tag names and values. See Tags in templates

DataPlaneAadOrApiKeyAuthOption

[Expand table](#)

Name	Description	Value
aadAuthFailureMode	Describes what response the data plane API of a search service would send for requests that failed authentication.	'http401WithBearerChallenge' 'http403'

DataPlaneAuthOptions

[Expand table](#)

Name	Description	Value
aadOrApiKey	Indicates that either the API key or an access token from a Microsoft Entra ID tenant can be used for authentication.	DataPlaneAadOrApiKeyAuthOption
apiKeyOnly	Indicates that only the API key can be used for authentication.	any

EncryptionWithCmk

[Expand table](#)

Name	Description	Value
enforcement	Describes how a search service should enforce compliance if it finds objects that aren't encrypted with the customer-managed key.	'Disabled' 'Enabled' 'Unspecified'

Identity

[Expand table](#)

Name	Description
type	The type of identity used for the resource. The type 'SystemAssigned, UserAssigned' includes both an identity created by the system and a set of assigned identities. The type 'None' will remove all identities from the service.
userAssignedIdentities	The list of user identities associated with the resource. The user identity dictionary key references will be ARM resource IDs in the form: '/subscriptions/{subscriptionId}/resourceGroups/{resourceGroupName}/providers/Microsoft.ManagedIdentity/userAssignedIdentities/{identityName}'

IpRule

[Expand table](#)

Name	Description	Value
value	Value corresponding to a single IPv4 address (eg., 123.1.2.3) or an IP range in CIDR format (eg., 123.1.2.3/24) to be allowed.	string

NetworkRuleSet

[Expand table](#)

Name	Description	Value
bypass	Possible origins of inbound traffic that can bypass the rules defined in the 'ipRules' section.	'AzureServices' 'None'
ipRules	A list of IP restriction rules that defines the inbound network(s) with allowing access to the search service endpoint. At the meantime, all other public IP networks are blocked by the firewall. These restriction rules are applied only when the 'publicNetworkAccess' of the search service is 'enabled'; otherwise, traffic over public interface is not allowed even with any public IP rules, and private endpoint connections would be the exclusive access method.	IpRule[]

SearchServiceProperties

[Expand table](#)

Name	Description	Value
authOptions	Defines the options for how the data plane API of a search service authenticates requests. This cannot be set if 'disableLocalAuth' is set to true.	DataPlaneAuthOptions
computeType	Configure this property to support the search service using either the Default Compute or Azure Confidential Compute.	'Confidential' 'Default'
dataExfiltrationProtections	A list of data exfiltration scenarios that are explicitly disallowed for the search service. Currently, the only supported value is 'All' to disable all possible data export scenarios with more fine grained controls planned for the future.	String array containing any of: 'BlockAll'
disableLocalAuth	When set to true, calls to the search service will not be permitted to utilize API keys for authentication. This cannot be set to true if 'dataPlaneAuthOptions' are defined.	bool
encryptionWithCmk	Specifies any policy regarding encryption of resources (such as indexes) using customer manager keys within a search service.	EncryptionWithCmk
endpoint	The endpoint of the Azure AI Search service.	string
hostingMode	Applicable only for the standard3 SKU. You can set this property to enable up to 3 high density partitions that allow up to 1000 indexes, which is much higher than the maximum indexes allowed for any other SKU. For the standard3 SKU, the value is either 'Default' or 'HighDensity'. For all other SKUs, this value must be 'Default'.	'Default' 'HighDensity'
networkRuleSet	Network specific rules that determine how the Azure AI Search service may be reached.	NetworkRuleSet
partitionCount	The number of partitions in the search service; if specified, it can be 1, 2, 3, 4, 6, or 12. Values greater than 1 are only valid for standard SKUs. For 'standard3' services with hostingMode set to 'highDensity', the allowed values are between 1 and 3.	int Constraints: Min value = 1 Max value = 12
publicNetworkAccess	This value can be set to 'Enabled' to avoid breaking changes on existing customer resources and templates. If set to 'Disabled', traffic over public interface is not allowed, and private endpoint connections would be the exclusive access method.	'Disabled' 'Enabled' 'SecuredByPerimeter'
replicaCount	The number of replicas in the search service. If specified, it must be a value between 1 and 12 inclusive for standard SKUs or between 1 and 3 inclusive for basic SKU.	int Constraints: Min value = 1 Max value = 12
semanticSearch	Sets options that control the availability of semantic search. This configuration is only possible for certain Azure AI Search SKUs in certain locations.	'disabled' 'free' 'standard'
upgradeAvailable	Indicates if the search service has an upgrade available.	'available' 'notAvailable'

Sku

[Expand table](#)

Name	Description	Value
name	The SKU of the search service. Valid values include: 'free': Shared service. 'basic': Dedicated service with up to 3 replicas. 'standard': Dedicated service with up to 12 partitions and 12 replicas. 'standard2': Similar to standard, but with more capacity per search unit. 'standard3': The largest Standard offering with up to 12 partitions and 12 replicas (or up to 3 partitions with more indexes if you also set the hostingMode property to 'highDensity'). 'storage_optimized_I1': Supports 1TB per partition, up to 12 partitions. 'storage_optimized_I2': Supports 2TB per partition, up to 12 partitions.'	'basic' 'free' 'standard' 'standard2' 'standard3' 'storage_optimized_I1' 'storage_optimized_I2'

Azure Policy built-in definitions for Azure Cognitive Search

Article • 12/10/2024

This page is an index of [Azure Policy](#) built-in policy definitions for Azure Cognitive Search. For additional Azure Policy built-ins for other services, see [Azure Policy built-in definitions](#).

The name of each built-in policy definition links to the policy definition in the Azure portal. Use the link in the **Version** column to view the source on the [Azure Policy GitHub repo](#) ↗.

Azure Cognitive Search

 Expand table

Name (Azure portal)	Description	Effect(s)	Version (GitHub)
[Preview]: Azure AI Search Service should be Zone Redundant ↗	Azure AI Search Service can be configured to be Zone Redundant or not. Availability zones are used when you add two or more replicas to your search service. Each replica is placed in a different availability zone within the region.	Audit, Deny, Disabled	1.0.0-preview ↗
Azure AI Services resources should have key access disabled (disable local authentication) ↗	Key access (local authentication) is recommended to be disabled for security. Azure OpenAI Studio, typically used in development/testing, requires key access and will not function if key access is disabled. After disabling, Microsoft Entra ID becomes the only access method, which allows maintaining minimum privilege principle and granular control. Learn more at: https://aka.ms/AI/auth ↗	Audit, Deny, Disabled	1.1.0 ↗
Azure AI Services resources should restrict network access ↗	By restricting network access, you can ensure that only allowed networks can access the service. This can be achieved by configuring network rules so that only applications from allowed networks can access the Azure AI service.	Audit, Deny, Disabled	3.2.0 ↗
Azure AI Services resources should use Azure Private Link ↗	Azure Private Link lets you connect your virtual network to Azure services without a public IP address at the source or destination. The Private Link platform reduces data leakage risks by handling the connectivity between the consumer and	Audit, Disabled	1.0.0 ↗

Name (Azure portal)	Description	Effect(s)	Version (GitHub)
	<p>services over the Azure backbone network.</p> <p>Learn more about private links at: https://aka.ms/AzurePrivateLink/Overview</p>		
Azure Cognitive Search service should use a SKU that supports private link	<p>With supported SKUs of Azure Cognitive Search, Azure Private Link lets you connect your virtual network to Azure services without a public IP address at the source or destination. The private link platform handles the connectivity between the consumer and services over the Azure backbone network. By mapping private endpoints to your Search service, data leakage risks are reduced. Learn more at: https://aka.ms/azure-cognitive-search/inbound-private-endpoints.</p>	Audit, Deny, Disabled	1.0.0
Azure Cognitive Search services should disable public network access	<p>Disabling public network access improves security by ensuring that your Azure Cognitive Search service is not exposed on the public internet. Creating private endpoints can limit exposure of your Search service. Learn more at: https://aka.ms/azure-cognitive-search/inbound-private-endpoints.</p>	Audit, Deny, Disabled	1.0.0
Azure Cognitive Search services should have local authentication methods disabled	<p>Disabling local authentication methods improves security by ensuring that Azure Cognitive Search services exclusively require Azure Active Directory identities for authentication. Learn more at: https://aka.ms/azure-cognitive-search/rbac. Note that while the disable local authentication parameter is still in preview, the deny effect for this policy may result in limited Azure Cognitive Search portal functionality since some features of the Portal use the GA API which does not support the parameter.</p>	Audit, Deny, Disabled	1.0.0
Azure Cognitive Search services should use customer-managed keys to encrypt data at rest	<p>Enabling encryption at rest using a customer-managed key on your Azure Cognitive Search services provides additional control over the key used to encrypt data at rest. This feature is often applicable to customers with special compliance requirements to manage data encryption keys using a key vault.</p>	Audit, Deny, Disabled	1.0.0

Name (Azure portal)	Description	Effect(s)	Version (GitHub)
Configure Azure AI Services resources to disable local key access (disable local authentication) ↗	<p>Key access (local authentication) is recommended to be disabled for security. Azure OpenAI Studio, typically used in development/testing, requires key access and will not function if key access is disabled. After disabling, Microsoft Entra ID becomes the only access method, which allows maintaining minimum privilege principle and granular control. Learn more at: https://aka.ms/AI/auth ↗</p>	DeployIfNotExists, Disabled	1.0.0 ↗
Configure Azure Cognitive Search services to disable local authentication ↗	<p>Disable local authentication methods so that your Azure Cognitive Search services exclusively require Azure Active Directory identities for authentication. Azure AI Search monitoring data reference

07/25/2025

This article contains all the monitoring reference information for this service.

See [Monitor Azure AI Search](#) for details on the data you can collect for Azure AI Search and how to use it.

Metrics

This section lists all the automatically collected platform metrics for this service. These metrics are also part of the global list of [all platform metrics supported in Azure Monitor](#).

For information on metric retention, see [Azure Monitor Metrics overview](#).

Supported metrics for Microsoft.Search/searchServices

The following table lists the metrics available for the Microsoft.Search/searchServices resource type.

- All columns might not be present in every table.
- Some columns might be beyond the viewing area of the page. Select **Expand table** to view all available columns.

Table headings

- **Category** - The metrics group or classification.
- **Metric** - The metric display name as it appears in the Azure portal.
- **Name in REST API** - The metric name as referred to in the [REST API](#).
- **Unit** - Unit of measure.
- **Aggregation** - The default [aggregation](#) type. Valid values: Average (Avg), Minimum (Min), Maximum (Max), Total (Sum), Count.
- **Dimensions** - [Dimensions](#) available for the metric.
- **Time Grains** - [Intervals](#) at which the metric is sampled. For example, `PT1M` indicates that the metric is sampled every minute, `PT30M` every 30 minutes, `PT1H` every hour, and so on.
- **DS Export** - Whether the metric is exportable to Azure Monitor Logs via diagnostic settings. For information on exporting metrics, see [Create diagnostic settings in Azure Monitor](#).

[\[+\] Expand table](#)

Metric	Name in REST API	Unit	Aggregation	Dimensions	Time Grains	DS Export
Document processed count	<code>DocumentsProcessedCount</code>	Count	Total (Sum), Count	<code>DataSourceName</code> , <code>Failed</code> , <code>IndexerName</code> , <code>IndexName</code> , <code>SkillsetName</code>	<code>PT1M</code>	Yes

Metric	Name in REST API	Unit	Aggregation	Dimensions	Time Grains	DS Export
documents processed						
Search Latency	SearchLatency	Seconds	Average	<none>	PT1M	Yes
Average search latency for the search service						
Search queries per second	SearchQueriesPerSecond	CountPerSecond	Average	<none>	PT1M	Yes
Search queries per second for the search service						
Skill execution invocation count	SkillExecutionCount	Count	Total (Sum), Count	DataSourceName, Failed, IndexerName, SkillName, SkillsetName, SkillType	PT1M	Yes
Number of skill executions						
Throttled search queries percentage	ThrottledSearchQueriesPercentage	Percent	Average	<none>	PT1M	Yes
Percentage of search queries that were throttled for the search service						

Search queries per second

This metric shows the average of the search queries per second (QPS) for the search service. It's common for queries to execute in milliseconds, so only queries that measure as seconds appear in a metric like

QPS. The minimum is the lowest value for search queries per second that was registered during that minute. Maximum is the highest value. Average is the aggregate across the entire minute.

[Expand table](#)

Aggregation type	Description
Average	The average number of seconds within a minute during which query execution occurred.
Count	The number of metrics emitted to the log within the one-minute interval.
Maximum	The highest number of search queries per second registered during a minute.
Minimum	The lowest number of search queries per second registered during a minute.
Sum	The sum of all queries executed within the minute.

For example, within one minute, you might have a pattern like this: one second of high load that is the maximum for SearchQueriesPerSecond, followed by 58 seconds of average load, and finally one second with only one query, which is the minimum.

Another example: if a node emits 100 metrics, where the value of each metric is 40, then "Count" is 100, "Sum" is 4000, "Average" is 40, and "Max" is 40.

Search latency

Search latency indicates how long a query takes to complete.

[Expand table](#)

Aggregation type	Latency
Average	Average query duration in milliseconds.
Count	The number of metrics emitted to the log within the one-minute interval.
Maximum	Longest running query in the sample.
Minimum	Shortest running query in the sample.
Total	Total execution time of all queries in the sample, executing within the interval (one minute).

Throttled search queries percentage

This metric refers to queries that are dropped instead of processed. Throttling occurs when the number of requests in execution exceed capacity. You might see an increase in throttled requests when a replica is taken out of rotation or during indexing. Both query and indexing requests are handled by the same set of resources.

The service determines whether to drop requests based on resource consumption. The percentage of resources consumed across memory, CPU, and disk IO are averaged over a period of time. If this

percentage exceeds a threshold, all requests to the index are throttled until the volume of requests is reduced.

Depending on your client, a throttled request is indicated in these ways:

- A service returns an error "You are sending too many requests. Please try again later."
- A service returns a 503 error code indicating the service is currently unavailable.
- If you're using the Azure portal (for example, Search Explorer), the query is dropped silently and you need to select **Search** again.

To confirm throttled queries, use **Throttled search queries** metric. You can explore metrics in the Azure portal or create an alert metric as described in this article. For queries that were dropped within the sampling interval, use *Total* to get the percentage of queries that didn't execute.

[+] [Expand table](#)

Aggregation type	Throttling
Average	Percentage of queries dropped within the interval.
Count	The number of metrics emitted to the log within the one-minute interval.
Maximum	Percentage of queries dropped within the interval.
Minimum	Percentage of queries dropped within the interval.
Total	Percentage of queries dropped within the interval.

For **Throttled Search Queries Percentage**, minimum, maximum, average and total, all have the same value: the percentage of search queries that were throttled, from the total number of search queries during one minute.

Metric dimensions

For information about what metric dimensions are, see [Multi-dimensional metrics](#).

Azure AI Search has dimensions associated with the following metrics that capture a count of documents or skills that were executed.

[+] [Expand table](#)

Metric name	Description	Dimensions	Sample use cases
Document processed count	Shows the number of indexer processed documents.	Data source name, failed, index name, indexer name, skillset name	Can be referenced as a rough measure of throughput (number of documents processed by indexer over time) - Set up to alert on failed documents
Skill execution invocation count	Shows the number of skill invocations.	Data source name, failed, index name, indexer name,	Reference to ensure skills are invoked as expected by comparing relative invocation numbers between skills and number of skill

Metric name	Description	Dimensions	Sample use cases
		skill name, skill type, skillset name	invocations to the number of documents. - Set up to alert on failed skill invocations

[+] [Expand table](#)

Dimension name	Description
DataSourceName	A named data source connection used during indexer execution. Valid values are one of the supported data source types .
Failed	Indicates whether the instance failed.
IndexerName	Name of an indexer.
IndexName	Name of an index.
SkillsetName	Name of a skillset used during indexer execution.
SkillName	Name of a skill within a skillset.
SkillType	The @odata.type of the skill.

Resource logs

This section lists the types of resource logs you can collect for this service. The section pulls from the list of [all resource logs category types supported in Azure Monitor](#).

Supported resource logs for Microsoft.Search/searchServices

[+] [Expand table](#)

Category	Category display name	Log table	Supports basic log plan	Supports ingestion-time transformation	Example queries	Costs to export
OperationLogs	Operation Logs	AzureDiagnostics Logs from multiple Azure resources.	No	No		No

Azure Monitor Logs tables

This section lists the Azure Monitor Logs tables relevant to this service, which are available for query by Log Analytics using Kusto queries. The tables contain resource log data and possibly more depending on what is collected and routed to them.

Search Services

[] Expand table

Table	Description
AzureActivity	Entries from the Azure activity log provide insight into control plane operations. Tasks invoked on the control plane, such as adding or removing replicas and partitions, are represented through a "Get Admin Key" activity.
AzureDiagnostics	Logged query and indexing operations. Queries against the AzureDiagnostics table in Log Analytics can include the common properties, the search-specific properties , and the search-specific operations listed in the schema reference section.
AzureMetrics	Metric data emitted by Azure AI Search that measures health and performance.

Resource log tables

The following table lists the properties of resource logs in Azure AI Search. The resource logs are collected into Azure Monitor Logs or Azure Storage. In Azure Monitor, logs are collected in the AzureDiagnostics table under the resource provider name of `Microsoft.Search`.

[] Expand table

Azure Storage field or property	Azure Monitor Logs property	Description
time	TIMESTAMP	The date and time (UTC) when the operation occurred.
resourceId	Concat("/", "/subscriptions", SubscriptionId, "resourceGroups", ResourceGroupName, "providers/Microsoft.Search/searchServices", ServiceName)	The Azure AI Search resource for which logs are enabled.
category	"OperationLogs"	Log categories include <code>Audit</code> , <code>Operational</code> , <code>Execution</code> , and <code>Request</code> .
operationName	Name	Name of the operation. The operation name can be <code>Indexes.ListIndexStatsSummaries</code> , <code>Indexes.Get</code> , <code>Indexes.Stats</code> , <code>Indexers.List</code> , <code>Query.Search</code> , <code>Query.Suggest</code> , <code>Query.Lookup</code> , <code>Query.Autocomplete</code> , <code>CORS.Preflight</code> , <code>Indexes.Update</code> , <code>Indexes.Prototype</code> , <code>ServiceStats</code> , <code>DataSources.List</code> , <code>Indexers.Warmup</code> .
durationMS	DurationMilliseconds	The duration of the operation, in milliseconds.
operationVersion	ApiVersion	The API version used on the request.
resultType	(Failed) ? "Failed" : "Success"	The type of response.

Azure Storage field or property	Azure Monitor Logs property	Description
resultSignature	Status	The HTTP response status of the operation.
properties	Properties	Any extended properties related to this category of events.

Activity log

The linked table lists the operations that can be recorded in the activity log for this service. These operations are a subset of [all the possible resource provider operations in the activity log](#).

For more information on the schema of activity log entries, see [Activity Log schema](#).

The following table lists common operations related to Azure AI Search that may be recorded in the activity log. For a complete listing of all Microsoft.Search operations, see [Microsoft.Search resource provider operations](#).

[] [Expand table](#)

Operation	Description
Get Admin Key	Any operation that requires administrative rights is logged as a "Get Admin Key" operation.
Get Query Key	Any read-only operation against the documents collection of an index.
Regenerate Admin Key	A request to regenerate either the primary or secondary admin API key.

Common entries include references to API keys - generic informational notifications like *Get Admin Key* and *Get Query keys*. These activities indicate requests that were made using the admin key (create or delete objects) or query key, but don't show the request itself. For information of this grain, you must configure resource logging.

Alternatively, you might gain some insight through change history. In the Azure portal, select the activity to open the detail page and then select "Change history" for information about the underlying operation.

Other schemas

The following schemas are in use for this service.

If you're building queries or custom reports, the data structures that contain Azure AI Search resource logs conform to the following schemas.

For resource logs sent to blob storage, each blob has one root object called **records** containing an array of log objects. Each blob contains records for all the operations that took place during the same hour.

Resource log schema

All resource logs available through Azure Monitor share a [common top-level schema](#). Azure AI Search supplements with [more properties](#) and [operations](#) that are unique to a search service.

The following example illustrates a resource log that includes common properties (TimeGenerated, Resource, Category, and so forth) and search-specific properties (OperationName and OperationVersion).

[+] [Expand table](#)

Name	Type	Description and example
TimeGenerated	Datetime	Timestamp of the operation. For example: <code>2021-12-07T00:00:43.6872559Z</code>
Resource	String	Resource ID. For example: <code>/subscriptions/<your-subscription-id>/resourceGroups/<your-resource-group-name>/providers/Microsoft.Search/searchServices/<your-search-service-name></code>
Category	String	"OperationLogs". This value is a constant. OperationLogs is the only category used for resource logs.
OperationName	String	The name of the operation (see the full list of operations). An example is <code>Query.Search</code>
OperationVersion	String	The api-version used on the request. For example: <code>2024-07-01</code>
ResultType	String	"Success". Other possible values: Success or Failure
ResultSignature	Int	An HTTP result code. For example: <code>200</code>
DurationMS	Int	Duration of the operation in milliseconds.
Properties	Object	Object containing operation-specific data. See the following properties schema table.

Properties schema

The following properties are specific to Azure AI Search.

[+] [Expand table](#)

Name	Type	Description and example
Description_s	String	The operation's endpoint. For example: <code>GET /indexes('content')/docs</code>
Documents_d	Int	Number of documents processed.
IndexName_s	String	Name of the index associated with the operation.
Query_s	String	The query parameters used in the request. For example: <code>?search=beach access\$count=true&api-version=2024-07-01</code>

OperationName values (logged operations)

The following operations can appear in a resource log.

OperationName	Description
DataSources.*	Applies to indexer data sources. Can be Create, Delete, Get, List.
DebugSessions.*	Applies to a debug session. Can be Create, Delete, Get, List, Start, and Status.
DebugSessions.DocumentStructure	An enriched document is loaded into a debug session.
DebugSessions.RetrieveIndexerExecutionHistoricalData	A request for indexer execution details.
DebugSessions.RetrieveProjectedIndexerExecutionHistoricalData	Execution history for enrichments projected to a knowledge store.
Indexers.*	Applies to an indexer. Can be Create, Delete, Get, List, and Status.
Indexes.*	Applies to a search index. Can be Create, Delete, Get, List.
indexes.Prototype	This index is created by the Import Data wizard.
Indexing.Index	This operation is a call to Index Documents .
Metadata.GetMetadata	A request for search service system data.
Query.Autocomplete	An autocomplete query against an index. See Query types and composition .
Query.Lookup	A lookup query against an index. See Query types and composition .
Query.Search	A full text search request against an index. See Query types and composition .
Query.Suggest	Type ahead query against an index. See Query types and composition .
ServiceStats	This operation is a routine call to Get Service Statistics , either called directly or implicitly to populate a portal overview page when it's loaded or refreshed.
Skillsets.*	Applies to a skillset. Can be Create, Delete, Get, List.

Azure Policy Regulatory Compliance controls for Azure AI Search

08/18/2025

If you are using [Azure Policy](#) to enforce the recommendations in [Microsoft cloud security benchmark](#), then you probably already know that you can create policies for identifying and fixing non-compliant services. These policies might be custom, or they might be based on built-in definitions that provide compliance criteria and appropriate solutions for well-understood best practices.

For Azure AI Search, there is currently one built-definition, listed below, that you can use in a policy assignment. The built-in is for logging and monitoring. By using this built-in definition in a [policy that you create](#), the system will scan for search services that do not have [resource logging](#), and then enable it accordingly.

[Regulatory Compliance in Azure Policy](#) provides Microsoft-created and managed initiative definitions, known as *built-ins*, for the **compliance domains** and **security controls** related to different compliance standards. This page lists the **compliance domains** and **security controls** for Azure AI Search. You can assign the built-ins for a **security control** individually to help make your Azure resources compliant with the specific standard.

The title of each built-in policy definition links to the policy definition in the Azure portal. Use the link in the **Policy Version** column to view the source on the [Azure Policy GitHub repo](#).

Important

Each control is associated with one or more [Azure Policy](#) definitions. These policies might help you [assess compliance](#) with the control. However, there often isn't a one-to-one or complete match between a control and one or more policies. As such, **Compliant** in Azure Policy refers only to the policies themselves. This doesn't ensure that you're fully compliant with all requirements of a control. In addition, the compliance standard includes controls that aren't addressed by any Azure Policy definitions at this time. Therefore, compliance in Azure Policy is only a partial view of your overall compliance status. The associations between controls and Azure Policy Regulatory Compliance definitions for these compliance standards can change over time.

Azure security baseline for Azure AI Search

Article • 02/25/2025

This security baseline applies guidance from the [Microsoft cloud security benchmark version 1.0](#) to Azure AI Search. The Microsoft cloud security benchmark provides recommendations on how you can secure your cloud solutions on Azure. The content is grouped by the security controls defined by the Microsoft cloud security benchmark and the related guidance applicable to Azure Cognitive Search.

You can monitor this security baseline and its recommendations using Microsoft Defender for Cloud. Azure Policy definitions will be listed in the Regulatory Compliance section of the Microsoft Defender for Cloud portal page.

When a feature has relevant Azure Policy Definitions, they are listed in this baseline to help you measure compliance with the Microsoft cloud security benchmark controls and recommendations. Some recommendations may require a paid Microsoft Defender plan to enable certain security scenarios.

ⓘ Note

Features not applicable to Azure AI Search have been excluded. To see how Azure AI Search completely maps to the Microsoft cloud security benchmark, see the [full Azure AI Search security baseline mapping file ↗](#).

Security profile

The security profile summarizes high-impact behaviors of Azure AI Search, which may result in increased security considerations.

ⓘ [Expand table](#)

Service Behavior Attribute	Value
Product Category	AI+ML, Mobile, Web
Customer can access HOST / OS	No Access
Service can be deployed into customer's virtual network	False
Stores customer content at rest	True

Network security

For more information, see the [Microsoft cloud security benchmark: Network security](#).

NS-1: Establish network segmentation boundaries

Features

Virtual Network Integration

Description: Service supports deployment into customer's private Virtual Network (VNet).

[Learn more.](#)

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

Network Security Group Support

Description: Service network traffic respects Network Security Groups rule assignment on its subnets. [Learn more.](#)

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

NS-2: Secure cloud services with network controls

Features

Azure Private Link

Description: Service native IP filtering capability for filtering network traffic (not to be confused with NSG or Azure Firewall). [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: For outbound connections through a private endpoint, refer to: [Make outbound connections through a private endpoint](#)

Configuration Guidance: Deploy private endpoints to establish a private access point for the resources. Block all connections on the public endpoint for your search service. Increase security for the virtual network, by enabling you to block exfiltration of data from the virtual network.

Reference: [Create a Private Endpoint for a secure connection to Azure AI Search](#)

Disable Public Network Access

Description: Service supports disabling public network access either through using service-level IP ACL filtering rule (not NSG or Azure Firewall) or using a 'Disable Public Network Access' toggle switch. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Azure AI Search supports IP rules for inbound access through a firewall, similar to the IP rules you'll find in an Azure virtual network security group. By leveraging IP rules, you can restrict search service access to an approved set of machines and cloud services. Access to data stored in your search service from the approved sets of machines and services will still require the caller to present a valid authorization token.

Reference: [Configure an IP firewall for Azure AI Search](#)

Identity management

For more information, see the [Microsoft cloud security benchmark: Identity management](#).

IM-1: Use centralized identity and authentication system

Features

Azure AD Authentication Required for Data Plane Access

Description: Service supports using Azure AD authentication for data plane access. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	True	Microsoft

Configuration Guidance: No additional configurations are required as this is enabled on a default deployment.

Local Authentication Methods for Data Plane Access

Description: Local authentications methods supported for data plane access, such as a local username and password. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Avoid the usage of local authentication methods or accounts, these should be disabled wherever possible. Instead use Azure AD to authenticate where possible.

Reference: [Use roles for Azure AI Search authentication](#)

IM-3: Manage application identities securely and automatically

Features

Managed Identities

Description: Data plane actions support authentication using managed identities. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Azure managed identities instead of service principals when possible, which can authenticate to Azure services and resources that support Azure Active Directory (Azure AD) authentication. Managed identity credentials are fully managed, rotated, and protected by the platform, avoiding hard-coded credentials in source code or configuration files.

Reference: [Authorize access to a search app using Azure Active Directory](#)

Service Principals

Description: Data plane supports authentication using service principals. [Learn more](#).

 [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: There is no current Microsoft guidance for this feature configuration. Please review and determine if your organization wants to configure this security feature.

IM-7: Restrict resource access based on conditions

Features

Conditional Access for Data Plane

Description: Data plane access can be controlled using Azure AD Conditional Access Policies. [Learn more](#).

 [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Define the applicable conditions and criteria for Azure Active Directory (Azure AD) conditional access in the workload. Consider common use cases such as

blocking or granting access from specific locations, blocking risky sign-in behavior, or requiring organization-managed devices for specific applications.

IM-8: Restrict the exposure of credential and secrets

Features

Service Credential and Secrets Support Integration and Storage in Azure Key Vault

Description: Data plane supports native use of Azure Key Vault for credential and secrets store. [Learn more.](#)

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

Privileged access

For more information, see the [Microsoft cloud security benchmark: Privileged access](#).

PA-1: Separate and limit highly privileged/administrative users

Features

Local Admin Accounts

Description: Service has the concept of a local administrative account. [Learn more.](#)

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

PA-7: Follow just enough administration (least privilege) principle

Features

Azure RBAC for Data Plane

Description: Azure Role-Based Access Control (Azure RBAC) can be used to manage access to service's data plane actions. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Azure provides a global role-based access control (RBAC) authorization system for all services running on the platform. In AI Search, you can use Azure roles for:

- Control plane operations (service administration tasks through Azure Resource Manager).
- Data plane operations, such as creating, loading, and querying indexes.

Reference: [Use Azure role-based access controls \(Azure RBAC\) in Azure AI Search](#)

PA-8: Determine access process for cloud provider support

Features

Customer Lockbox

Description: Customer Lockbox can be used for Microsoft support access. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: In support scenarios where Microsoft needs to access your data, use Customer Lockbox to review, then approve or reject each of Microsoft's data access requests.

Data protection

For more information, see the [Microsoft cloud security benchmark: Data protection](#).

DP-1: Discover, classify, and label sensitive data

Features

Sensitive Data Discovery and Classification

Description: Tools (such as Azure Purview or Azure Information Protection) can be used for data discovery and classification in the service. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

DP-2: Monitor anomalies and threats targeting sensitive data

Features

Data Leakage/Loss Prevention

Description: Service supports DLP solution to monitor sensitive data movement (in customer's content). [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

DP-3: Encrypt sensitive data in transit

Features

Data in Transit Encryption

Description: Service supports data in-transit encryption for data plane. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	True	Microsoft

Configuration Guidance: No additional configurations are required as this is enabled on a default deployment.

Reference: [Azure AI Search data in transit encryption](#)

DP-4: Enable data at rest encryption by default

Features

Data at Rest Encryption Using Platform Keys

Description: Data at-rest encryption using platform keys is supported, any customer content at rest is encrypted with these Microsoft managed keys. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	True	Microsoft

Configuration Guidance: No additional configurations are required as this is enabled on a default deployment.

Reference: [Azure AI Search default data encryption using service-managed keys](#)

DP-5: Use customer-managed key option in data at rest encryption when required

Features

Data at Rest Encryption Using CMK

Description: Data at-rest encryption using customer-managed keys is supported for customer content stored by the service. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: If required for regulatory compliance, define the use case and service scope where encryption using customer-managed keys are needed. Enable and implement data at rest encryption using customer-managed key for those services.

Reference: [Configure customer-managed keys for data encryption in Azure AI Search](#)

DP-6: Use a secure key management process

Features

Key Management in Azure Key Vault

Description: The service supports Azure Key Vault integration for any customer keys, secrets, or certificates. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Azure Key Vault to create and control the life cycle of your encryption keys, including key generation, distribution, and storage. Rotate and revoke your keys in Azure Key Vault and your service based on a defined schedule or when there is a key retirement or compromise. When there is a need to use customer-managed key (CMK) in the workload, service, or application level, ensure you follow the best practices for key management: Use a key hierarchy to generate a separate data encryption key (DEK) with your key encryption key (KEK) in your key vault. Ensure keys are registered with Azure Key Vault and referenced via key IDs from the service or application. If you need to bring your own key (BYOK) to the service (such as importing HSM-protected keys from your on-premises HSMs

into Azure Key Vault), follow recommended guidelines to perform initial key generation and key transfer.

Reference: [Configure customer-managed keys for data encryption in Azure AI Search](#)

DP-7: Use a secure certificate management process

Features

Certificate Management in Azure Key Vault

Description: The service supports Azure Key Vault integration for any customer certificates.
[Learn more.](#)

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

Asset management

For more information, see the [Microsoft cloud security benchmark: Asset management](#).

AM-2: Use only approved services

Features

Azure Policy Support

Description: Service configurations can be monitored and enforced via Azure Policy. [Learn more.](#)

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Microsoft Defender for Cloud to configure Azure Policy to audit and enforce configurations of your Azure resources. Use Azure Monitor to create alerts when there is a configuration deviation detected on the resources. Use Azure Policy [deny] and [deploy if not exists] effects to enforce secure configuration across Azure resources.

Reference: [Azure Ai Search Policies](#)

Logging and threat detection

For more information, see the [Microsoft cloud security benchmark: Logging and threat detection](#).

LT-1: Enable threat detection capabilities

Features

Microsoft Defender for Service / Product Offering

Description: Service has an offering-specific Microsoft Defender solution to monitor and alert on security issues. [Learn more](#).

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

LT-4: Enable logging for security investigation

Features

Azure Resource Logs

Description: Service produces resource logs that can provide enhanced service-specific metrics and logging. The customer can configure these resource logs and send them to their own data sink like a storage account or log analytics workspace. [Learn more](#).

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Enable resource logs for the service to view the Azure AI Search operations logs, search metrics, and etc.

Reference: [Azure AI Search resource log](#)

Backup and recovery

For more information, see the [Microsoft cloud security benchmark: Backup and recovery](#).

BR-1: Ensure regular automated backups

Features

Azure Backup

Description: The service can be backed up by the Azure Backup service. [Learn more](#).

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

Service Native Backup Capability

Description: Service supports its own native backup capability (if not using Azure Backup).

[Learn more](#).

[] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Feature notes: Because Azure AI Search isn't a primary data storage solution, Microsoft doesn't provide a formal mechanism for self-service backup and restore. However, you can backup and

restore the index using your own code. Refer to: [Back up and restore alternatives](#)

Configuration Guidance: This feature is not supported to secure this service.

Skills for extra processing during indexing (Azure AI Search)

This article describes the skills in Azure AI Search that you can include in a [skillset](#) to access external processing.

A *skill* is an atomic operation that transforms content in some way. Often, it's an operation that recognizes or extracts text, but it can also be a utility skill that reshapes existing enrichments. The output is usually text-based for use in [full-text search](#) or vectors for use in [vector search](#).

Skills are organized into the following categories:

- A *built-in skill* wraps API calls to another Azure resource, where the inputs, outputs, and processing steps are well understood. Some built-in skills require an attached resource solely for billing, while others use your Azure-hosted model or resource for both billing and processing.
- A *custom skill* provides custom code that executes externally to the search service. It's accessed through a URI. Custom code is often made available through an Azure function app. To attach an open-source or third-party vectorization model, use a custom skill.
- A *utility skill* is internal to Azure AI Search, with no dependency on external resources or outbound connections. Most utility skills are nonbillable.

Built-in skills

There are two types of built-in skills:

- Skills that connect to a [Microsoft Foundry resource](#) (for billing only)
- Skills that connect to an [Azure-hosted model or resource](#) (for billing and processing)

Foundry resource

Skills in this category call subservices of Foundry Tools. For billing rather than processing, you must [attach a Foundry resource to your skillset](#). Azure AI Search uses internal resources to execute these skills and only uses your Foundry resource for billing purposes.

A small quantity of processing is nonbillable, but at larger volumes, processing is billable. These skills are based on pretrained models from Foundry Tools, which means you can't train the models using your own data.

These skills are billed at the Standard rate.

Skill	Description	Metered by
Azure Vision multimodal embeddings	Multimodal image and text vectorization.	Foundry Tools (pricing ↗)
Custom Entity Lookup	Looks for text from a custom, user-defined list of words and phrases.	Azure AI Search (pricing ↗)
Entity Linking	This skill uses a pretrained model to generate links for recognized entities to articles in Wikipedia.	Foundry Tools (pricing ↗)
Entity Recognition	This skill uses a pretrained model to establish entities for a fixed set of categories: "Person", "Location", "Organization", "Quantity", "DateTime", "URL", "Email", "PersonType", "Event", "Product", "Skill", "Address", "Phone Number" and "IP Address" fields.	Foundry Tools (pricing ↗)
Image Analysis	This skill uses an image detection algorithm to identify the content of an image and generate a text description.	Foundry Tools (pricing ↗)
Key Phrase Extraction	This skill uses a pretrained model to detect important phrases based on term placement, linguistic rules, proximity to other terms, and how unusual the term is within the source data.	Foundry Tools (pricing ↗)
Language Detection	This skill uses a pretrained model to detect which language is used (one language ID per document). When multiple languages are used within the same text segments, the output is the LCID of the predominantly used language.	Foundry Tools (pricing ↗)
OCR	Optical character recognition.	Foundry Tools (pricing ↗)
PII Detection	This skill uses a pretrained model to extract personal information from a given text. The skill also gives various options for masking the detected personal information entities in the text.	Foundry Tools (pricing ↗)
Sentiment	This skill uses a pretrained model to assign sentiment labels (such as "negative", "neutral" and "positive") based on the highest confidence score found by the service at a sentence and document-level on a record by record basis.	Foundry Tools (pricing ↗)
Text Translation	This skill uses a pretrained model to translate the input text into various languages for normalization or localization use cases.	Foundry Tools (pricing ↗)

Azure-hosted model or resource

Skills in this category call Azure-hosted models or resources that you own for both billing and processing. Although Azure Content Understanding is part of Foundry Tools, the Azure Content Understanding skill connects to your deployed resource for processing, not just billing.

These skills are billed at the Standard rate.

[+] [Expand table](#)

Skill	Description	Metered by
Azure Content Understanding	Connects to Azure Content Understanding for advanced document analysis and semantic chunking.	Azure Content Understanding (pricing ↗)
Azure OpenAI Embedding	Connects to a deployed Azure OpenAI embedding model for integrated vectorization.	Azure OpenAI (pricing ↗)
GenAI Prompt	Extends an AI enrichment pipeline with a Foundry chat completion model.	Azure OpenAI (pricing ↗)

Custom skills

Skills in this category wrap external code that you design, develop, and deploy to the web. You can then call the module from within a skillset as a custom skill.

For guidance on creating a custom skill, see [Define a custom interface](#) and [Example: Creating a custom skill for AI enrichment](#).

[+] [Expand table](#)

Skill	Description	Metered by
AML	Extends an AI enrichment pipeline with a Foundry or Azure Machine Learning model.	None, unless your solution uses a metered Azure service.
Custom Entity Lookup	Extends an AI enrichment pipeline by detecting user-defined entities.	None, unless your solution uses a metered Azure service.
Web API	Extends an AI enrichment pipeline by making an HTTP call into a custom Web API.	None, unless your solution uses a metered Azure service.

Utility skills

Skills in this category execute only on Azure AI Search, iterate mostly on nodes in the enrichment cache, and are mostly nonbillable.

Skill	Description	Metered by
Conditional	Allows filtering, assigning a default value, and merging data based on a condition.	Not applicable
Document Extraction	Extracts content from a file within the enrichment pipeline.	Azure AI Search (pricing ↗) for image extraction
Shaper	Maps output to a complex type (a multi-part data type, which might be used for a full name, a multi-line address, or a combination of last name and a personal identifier.)	Not applicable
Text Merge	Consolidates text from a collection of fields into a single field.	Not applicable
Text Split	Splits text into pages so that you can enrich or augment content incrementally.	Not applicable

Skill context and input annotation language

07/14/2025

This article is the reference documentation for skill context and input syntax. It's a full description of the expression language used to construct paths to nodes in an enriched document.

Azure AI Search skills can use and [enrich the data coming from the data source and from the output of other skills](#). The data working set that represents the current state of the indexer work for the current document starts from the raw data coming from the data source and is progressively enriched with each skill iteration's output data. That data is internally organized in a tree-like structure that can be queried to be used as skill inputs or to be added to the index. The nodes in the tree can be simple values such as strings and numbers, arrays, or complex objects and even binary files. Even simple values can be enriched with additional structured information. For example, a string can be annotated with additional information that is stored beneath it in the enrichment tree. The expressions used to query that internal structure use a rich syntax that is detailed in this article. The enriched data structure can be [inspected from debug sessions](#). Expressions querying the structure can also be tested from debug sessions.

Throughout the article, we'll use the following enriched data as an example. This data is typical of the kind of structure you would get when enriching a document using a skillset with [OCR](#), [key phrase extraction](#), [text translation](#), [language detection](#), and [entity recognition](#) skills, as well as a custom tokenizer skill.

[\[+\] Expand table](#)

...	
...	
...	

Document root

All the data is under one root element, for which the path is `"/document"`. The root element is the default context for skills.

Simple paths

Simple paths through the internal enriched document can be expressed with simple tokens separated by slashes. This syntax is similar to [the JSON Pointer specification](#).

Object properties

The properties of nodes that represent objects add their values to the tree under the property's name. Those values can be obtained by appending the property name as a token separated by a slash:

[] [Expand table](#)

Expression	Value
<code>/document/merged_content/language</code>	"en"

Property name tokens are case-sensitive.

Array item index

Specific elements of an array can be referenced by using their numeric index like a property name:

[+] Expand table

Expression	Value
/document/merged_content/keyphrases/1	"Syndrome"
/document/merged_content/entities/0/text	"BMN"

Escape sequences

There are several characters that have a special meaning and need to be escaped if they are to be interpreted as-is instead of a syntax element. These characters include `#`, `/`, and `~` among others.

[+] Expand table

Escape sequence	Special meaning (usage in path syntax)	Example
<code>~0</code>	Used for escaping <code>~</code>	" <code>~0</code> " for <code>~</code> , where " <code>~/documents</code> " becomes " <code>~0~1documents</code> "
<code>~1</code>	Used for escaping <code>/</code>	" <code>~1</code> " for <code>/</code> , where " <code>~/documents</code> " becomes " <code>~0~1documents</code> "
<code>~2</code>	Used for generically to escape arbitrary sequences (including but not limited to <code>#</code> and <code>*</code>)	" <code>~2#~2</code> " where " <code>readme#requirements</code> " becomes " <code>readme~2#~2requirements</code> "

Array enumeration

An array of values can be obtained using the `'*' token`:

[+] Expand table

Expression	Value
/document/normalized_images/0/text/words/*	["Study", "of", "BMN", "110" ...]

The '*' token doesn't have to be at the end of the path. It's possible to enumerate all nodes matching a path with a star in the middle or with multiple stars:

[Expand table](#)

Expression	Value
/document/normalized_images/*/text/words/*	["Study", "of", "BMN", "110" ... "it", "is", "certainly" ...]

This example returns a flat list of all matching nodes.

It's possible to maintain more structure and get a separate array for the words of each page by using a '#' token instead of the second '*' token:

[Expand table](#)

Expression	Value
/document/normalized_images/*/text/words/#	[["Study", "of", "BMN", "110" ...], ["it", "is", "certainly" ...] ...]

The '#' token expresses that the array should be treated as a single value instead of being enumerated.

Enumerating arrays in context

It's often useful to process each element of an array in isolation and have a different set of skill inputs and outputs for each. This can be done by setting the context of the skill to an enumeration instead of the default "/document".

In the following example, we use one of the input expressions we used before, but with a different context that changes the resulting value.

[Expand table](#)

Context	Expression	Values
/document/normalized_images/*	/document/normalized_images/*/text/words/*	["Study", "of", "BMN", "110" ...] ["it", "is", "certainly" ...] ...

For this combination of context and input, the skill gets executed once for each normalized image: once for `"/document/normalized_images/0"` and once for `"/document/normalized_images/1"`. The two input values corresponding to each skill execution are detailed in the values column.

When enumerating an array in context, any outputs the skill produces will also be added to the document as enrichments of the context. In the above example, an output named `"out"` has its values for each execution added to the document respectively under `"/document/normalized_images/0/out"` and `"/document/normalized_images/1/out"`.

Literal values

Skill inputs can take literal values as their inputs instead of dynamic values queried from the existing document. This can be achieved by prefixing the value with an equal sign. Values can be numbers, strings or Boolean. String values can be enclosed in single '`'` or double '`"`' quotes.

 Expand table

Expression	Value
<code>=42</code>	<code>42</code>
<code>=2.45E-4</code>	<code>0.000245</code>
<code>="some string"</code>	<code>"some string"</code>
<code>='some other string'</code>	<code>"some other string"</code>
<code>="unicod\u0065"</code>	<code>"unicode"</code>
<code>=false</code>	<code>false</code>

In line arrays

If a certain skill input requires an array of data, but the data is represented as a single value currently or you need to combine multiple different single values into an array field, then you can create an array value inline as part of a skill input expression by wrapping a comma separated list of expressions in brackets (`[` and `]`). The array value can be a combination of expression paths or literal values as needed. You can also create nested arrays within arrays this way.

 Expand table

Expression	Value
=['item']	["item"]
=[\$(/document/merged_content/entities/0/text), 'item']	["BMN", "item"]
=[1, 3, 5]	[1, 3, 5]
=[true, true, false]	[true, true, false]
=[[\$(/document/merged_content/entities/0/text), 'item'], ['item2', \$(/document/merged_content/keyphrases/1)]]	[["BMN", "item"], ["item2", "Syndrome"]]

If the skill has a context that explains to run the skill per an array input (that is, how "context": "/document/pages/*" means the skill runs once per "page" in `pages`) then passing that value as the expression as input to an in line array uses one of those values at a time.

For an example with our sample enriched data, if your skill's `context` is

`/document/merged_content/keyphrases/*` and then you create an inline array of the following `= ['key phrase', $(/document/merged_content/keyphrases/*)]` on an input of that skill, then the skill is executed three times, once with a value of `["key phrase", "Study of BMN"]`, another with a value of `["key phrase", "Syndrome"]`, and finally with a value of `["key phrase", "Pediatric Patients"]`. The literal "key phrase" value stays the same each time, but the value of the expression path changes with each skill execution.

Composite expressions

It's possible to combine values together using unary, binary, and ternary operators. Operators can combine literal values and values resulting from path evaluation. When used inside an expression, paths should be enclosed between `"$("` and `")"`.

Boolean not `'!'`

[\[\] Expand table](#)

<code>=\$(/document/merged_content/entities/0/offset)/3</code>	3

Modulo '%'

[+] [Expand table](#)

Expression	Value
<code>=15%4</code>	3
<code>=\$(/document/merged_content/entities/0/offset)%2</code>	1

String concatenation '+'

[+] [Expand table](#)

Expression	Value
<code>="Hello," + "world!"</code>	"Hello, world!"
<code>=\$(/document/merged_content/entities/0/text) + \$(/document/merged_content/entities/0/category)</code>	"BMN Organization"

Less than, less than or equal, greater than and greater than or equal '`<`' '`<=`' '`>`' '`>=`'

[+] [Expand table](#)

Expression	Value
<code>=15<4</code>	false
<code>=4<=4</code>	true
<code>=15>4</code>	true
<code>=1>=2</code>	false

Equality and nonequality '`==`' '`!=`'

[\[+\] Expand table](#)

Expression	Value
=15==4	false
=4==4	true
=15!=4	true
=1!=1	false

Logical operations and, or and exclusive or `'&&'` `'||'` `'^'`

[\[+\] Expand table](#)

Expression	Value
=true&&true	true
=true&&false	false
=true true	true
=true false	true
=false false	false
=true^false	true
=true^true	false

Ternary operator `'?:'`

It's possible to give an input different values based on the evaluation of a Boolean expression using the ternary operator.

[\[+\] Expand table](#)

Expression	Value
=true?"true":"false"	"true"
=\$(/document/merged_content/entities/0/offset)==9?"nine":"not nine"	"nine"

Parentheses and operator priority

Operators are evaluated with priorities that match usual conventions: unary operators, then multiplication, division and modulo, then addition and subtraction, then comparison, then equality, and then logical operators. Usual associativity rules also apply.

Parentheses can be used to change or disambiguate evaluation order.

[+] [Expand table](#)

Expression	Value
=3*2+5	11
=3*(2+5)	21

Azure Vision multimodal embeddings skill

Important

This skill is in public preview under [Supplemental Terms of Use](#). The [2024-05-01-Preview REST API](#) and newer preview APIs support this feature.

The Azure Vision multimodal embeddings skill uses the [multimodal embeddings API](#) from Azure Vision in Foundry Tools to generate embeddings for text or image input.

For transactions that exceed 20 documents per indexer per day, this skill requires that you [attach a billable Microsoft Foundry resource to your skillset](#). Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#). Image extraction is also [billable by Azure AI Search](#).

Location of resources is a consideration for billing. Because you're using a preview REST API version to create a skillset that contains preview skills, you can use a [keyless connection](#) to bypass the same-region requirement. However, for key-based connections, Azure AI Search and Foundry must be in the same region. To ensure region compatibility:

1. Find a [supported region for multimodal embeddings](#).
2. Verify the [region provides AI enrichment](#).

The Foundry resource is used for billing purposes only. Content processing occurs on separate resources managed and maintained by Azure AI Search within the same geo. Your data is processed in the [Geo](#) where your resource is deployed.

@odata.type

Microsoft.Skills.Vision.VectorizeSkill

Data limits

The input limits for the skill can be found in the [Azure Vision documentation](#) for images and text. Consider using the [Text Split skill](#) if you need data chunking for text inputs.

Applicable inputs include:

- Image input file size must be less than 20 megabytes (MB). Image size must be greater than 10 x 10 pixels and less than 16,000 x 16,000 pixels.
- Text input string must be between (inclusive) one word and 70 words.

Skill parameters

Parameters are case sensitive.

[] [Expand table](#)

Inputs	Description
<code>modelVersion</code>	(Required) The model version (<code>2023-04-15</code>) to be passed to the Azure Vision multimodal embeddings API for generating embeddings. Vector embeddings can only be compared and matched if they're from the same model type. Images vectorized by one model won't be searchable through a different model. The latest Image Analysis API offers two models: <ul style="list-style-type: none">• The <code>2023-04-15</code> version, which supports text search in many languages. Azure AI Search uses this version.• The legacy <code>2022-04-11</code> model, which supports only English.

Skill inputs

Skill definition inputs include name, source, and inputs. The following table provides valid values for name of the input. You can also specify recursive inputs. For more information, see the [REST API reference](#) and [Create a skillset](#).

[] [Expand table](#)

Input	Description
<code>text</code>	The input text to be vectorized. If you're using data chunking, the source might be <code>/document/pages/*</code> .
<code>image</code>	Complex Type. Currently only works with <code>/document/normalized_images</code> field, produced by the Azure blob indexer when <code>imageAction</code> is set to a value other than <code>none</code> .
<code>url</code>	The URL to download the image to be vectorized.
<code>queryString</code>	The query string of the URL to download the image to be vectorized. Useful if you store the URL and SAS token in separate paths.

Only one of `text`, `image` or `url/queryString` can be configured for a single instance of the skill. If you want to vectorize both images and text within the same skillset, include two instances of this skill in the skillset definition, one for each input type you would like to use.

Skill outputs

Output	Description
vector	Output embedding array of floats for the input text or image.

Sample definition

For text input, consider a blob that has the following content:

JSON

```
{
    "content": "Forests, grasslands, deserts, and mountains are all part of the
Patagonian landscape that spans more than a million square kilometers of South
America."
}
```

For text inputs, your skill definition might look like this:

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Vision.VectorizeSkill",
    "context": "/document",
    "modelVersion": "2023-04-15",
    "inputs": [
        {
            "name": "text",
            "source": "/document/content"
        }
    ],
    "outputs": [
        {
            "name": "vector",
            "targetName": "text_vector"
        }
    ]
}
```

For image input, a second skill definition in the same skillset might look like this:

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Vision.VectorizeSkill",
    "context": "/document/normalized_images/*",
    "modelVersion": "2023-04-15",
```

```
"inputs": [
  {
    "name": "image",
    "source": "/document/normalized_images/*"
  }
],
"outputs": [
  {
    "name": "vector",
    "targetName": "image_vector"
  }
]
```

If you want to vectorize images directly from your blob storage data source rather than extract images during indexing, your skill definition should specify a URL, and perhaps a SAS token depending on storage security. For this scenario, your skill definition might look like this:

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Vision.VectorizeSkill",
  "context": "/document",
  "modelVersion": "2023-04-15",
  "inputs": [
    {
      "name": "url",
      "source": "/document/metadata_storage_path"
    },
    {
      "name": "queryString",
      "source": "/document/metadata_storage_sas_token"
    }
  ],
  "outputs": [
    {
      "name": "vector",
      "targetName": "image_vector"
    }
  ]
}
```

Sample output

For the given input, a vectorized embedding output is produced. Output is 1,024 dimensions, which is the number of dimensions supported by the Azure Vision multimodal API.

JSON

```
{  
  "text_vector": [  
    0.018990106880664825,  
    -0.0073809814639389515,  
    ....  
    0.021276434883475304,  
  ]  
}
```

The output resides in memory. To send this output to a field in the search index, you must define an [outputFieldMapping](#) that maps the vectorized embedding output (which is an array) to a [vector field](#). Assuming the skill output resides in the document's **vector** node, and **content_vector** is the field in the search index, the outputFieldMapping in the indexer should look like:

JSON

```
"outputFieldMappings": [  
  {  
    "sourceFieldName": "/document/vector/*",  
    "targetFieldName": "content_vector"  
  }  
]
```

For mapping image embeddings to the index, you use [index projections](#). The payload for `indexProjections` might look something like the following example. `image_content_vector` is a field in the index, and it's populated with the content found in the **vector** of the **normalized_images** array.

JSON

```
"indexProjections": {  
  "selectors": [  
    {  
      "targetIndexName": "myTargetIndex",  
      "parentKeyFieldName": "ParentKey",  
      "sourceContext": "/document/normalized_images/*",  
      "mappings": [  
        {  
          "name": "image_content_vector",  
          "source": "/document/normalized_images/*/vector"  
        }  
      ]  
    }  
  ]  
}
```

Document Layout skill

The Document Layout skill analyzes a document to detect structure and characteristics, and produces a syntactical representation of the document in Markdown or Text format. You can use it to extract text and images, where image extraction includes location metadata that preserves image position within the document. Image proximity to related content is beneficial in Retrieval Augmented Generation (RAG) workloads and [multimodal search](#) scenarios.

This article is the reference documentation for the Document Layout skill. For usage information, see [How to chunk and vectorize by document layout](#).

This skill uses the [layout model](#) from [Azure Document Intelligence in Foundry Tools](#).

This skill is bound to a [billable Microsoft Foundry resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

💡 Tip

It's common to use this skill on content such as PDFs that have structure and images. The following tutorials demonstrate image verbalization with two different data chunking techniques:

- [Tutorial: Verbalize images from a structured document layout](#)
- [Tutorial: Vectorize from a structured document layout](#)

Limitations

This skill has the following limitations:

- The skill isn't suitable for large documents requiring more than 5 minutes of processing in the Azure Document Intelligence layout model. The skill times out, but charges still apply to the Foundry resource if it's attached to the skillset for billing purposes. Ensure documents are optimized to stay within processing limits to avoid unnecessary costs.
- Since this skill calls the Azure Document Intelligence layout model, all documented [service behaviors for different document types](#) for different file types apply to its output. For example, Word (DOCX) and PDF files may produce different results due to differences in how images are handled. If consistent image behavior across DOCX and PDF is required, consider converting documents to PDF or reviewing the [multimodal search documentation](#) for alternative approaches.

Supported regions

The Document Layout skill calls the [Azure Document Intelligence 2024-11-30 API version V4.0](#).

Supported regions vary by modality and how the skill connects to the Azure Document Intelligence layout model.

 [Expand table](#)

Approach	Requirement
Import data (new) wizard	Create a Foundry resource in one of these regions to get the portal experience: East US, West Europe, North Central US .
Programmatic, using Microsoft Entra ID authentication (preview) for billing	Create Azure AI Search in one of the regions where the service is supported, according to Product availability by region . Create the Foundry resource in any region listed in the Product availability by region table.
Programmatic, using a Foundry resource key for billing	Create your Azure AI Search service and Foundry resource in the same region. This means that the region chosen must have support for both Azure AI Search and Azure Document Intelligence services .

The implemented version of Document Layout model doesn't have support for [21Vianet](#) regions at this time.

Supported file formats

This skill recognizes the following file formats.

- .PDF
- .JPEG
- .JPG
- .PNG
- .BMP
- .TIFF
- .DOCX
- .XLSX
- .PPTX
- .HTML

Supported languages

Refer to [Azure Document Intelligence layout model supported languages](#) for printed text.

@odata.type

Microsoft.Skills.Util.DocumentIntelligenceLayoutSkill

Data limits

- For PDF and TIFF, up to 2,000 pages can be processed (with a free tier subscription, only the first two pages are processed).
- Even if the file size for analyzing documents is 500 MB for [Azure Document Intelligence paid \(S0\) tier](#) and 4 MB for [Azure Document Intelligence free \(F0\) tier](#), indexing is subject to the [indexer limits](#) of your search service tier.
- Image dimensions must be between 50 pixels x 50 pixels or 10,000 pixels x 10,000 pixels.
- If your PDFs are password-locked, remove the lock before running the indexer.

Skill parameters

Parameters are case sensitive. Several parameters were introduced in specific preview versions of the REST API. We recommend using the generally available version (2025-09-01) or the latest preview (2025-11-01-preview) for full access to all parameters.

[] Expand table

Parameter name	Allowed Values	Description
outputMode	oneToMany	Controls the cardinality of the output produced by the skill.
markdownHeaderDepth	h1, h2, h3, h4, h5, h6(default)	Only applies if <code>outputFormat</code> is set to <code>markdown</code> . This parameter describes the deepest nesting level that should be considered. For instance, if the <code>markdownHeaderDepth</code> is <code>h3</code> , any sections that are deeper such as <code>h4</code> , are rolled into <code>h3</code> .
outputFormat	markdown(default), text	New. Controls the format of the output generated by the skill.
extractionOptions	["images"], ["images", "locationMetadata"], ["locationMetadata"]	New. Identify any extra content extracted from the document. Define an array of enums that correspond to the content to be included in the output. For instance, if the <code>extractionOptions</code> is <code>["images", "locationMetadata"]</code> , the output includes images and location metadata which provides page location

Parameter name	Allowed Values	Description
		information related to where the content was extracted, such as a page number or section. This parameter applies to both output formats.
chunkingProperties	See below.	New. Only applies if <code>outputFormat</code> is set to <code>text</code> . Options that encapsulate how to chunk text content while recomputing other metadata.

[+] [Expand table](#)

ChunkingProperties Parameter	Version	Allowed Values	Description
<code>unit</code>	<code>Characters</code> . currently the only allowed value. Chunk length is measured in characters, as opposed to words or tokens	New. Controls the cardinality of the chunk unit.	
<code>maxLength</code>	Any integer between 300-50000	New. The maximum chunk length in characters as measured by <code>String.Length</code> .	
<code>overlapLength</code>	Integer. The value needs to be less than the half of the <code>maxLength</code>	New. The length of overlap provided between two text chunks.	

Skill inputs

[+] [Expand table](#)

Input name	Description
<code>file_data</code>	The file that content should be extracted from.

The "file_data" input must be an object defined as:

JSON

```
{
  "$type": "file",
  "data": "BASE64 encoded string of the file"
}
```

Alternatively, it can be defined as:

JSON

```
{  
  "$type": "file",  
  "url": "URL to download file",  
  "sasToken": "OPTIONAL: SAS token for authentication if the URL provided is for a  
file in blob storage"  
}
```

The file reference object can be generated in one of following ways:

- Setting the `allowSkillsetToReadFileData` parameter on your indexer definition to true. This setting creates a path `/document/file_data` that's an object representing the original file data downloaded from your blob data source. This parameter only applies to files in Azure Blob storage.
- Having a custom skill returning a JSON object definition that provides `$type`, `data`, or `url` and `sastoken`. The `$type` parameter must be set to `file`, and `data` must be the base 64-encoded byte array of the file content. The `url` parameter must be a valid URL with access for downloading the file at that location.

Skill outputs

 Expand table

Output name	Description
<code>markdown_document</code>	Only applies if <code>outputFormat</code> is set to <code>markdown</code> . A collection of "sections" objects, which represent each individual section in the Markdown document.
<code>text_sections</code>	Only applies if <code>outputFormat</code> is set to <code>text</code> . A collection of text chunk objects, which represent the text within the bounds of a page (factoring in any more chunking configured), <i>inclusive</i> of any section headers themselves. The text chunk object includes <code>locationMetadata</code> if applicable.
<code>normalized_images</code>	Only applies if <code>outputFormat</code> is set to <code>text</code> and <code>extractionOptions</code> includes <code>images</code> . A collection of images that were extracted from the document, including <code>locationMetadata</code> if applicable.

Sample definition for markdown output mode

JSON

```
{  
  "skills": [  
    {
```

```
{
  "description": "Analyze a document",
  "@odata.type": "#Microsoft.Skills.Util.DocumentIntelligenceLayoutSkill",
  "context": "/document",
  "outputMode": "oneToMany",
  "markdownHeaderDepth": "h3",
  "inputs": [
    {
      "name": "file_data",
      "source": "/document/file_data"
    }
  ],
  "outputs": [
    {
      "name": "markdown_document",
      "targetName": "markdown_document"
    }
  ]
}
```

Sample output for markdown output mode

JSON

```
{
  "markdown_document": [
    {
      "content": "Hi this is Jim \r\nHi this is Joe",
      "sections": {
        "h1": "Foo",
        "h2": "Bar",
        "h3": ""
      },
      "ordinal_position": 0
    },
    {
      "content": "Hi this is Lance",
      "sections": {
        "h1": "Foo",
        "h2": "Bar",
        "h3": "Boo"
      },
      "ordinal_position": 1,
    }
  ]
}
```

The value of the `markdownHeaderDepth` controls the number of keys in the "sections" dictionary. In the example skill definition, since the `markdownHeaderDepth` is "h3," there are three keys in the

"sections" dictionary: h1, h2, h3.

Example for text output mode and image and metadata extraction

This example demonstrates how to output text content in fixed-sized chunks and extract images along with location metadata from the document.

Sample definition for text output mode and image and metadata extraction

JSON

```
{  
  "skills": [  
    {  
      "description": "Analyze a document",  
      "@odata.type": "#Microsoft.Skills.Util.DocumentIntelligenceLayoutSkill",  
      "context": "/document",  
      "outputMode": "oneToMany",  
      "outputFormat": "text",  
      "extractionOptions": ["images", "locationMetadata"],  
      "chunkingProperties": {  
        "unit": "characters",  
        "maxLength": 2000,  
        "overlapLength": 200  
      },  
      "inputs": [  
        {  
          "name": "file_data",  
          "source": "/document/file_data"  
        }  
      ],  
      "outputs": [  
        {  
          "name": "text_sections",  
          "targetName": "text_sections"  
        },  
        {  
          "name": "normalized_images",  
          "targetName": "normalized_images"  
        }  
      ]  
    }  
  ]  
}
```

Sample output for text output mode and image and metadata extraction

JSON

```
"text_sections": [
{
    "id": "1_7e6ef1f0-d2c0-479c-b11c-5d3c0fc88f56",
    "content": "the effects of analyzers using Analyze Text (REST). For more information about analyzers, see Analyzers for text processing. During indexing, an indexer only checks field names and types. There's no validation step that ensures incoming content is correct for the corresponding search field in the index. Create an indexerWhen you're ready to create an indexer on a remote search service, you need a search client. A search client can be the Azure portal, a REST client, or code that instantiates an indexer client. We recommend the Azure portal or REST APIs for early development and proof-of-concept testing. Azure portal1. Sign in to the Azure portal 2, then find your search service.2. On the search service Overview page, choose from two options:· Import data wizard: The wizard is unique in that it creates all of the required elements. Other approaches require a predefined data source and index. You can override this behavior by setting disabled to true in the indexer definition. Indexer execution is the moment of truth where you find out if there are problems with connections, field mappings, or skillset construction. There are several ways to run an indexer:: Run on indexer creation or update (default).. Run on demand when there

```

are no changes to the definition, or precede with `reset` for full indexing. For more information, see Run or reset indexers.. Schedule indexer processing to invoke execution at regular intervals.Scheduled execution is usually implemented when you have a need for incremental indexing so that you can pick up the latest changes. As such, scheduling has a dependency on change detection.Indexers are one of the few subsystems that make overt outbound calls to other Azure resources. In terms of Azure roles, indexers don't have separate identities; a connection from the search engine to another Azure resource is made using the system or user- assigned managed identity of a search service. If the indexer connects to an Azure resource on a virtual network, you should create a shared private link for that connection. For more information about secure connections, see Security in Azure AI Search.Check results",

}  
]
```

Note that the “sections” in the sample output above appear blank. To populate them, you’ll need to add an additional skill configured with `outputFormat` set to `markdown` to ensure the sections are properly filled.

The skill uses [Azure Document Intelligence](#) to compute locationMetadata. Refer to [Azure Document Intelligence layout model](#) for details on how pages and bounding polygon coordinates are defined.

The `imagePath` represents the relative path of a stored image. If the knowledge store file projection is configured in the skillset, this path matches the relative path of the image stored in the knowledge store.

Last updated on 11/19/2025

Entity Linking cognitive skill (v3)

The Entity Linking skill (v3) returns a list of recognized entities with links to articles in a well-known knowledge base (Wikipedia).

! Note

This skill is bound to the [Entity Linking](#) machine learning models in [Azure Vision in Foundry Tools](#). It requires a [billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

@odata.type

Microsoft.Skills.Text.V3.EntityLinkingSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the EntityLinking skill, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameter names are case-sensitive and are all optional.

[+] [Expand table](#)

Parameter name	Description
<code>defaultLanguageCode</code>	Language code of the input text. If the default language code isn't specified, English (en) is used as the default language code. See the full list of supported languages .
<code>minimumPrecision</code>	A value between 0 and 1. If the confidence score (in the <code>entities</code> output) is lower than this value, the entity isn't returned. The default is 0.
<code>modelVersion</code>	(Optional) Specifies the version of the model to use when calling entity linking. It defaults to the latest available when not specified. We recommend you don't specify this value unless it's necessary.

Skill inputs

[\[\] Expand table](#)

Input name	Description
languageCode	A string indicating the language of the records. If this parameter isn't specified, the default language code is used to analyze the records. See the full list of supported languages .
text	The text to analyze.

Skill outputs

[\[\] Expand table](#)

Output	Description
name	
entities	An array of complex types that contains the following fields: <ul style="list-style-type: none">• "name" (The actual entity name as it appears in the text)• "id"• "language" (The language of the text as determined by the skill)• "url" (The linked url to this entity)• "bingId" (The bingId for this linked entity)• "dataSource" (The data source associated with the url)• "matches" (An array of complex types that contains: <code>text</code>, <code>offset</code>, <code>length</code> and <code>confidenceScore</code>)

Sample definition

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Text.V3.EntityLinkingSkill",  
  "context": "/document",  
  "defaultLanguageCode": "en",  
  "minimumPrecision": 0.5,  
  "inputs": [  
    {  
      "name": "text",  
      "source": "/document/content"  
    },  
    {  
      "name": "languageCode",  
      "source": "/document/languageCode"  
    }  
  ]}
```

```
        "source": "/document/language"
    }
],
"outputs": [
{
    "name": "entities",
    "targetName": "entities"
}
]
}
```

Sample input

JSON

```
{
    "values": [
        {
            "recordId": "1",
            "data":
            {
                "text": "Microsoft is liked by many.",
                "languageCode": "en"
            }
        }
    ]
}
```

Sample output

JSON

```
{
    "values": [
        {
            "recordId": "1",
            "data" :
            {
                "entities": [
                    {
                        "name": "Microsoft",
                        "id": "Microsoft",
                        "language": "en",
                        "url": "https://en.wikipedia.org/wiki/Microsoft",
                        "bingId": "a093e9b9-90f5-a3d5-c4b8-5855e1b01f85",
                        "dataSource": "Wikipedia",
                        "matches": [
                            {
                                "text": "Microsoft",

```

```
        "offset": 0,
        "length": 9,
        "confidenceScore": 0.13
    }
]
}
],
}
]
}
```

The offsets returned for entities in the output of this skill are directly returned from the [Language Service APIs](#), which means if you're using them to index into the original string, you should use the [StringInfo](#) class in .NET in order to extract the correct content. For more information, see [Multilingual and emoji support in Language service features](#).

Warning cases

If the language code for the document is unsupported, a warning is returned and no entities are extracted.

Entity Recognition cognitive skill (v3)

The Entity Recognition skill (v3) extracts entities of different types from text. These entities fall under 14 distinct categories, ranging from people and organizations to URLs and phone numbers. This skill uses the [Named Entity Recognition](#) machine learning models provided by [Azure Language in Foundry Tools](#).

! Note

This skill is bound to Foundry Tools and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

@odata.type

Microsoft.Skills.Text.V3.EntityRecognitionSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the EntityRecognition skill, consider using the [Text Split skill](#). When using a split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameters are case sensitive and are all optional.

[] Expand table

Parameter name	Description
categories	Array of categories that should be extracted. Possible category types: "Person", "Location", "Organization", "Quantity", "DateTime", "URL", "Email", "personType", "Event", "Product", "Skill", "Address", "phoneNumber", "ipAddress". If no category is provided, all types are returned.
defaultLanguageCode	Language code of the input text. If the default language code is not specified, English (en) will be used as the default language code. See the full list of supported languages . Not all entity categories are supported for all languages; see note below.

Parameter name	Description
<code>minimumPrecision</code>	A value between 0 and 1. If the confidence score (in the <code>namedEntities</code> output) is lower than this value, the entity is not returned. The default is 0.
<code>modelVersion</code>	(Optional) Specifies the version of the model to use when calling the entity recognition API. It will default to the latest available when not specified. We recommend you do not specify this value unless it's necessary.

Skill inputs

[] [Expand table](#)

Input name	Description
<code>languageCode</code>	A string indicating the language of the records. If this parameter is not specified, the default language code will be used to analyze the records. See the full list of supported languages .
<code>text</code>	The text to analyze.

Skill outputs

! Note

Not all entity categories are supported for all languages. See [Supported Named Entity Recognition \(NER\) entity categories](#) to know which entity categories are supported for the language you will be using.

[] [Expand table](#)

Output name	Description
<code>persons</code>	An array of strings where each string represents the name of a person.
<code>locations</code>	An array of strings where each string represents a location.
<code>organizations</code>	An array of strings where each string represents an organization.
<code>quantities</code>	An array of strings where each string represents a quantity.
<code>dateTimes</code>	An array of strings where each string represents a DateTime (as it appears in the text) value.

Output name	Description
urls	An array of strings where each string represents a URL
emails	An array of strings where each string represents an email
personTypes	An array of strings where each string represents a PersonType
events	An array of strings where each string represents an event
products	An array of strings where each string represents a product
skills	An array of strings where each string represents a skill
addresses	An array of strings where each string represents an address
phoneNumbers	An array of strings where each string represents a telephone number
ipAddresses	An array of strings where each string represents an IP Address
namedEntities	An array of complex types that contains the following fields: <ul style="list-style-type: none"> category subcategory confidenceScore (Higher value means it's more likely to be a real entity) length (The length(number of characters) of this entity) offset (The location where it was found in the text) text (The actual entity name as it appears in the text)

Sample definition

        "text": "contact@contoso.com"
    }
],
}
}
]
}
```

The offsets returned for entities in the output of this skill are directly returned from the [Language Service APIs](#), which means if you are using them to index into the original string, you should use the [StringInfo](#) class in .NET in order to extract the correct content. For more information, see [Multilingual and emoji support in Language service features](#).

Warning cases

If the language code for the document is unsupported, a warning is returned and no entities are extracted.

Image Analysis cognitive skill

The **Image Analysis** skill extracts a rich set of visual features based on the image content. For example, you can generate a caption from an image, generate tags, or identify celebrities and landmarks. This article is the reference documentation for the **Image Analysis** skill. See [Extract text and information from images](#) for usage instructions.

This skill uses the machine learning models provided by [Azure Vision in Foundry Tools](#). **Image Analysis** works on images that meet the following requirements:

- The image must be presented in JPEG, PNG, GIF or BMP format
- The file size of the image must be less than 4 megabytes (MB)
- The dimensions of the image must be greater than 50 x 50 pixels

Supported data sources for OCR and image analysis are blobs in Azure Blob Storage and Azure Data Lake Storage (ADLS) Gen2, and image content in Microsoft OneLake. Images can be standalone files or embedded images in a PDF or other files.

This skill is implemented using the [AI Image Analysis API](#) version 3.2. If your solution requires calling a newer version of that service API (such as version 4.0), consider implementing through [Web API custom skill](#) or use the [ImageAnalysisV4 power skill](#).

(!) Note

This skill is bound to Foundry Tools and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

In addition, image extraction is [billable by Azure AI Search](#).

Skill parameters

Parameters are case sensitive.

[+] [Expand table](#)

Parameter name	Description
<code>defaultLanguageCode</code>	<p>A string indicating the language to return. The service returns recognition results in a specified language. If this parameter isn't specified, the default value is "en".</p> <p>Supported languages include a subset of generally available languages of Azure Vision. When a language is newly introduced with general availability status into Azure Vision, there is expected delay before they are fully integrated within this skill.</p>
<code>visualFeatures</code>	<p>An array of strings indicating the visual feature types to return. Valid visual feature types include:</p> <ul style="list-style-type: none"> • <i>adult</i> - detects if the image is pornographic (depicts nudity or a sex act), gory (depicts extreme violence or blood) or suggestive (also known as racy content). • <i>brands</i> - detects various brands within an image, including the approximate location. • <i>categories</i> - categorizes image content according to a taxonomy defined by Foundry Tools. • <i>description</i> - describes the image content with a complete sentence in supported languages. • <i>faces</i> - detects if faces are present. If present, generates coordinates, gender and age. • <i>objects</i> - detects various objects within an image, including the approximate location. • <i>tags</i> - tags the image with a detailed list of words related to the image content. <p>Names of visual features are case-sensitive. Both <i>color</i> and <i>imageType</i> visual features have been deprecated, but you can access this functionality through a custom skill. Refer to the Azure Vision Image Analysis documentation on which visual features are supported with each <code>defaultLanguageCode</code>.</p>
<code>details</code>	<p>An array of strings indicating which domain-specific details to return. Valid visual feature types include:</p> <ul style="list-style-type: none"> • <i>celebrities</i> - identifies celebrities if detected in the image. • <i>landmarks</i> - identifies landmarks if detected in the image.

Skill inputs

 Expand table

Input name	Description
<code>image</code>	Complex Type. Currently only works with "/document/normalized_images" field, produced by the Azure blob indexer when <code>imageAction</code> is set to a value other than <code>none</code> .

Skill outputs

[Expand table](#)

Output	Description
<code>name</code>	
<code>adult</code>	Output is a single <code>adult</code> object of a complex type, consisting of boolean fields (<code>isAdultContent</code> , <code>isGoryContent</code> , <code>isRacyContent</code>) and double type scores (<code>adultScore</code> , <code>goreScore</code> , <code>racyScore</code>).
<code>brands</code>	Output is an array of <code>brand</code> objects, where the object is a complex type consisting of <code>name</code> (string) and a <code>confidence</code> score (double). It also returns a <code>rectangle</code> with four bounding box coordinates (<code>x</code> , <code>y</code> , <code>w</code> , <code>h</code> , in pixels) indicating placement inside the image. For the rectangle, <code>x</code> and <code>y</code> are the top left. Bottom left is <code>x</code> , <code>y+h</code> . Top right is <code>x+w</code> , <code>y</code> . Bottom right is <code>x+w</code> , <code>y+h</code> .
<code>categories</code>	Output is an array of <code>category</code> objects, where each category object is a complex type consisting of a <code>name</code> (string), <code>score</code> (double), and optional <code>detail</code> that contains celebrity or landmark details. See the category taxonomy for the full list of category names. A detail is a nested complex type. A celebrity detail consists of a name, confidence score, and face bounding box. A landmark detail consists of a name and confidence score.
<code>description</code>	Output is a single <code>description</code> object of a complex type, consisting of lists of <code>tags</code> and <code>caption</code> (an array consisting of <code>Text</code> (string) and <code>confidence</code> (double)).
<code>faces</code>	Complex type consisting of <code>age</code> , <code>gender</code> , and <code>faceBoundingBox</code> having four bounding box coordinates (in pixels) indicating placement inside the image. Coordinates are <code>top</code> , <code>left</code> , <code>width</code> , <code>height</code> .
<code>objects</code>	Output is an array of visual feature objects . Each object is a complex type, consisting of <code>object</code> (string), <code>confidence</code> (double), <code>rectangle</code> (with four bounding box coordinates indicating placement inside the image), and a <code>parent</code> that contains an object name and confidence .
<code>tags</code>	Output is an array of <code>imageTag</code> objects, where a tag object is a complex type consisting of <code>name</code> (string), <code>hint</code> (string), and <code>confidence</code> (double). The addition of a hint is rare. It's only generated if a tag is ambiguous. For example, an image tagged as "curling" might have a hint of "sports" to better indicate its content.

Sample skill definition

JSON

}
```

Sample index

For single objects (such as `adult` and `description`), you can structure them in the index as a `Collection(Edm.ComplexType)` to return `adult` and `description` output for all of them. For more information about mapping outputs to index fields, see [Flattening information from complex types](#).

        "filterable": false,
        "facetable": false
    }
]
}
]
}

```

Sample output field mapping

The target field can be a complex field or collection. The index definition specifies any subfields.

JSON

```

"outputFieldMappings": [
    {
        "sourceFieldName": "/document/normalized_images/*/adult",
        "targetFieldName": "adult"
    },
    {
        "sourceFieldName": "/document/normalized_images/*/brands/*",
        "targetFieldName": "brands"
    },
    {
        "sourceFieldName": "/document/normalized_images/*/categories/*",
        "targetFieldName": "categories"
    },
    {
        "sourceFieldName": "/document/normalized_images/*/description",
        "targetFieldName": "description"
    },
    {
        "sourceFieldName": "/document/normalized_images/*/faces/*",
        "targetFieldName": "faces"
    },
    {

```

```

        "sourceFieldName": "/document/normalized_images/*/objects/*",
        "targetFieldName": "objects"
    },
{
    "sourceFieldName": "/document/normalized_images/*/tags/*",
    "targetFieldName": "tags"
}

```

Variation on output field mappings (nested properties)

You can define output field mappings to lower-level properties, such as just celebrities or landmarks. In this case, make sure your index schema has a field to contain each detail specifically.

JSON

```

"outputFieldMappings": [
    {
        "sourceFieldName":
        "/document/normalized_images/*/categories/detail/celebrities/*",
        "targetFieldName": "celebrities"
    },
    {
        "sourceFieldName":
        "/document/normalized_images/*/categories/detail/landmarks/*",
        "targetFieldName": "landmarks"
    }
]

```

Sample input

JSON

```
{
    "values": [
        {
            "recordId": "1",
            "data": {
                "image": {
                    "data": "BASE64 ENCODED STRING OF A JPEG IMAGE",
                    "width": 500,
                    "height": 300,
                    "originalWidth": 5000,
                    "originalHeight": 3000,
                    "rotationFromOriginal": 90,
                    "contentOffset": 500,
                    "pageNumber": 2
                }
            }
        }
    ]
}
```

```
]  
}
```

Sample output

JSON

```
{  
  "values": [  
    {  
      "recordId": "1",  
      "data": {  
        "categories": [  
          {  
            "name": "abstract_",  
            "score": 0.00390625  
          },  
          {  
            "name": "people_",

Error cases

In the following error cases, no elements are extracted.

 [Expand table](#)

Error Code	Description
NotSupportedLanguage	The language provided isn't supported.
InvalidImageUrl	Image URL is badly formatted or not accessible.
InvalidImageFormat	Input data isn't a valid image.
InvalidImageSize	Input image is too large.

Error Code	Description
NotSupportedVisualFeature	Specified feature type isn't valid.
NotSupportedImage	Unsupported image, for example, child pornography.
InvalidDetails	Unsupported domain-specific model.

If you get the error similar to "One or more skills are invalid. Details: Error in skill # <num>: Outputs are not supported by skill: Landmarks", check the path. Both celebrities and landmarks are properties under `detail`.

JSON

```
"categories": [
  {

Last updated on 11/18/2025

Key Phrase Extraction cognitive skill

The **Key Phrase Extraction** skill evaluates unstructured text, and for each record, returns a list of key phrases. This skill uses the [Key Phrase](#) machine learning models provided by [Azure Language in Foundry Tools](#).

This capability is useful if you need to quickly identify the main talking points in the record. For example, given input text "The food was delicious and there were wonderful staff", the service returns "food" and "wonderful staff".

! Note

This skill is bound to Foundry Tools and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

@odata.type

Microsoft.Skills.Text.KeyPhraseExtractionSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the key phrase extractor, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameters are case sensitive.

[\[\] Expand table](#)

Inputs	Description
<code>defaultLanguageCode</code>	(Optional) The language code to apply to documents that don't specify language explicitly. If the default language code isn't specified, English (en) is used as the default language code. See the full list of supported languages .
<code>maxKeyPhraseCount</code>	(Optional) The maximum number of key phrases to produce.

Inputs	Description
<code>modelVersion</code>	(Optional) Specifies the version of the model to use when calling the key phrase API. It defaults to the latest available when not specified. We recommend you don't specify this value unless it's necessary.

Skill inputs

[+] [Expand table](#)

Input	Description
<code>text</code>	The text to be analyzed.
<code>languageCode</code>	A string indicating the language of the records. If this parameter isn't specified, the default language code is used to analyze the records. See the full list of supported languages .

Skill outputs

[+] [Expand table](#)

Output	Description
<code>keyPhrases</code>	A list of key phrases extracted from the input text. The key phrases are returned in order of importance.

Sample definition

Consider a SQL record that has the following fields:

JSON
<pre>{ "content": "Glaciers are huge rivers of ice that ooze their way over land, powered by gravity and their own sheer weight. They accumulate ice from snowfall and lose it through melting. As global temperatures have risen, many of the world's glaciers have already started to shrink and retreat. Continued warming could see many iconic landscapes - from the Canadian Rockies to the Mount Everest region of the Himalayas - lose almost all their glaciers by the end of the century.", "language": "en" }</pre>

Then your skill definition might look like this:

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.KeyPhraseExtractionSkill",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        },  
        {  
            "name": "languageCode",  
            "source": "/document/language"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "keyPhrases",  
            "targetName": "myKeyPhrases"  
        }  
    ]  
}
```

Sample output

For the previous example, the output of your skill is written to a new node in the enriched tree called "document/myKeyPhrases" since that is the `targetName` that we specified. If you don't specify a `targetName`, then it would be "document/keyPhrases".

document/myKeyPhrases

JSON

```
[  
    "world's glaciers",  
    "huge rivers of ice",  
    "Canadian Rockies",  
    "iconic landscapes",  
    "Mount Everest region",  
    "Continued warming"  
]
```

You can use "document/myKeyPhrases" as input into other skills, or as a source of an [output field mapping](#).

Warnings

If you provide an unsupported language code, a warning is generated and key phrases aren't extracted. If your text is empty, a warning is produced. If your text is larger than 50,000 characters, only the first 50,000 characters are analyzed and a warning is issued.

Last updated on 11/18/2025

Language detection cognitive skill

The **Language Detection** skill detects the language of input text and reports a single language code for every document submitted on the request. The language code is paired with a score indicating the strength of the analysis. This skill uses the machine learning models provided in [Azure AI Language](#).

This capability is especially useful when you need to provide the language of the text as input to other skills (for example, the [Sentiment Analysis skill](#) or [Text Split skill](#)).

See [supported languages](#) for Language Detection. If you have content expressed in an unsupported language, the response is `(Unknown)`.

! Note

This skill is bound to Azure AI services and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Azure AI services Standard price](#).

@odata.type

Microsoft.Skills.Text.LanguageDetectionSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the language detection skill, you can use the [Text Split skill](#).

Skill parameters

Parameters are case-sensitive.

[+] [Expand table](#)

Inputs	Description
<code>defaultCountryHint</code>	(Optional) An ISO 3166-1 alpha-2 two letter country code can be provided to use as a hint to the language detection model if it can't disambiguate the language . Specifically, the <code>defaultCountryHint</code> parameter is used with documents that don't specify the <code>countryHint</code> input explicitly.

Inputs	Description
<code>modelVersion</code>	(Optional) Specifies the version of the model to use when calling language detection. It defaults to the latest available when not specified. We recommend you don't specify this value unless it's necessary.

Skill inputs

Parameters are case-sensitive.

[\[+\] Expand table](#)

Inputs	Description
<code>text</code>	The text to be analyzed.
<code>countryHint</code>	An ISO 3166-1 alpha-2 two letter country code to use as a hint to the language detection model if it can't disambiguate the language .

Skill outputs

[\[+\] Expand table](#)

Output	Description
Name	
<code>languageCode</code>	The ISO 6391 language code for the language identified. For example, "en".
<code>languageName</code>	The name of language. For example, "English".
<code>score</code>	A value between 0 and 1. The likelihood that language is correctly identified. The score can be lower than 1 if the sentence has mixed languages.

Sample definition

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Text.LanguageDetectionSkill",
  "inputs": [
    {
      "name": "text",
      "source": "/document/text"
    },
    {

OCR cognitive skill

The **optical character recognition (OCR)** skill recognizes printed and handwritten text in image files. This article is the reference documentation for the OCR skill. See [Extract text from images](#) for usage instructions.

The **OCR** skill uses the machine learning models provided by [Azure Vision in Foundry Tools API v3.2](#). The **OCR** skill maps to the following functionality:

- For the languages listed under [Azure Vision language support](#), the [Read API](#) is used.
- For Greek and Serbian Cyrillic, the legacy [OCR in version 3.2](#) API is used.

The **OCR** skill extracts text from image files and embedded images. Supported file formats include:

- .JPEG
- .JPG
- .PNG
- .BMP
- .TIFF

Supported data sources for OCR and image analysis are blobs in Azure Blob Storage and Azure Data Lake Storage (ADLS) Gen2, and image content in Microsoft OneLake. Images can be standalone files or embedded images in a PDF or other files.

ⓘ Note

This skill is bound to Foundry Tools and requires a [billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the [Foundry Tools Standard price](#).

In addition, image extraction is [billable by Azure AI Search](#).

Skill parameters

Parameters are case sensitive.

[] [Expand table](#)

Parameter name	Description
<code>detectOrientation</code>	Detects image orientation. Valid values are <code>true</code> or <code>false</code> .

Parameter name	Description
	This parameter only applies if the legacy OCR version 3.2 API is used.
<code>defaultLanguageCode</code>	Language code of the input text. Supported languages include all of the generally available languages of Azure Vision. You can also specify <code>unk</code> (Unknown). If the language code is unspecified or null, the language is set to English. If the language is explicitly set to <code>unk</code> , all languages found are auto-detected and returned.
<code>lineEnding</code>	The value to use as a line separator. Possible values: "Space", "CarriageReturn", "LineFeed". The default is "Space".

In previous versions, there was a parameter called "textExtractionAlgorithm" to specify extraction of "printed" or "handwritten" text. This parameter is deprecated because the current Read API algorithm extracts both types of text at once. If your skill includes this parameter, you don't need to remove it, but it won't be used during skill execution.

Skill inputs

 [Expand table](#)

Input	Description
<code>name</code>	
<code>image</code>	Complex Type. Currently only works with "/document/normalized_images" field, produced by the Azure blob indexer when <code>imageAction</code> is set to a value other than <code>none</code> .

Skill outputs

 [Expand table](#)

Output	Description
<code>name</code>	
<code>text</code>	Plain text extracted from the image.
<code>layoutText</code>	Complex type that describes the extracted text and the location where the text was found.

If you call OCR on images embedded in PDFs or other application files, the OCR output will be located at the bottom of the page, after any text that was extracted and processed.

Sample definition

JSON

```
{  
  "skills": [  
    {  
      "description": "Extracts text (plain and structured) from image.",  
      "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",  
      "context": "/document/normalized_images/*",  
      "defaultLanguageCode": null,  
      "detectOrientation": true,  
      "inputs": [  
        {  
          "name": "image",  
          "source": "/document/normalized_images/*"  
        }  
      ],  
      "outputs": [  
        {  
          "name": "text",  
          "targetName": "myText"  
        },  
        {  
          "name": "layoutText",  
          "targetName": "myLayoutText"  
        }  
      ]  
    }  
  ]  
}
```

Sample text and layoutText output

JSON

```
{  
  "text": "Hello World. -John",  
  "layoutText":  
  {  
    "language" : "en",  
    "text" : "Hello World. -John",  
    "lines" : [  
      {  
        "boundingBox":  
          [ {"x":10, "y":10}, {"x":50, "y":10}, {"x":50, "y":30},{ "x":10, "y":30}],  
        "text": "Hello World."  
      },  
      {  
        "boundingBox": [ {"x":110, "y":10}, {"x":150, "y":10}, {"x":150, "y":30},  
        {"x":110, "y":30}],  
        "text": "Hello World."  
      }  
    ]  
  }  
}
```

```

        "text": "-John"
    }
],
"words": [
{
    "boundingBox": [ {"x":110, "y":10}, {"x":150, "y":10}, {"x":150, "y":30},
{"x":110, "y":30}],
    "text": "Hello"
},
{
    "boundingBox": [ {"x":110, "y":10}, {"x":150, "y":10}, {"x":150, "y":30},
{"x":110, "y":30}],
    "text": "World."
},
{
    "boundingBox": [ {"x":110, "y":10}, {"x":150, "y":10}, {"x":150, "y":30},
{"x":110, "y":30}],
    "text": "-John"
}
]
}
}

```

Sample: Merging text extracted from embedded images with the content of the document

Document cracking, the first step in skillset execution, separates text and image content. A common use case for Text Merger is merging the textual representation of images (text from an OCR skill, or the caption of an image) into the content field of a document. This is for scenarios where the source document is a PDF or Word document that combines text with embedded images.

The following example skillset creates a *merged_text* field. This field contains the textual content of your document and the OCRed text from each of the images embedded in that document.

Request Body Syntax

JSON
<pre>{ "description": "Extract text from images and merge with content text to produce merged_text", "skills": [{ "description": "Extract text (plain and structured) from image." }] }</pre>

```

"@odata.type": "#Microsoft.Skills.Vision.OcrSkill",
"context": "/document/normalized_images/*",
"defaultLanguageCode": "en",
"detectOrientation": true,
"inputs": [
  {
    "name": "image",
    "source": "/document/normalized_images/*"
  }
],
"outputs": [
  {
    "name": "text"
  }
]
},
{
  "@odata.type": "#Microsoft.Skills.Text.MergeSkill",
  "description": "Create merged_text, which includes all the textual representation of each image inserted at the right location in the content field.",
  "context": "/document",
  "insertPreTag": " ",
  "insertPostTag": " ",
  "inputs": [
    {
      "name": "text",
      "source": "/document/content"
    },
    {
      "name": "itemsToInsert",
      "source": "/document/normalized_images/*/text"
    },
    {
      "name": "offsets",
      "source": "/document/normalized_images/*/contentOffset"
    }
  ],
  "outputs": [
    {
      "name": "mergedText",
      "targetName": "merged_text"
    }
  ]
}
]
}

```

The above skillset example assumes that a normalized-images field exists. To generate this field, set the *imageAction* configuration in your indexer definition to *generateNormalizedImages* as shown below:

JSON

```
{  
    //...rest of your indexer definition goes here ...  
    "parameters": {  
        "configuration": {  
            "dataToExtract": "contentAndMetadata",  
            "imageAction": "generateNormalizedImages"  
        }  
    }  
}
```

Personally Identifiable Information (PII) Detection cognitive skill

Article • 08/28/2024

The **PII Detection** skill extracts personal information from an input text and gives you the option of masking it. This skill uses the [detection models](#) provided in [Azure AI Language](#).

ⓘ Note

This skill is bound to Azure AI services and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Azure AI services pay-as-you go price](#).

@odata.type

Microsoft.Skills.Text.PIIDetectionSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). You can use [Text Split skill](#) for data chunking. Set the page length to 5000 for the best results.

Skill parameters

Parameters are case-sensitive and all are optional.

ⓘ [Expand table](#)

Parameter name	Description
<code>defaultLanguageCode</code>	(Optional) The language code to apply to documents that don't specify language explicitly. If the default language code isn't specified, English (en) is the default language code. See the full list of supported languages .
<code>minimumPrecision</code>	A value between 0.0 and 1.0. If the confidence score (in the <code>piiEntities</code> output) is lower than the set <code>minimumPrecision</code> value, the entity isn't

Parameter name	Description
	returned or masked. The default is 0.0.
maskingMode	A parameter that provides various ways to mask the personal information detected in the input text. The following options are supported: <ul style="list-style-type: none"> "none" (default): No masking occurs and the <code>maskedText</code> output isn't returned. "replace": Replaces the detected entities with the character given in the <code>maskingCharacter</code> parameter. The character is repeated to the length of the detected entity so that the offsets will correctly correspond to both the input text and the output <code>maskedText</code>.
maskingCharacter	The character used to mask the text if the <code>maskingMode</code> parameter is set to <code>replace</code> . The following option is supported: * (default). This parameter can only be <code>null</code> if <code>maskingMode</code> isn't set to <code>replace</code> .
domain	(Optional) A string value, if specified, sets the domain to a subset of the entity categories. Possible values include: "phi" (detect confidential health information only), "none".
piiCategories	(Optional) If you want to specify which entities are detected and returned, use this optional parameter (defined as a list of strings) with the appropriate entity categories. This parameter can also let you detect entities that aren't enabled by default for your document language. See Supported Personally Identifiable Information entity categories for the full list.
modelVersion	(Optional) Specifies the version of the model to use when calling personally identifiable information detection. It defaults to the most recent version when not specified. We recommend you don't specify this value unless it's necessary.

Skill inputs

[+] [Expand table](#)

Input name	Description
languageCode	A string indicating the language of the records. If this parameter isn't specified, the default language code is used to analyze the records. See the full list of supported languages .
text	The text to analyze.

Skill outputs

Output	Description
name	
piiEntities	An array of complex types that contains the following fields: <ul style="list-style-type: none"> • "text" (The actual personally identifiable information as extracted) • "type" • "subType" • "score" (Higher value means it's more likely to be a real entity) • "offset" (into the input text) • "length" <p>See Supported Personally Identifiable Information entity categories for the full list.</p>
maskedText	This output varies depending <code>maskingMode</code> . If <code>maskingMode</code> is <code>replace</code> , output is the string result of the masking performed over the input text, as described by the <code>maskingMode</code> . If <code>maskingMode</code> is <code>none</code> , there's no output.

Sample definition

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Text.PIIDetectionSkill",
  "defaultLanguageCode": "en",
  "minimumPrecision": 0.5,
  "maskingMode": "replace",
  "maskingCharacter": "*",
  "inputs": [
    {
      "name": "text",
      "source": "/document/content"
    }
  ],
  "outputs": [
    {
      "name": "piiEntities"
    },
    {
      "name": "maskedText"
    }
  ]
}
```

Sample input

JSON

```
{  
  "values": [  
    {  
      "recordId": "1",  
      "data":  
        {  
          "text": "Microsoft employee with ssn 859-98-0987 is using our  
awesome API's."  
        }  
    }  
  ]  
}
```

Sample output

JSON

```
{  
  "values": [  
    {  
      "recordId": "1",  
      "data" :  
        {  
          "piiEntities": [  
            {  
              "text": "859-98-0987",  
              "type": "U.S. Social Security Number (SSN)",  
              "subtype": "",  
              "offset": 28,  
              "length": 11,  
              "score": 0.65  
            }  
          ],  
          "maskedText": "Microsoft employee with ssn ***** is using our  
awesome API's."  
        }  
    }  
  ]  
}
```

The offsets returned for entities in the output of this skill are directly returned from the [Language Service APIs](#), which means if you're using them to index into the original string, you should use the [StringInfo](#) class in .NET in order to extract the correct content. For more information, see [Multilingual and emoji support in Language service features](#).

Errors and warnings

If the language code for the document is unsupported, a warning is returned and no entities are extracted. If your text is empty, a warning is returned. If your text is larger than 50,000 characters, only the first 50,000 characters are analyzed and a warning is issued.

If the skill returns a warning, the output `maskedText` may be empty, which can impact any downstream skills that expect the output. For this reason, be sure to investigate all warnings related to missing output when writing your skillset definition.

Sentiment cognitive skill (v3)

The **Sentiment** skill (v3) evaluates unstructured text and for each record, provides sentiment labels (such as "negative", "neutral" and "positive") based on the highest confidence score found by the service at a sentence and document-level. This skill uses the machine learning models provided by version 3 of [Language Service](#) in Foundry Tools. It also exposes [opinion mining capabilities](#), which provides more granular information about the opinions related to attributes of products or services in text.

! Note

This skill is bound to Foundry Tools and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

@odata.type

Microsoft.Skills.Text.V3.SentimentSkill

Data limits

The maximum size of a record should be 5000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the sentiment skill, use the [Text Split skill](#).

Skill parameters

Parameters are case sensitive.

[] Expand table

Parameter Name	Description
defaultLanguageCode	(optional) The language code to apply to documents that don't specify language explicitly. See the full list of supported languages .
modelVersion	(optional) Specifies the version of the model to use when calling sentiment analysis. It will default to the most recent version when not specified. We recommend you do not specify this value unless it's necessary.
includeOpinionMining	If set to <code>true</code> , enables the opinion mining feature , which allows aspect-based

Parameter Name	Description
	sentiment analysis to be included in your output results. Defaults to <code>false</code> .

Skill inputs

[+] Expand table

Input Name	Description
<code>text</code>	The text to be analyzed.
<code>languageCode</code>	(optional) A string indicating the language of the records. If this parameter is not specified, the default value is "en". See the full list of supported languages .

Skill outputs

[+] Expand table

Output Name	Description
<code>sentiment</code>	A string value that represents the sentiment label of the entire analyzed text (either positive, neutral or negative).
<code>confidenceScores</code>	A complex type with three double values, one for the positive rating, one for the neutral rating, and one for the negative rating. Values range from 0 to 1.00, where 1.00 represents the highest possible confidence in a given label assignment.
<code>sentences</code>	A collection of complex types that breaks down the sentiment of the text sentence by sentence. This is also where opinion mining results are returned in the form of targets and assessments if <code>includeOpinionMining</code> is set to <code>true</code> .

Sample definition

Last updated on 11/18/2025

Text Translation cognitive skill

The **Text Translation** skill evaluates text and, for each record, returns the text translated to the specified target language. This skill uses the [Translator Text API v3.0](#) available in Foundry Tools.

This capability is useful if you expect that your documents may not all be in one language, in which case you can normalize the text to a single language before indexing for search by translating it. It's also useful for localization use cases, where you might want to have copies of the same text available in multiple languages.

The [Translator Text API v3.0](#) is a non-regional Foundry Tool, meaning that your data isn't guaranteed to stay in the same region as your Azure AI Search or attached Microsoft Foundry resource.

(!) Note

This skill is bound to Foundry Tools and requires [a billable resource](#) for transactions that exceed 20 documents per indexer per day. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

When using this skill, all documents in the source are processed and billed for translation, even if the source and target languages are the same. This behavior is useful for multi-language support within the same document, but it can result in unnecessary processing. To avoid unexpected billing charges from documents that don't need processing, move them out of the data source container prior to running the skill.

@odata.type

Microsoft.Skills.Text.TranslationSkill

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the text translation skill, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameters are case sensitive.

[Expand table](#)

Inputs	Description
defaultToLanguageCode	(Required) The language code to translate documents into for documents that don't specify the "to" language explicitly. See the full list of supported languages .
defaultFromLanguageCode	(Optional) The language code to translate documents from for documents that don't specify the "from" language explicitly. If the defaultFromLanguageCode isn't specified, the automatic language detection provided by the Translator Text API will be used to determine the "from" language. See the full list of supported languages .
suggestedFrom	(Optional) The language code to translate documents from if <code>fromLanguageCode</code> or <code>defaultFromLanguageCode</code> are unspecified, and the automatic language detection is unsuccessful. If the suggestedFrom language isn't specified, English (en) will be used as the suggestedFrom language. See the full list of supported languages .

Skill inputs

[Expand table](#)

Input name	Description
text	The text to be translated.
toLanguageCode	A string indicating the language the text should be translated to. If this input isn't specified, the defaultToLanguageCode will be used to translate the text. See the full list of supported languages .
fromLanguageCode	A string indicating the current language of the text. If this parameter isn't specified, the defaultFromLanguageCode (or automatic language detection if the defaultFromLanguageCode isn't provided) will be used to translate the text. See the full list of supported languages .

Skill outputs

[Expand table](#)

Output name	Description
translatedText	The string result of the text translation from the translatedFromLanguageCode to the translatedToLanguageCode.
translatedToLanguageCode	A string indicating the language code the text was translated to. Useful if you're translating to multiple languages and want to be able to keep track of which text is which language.
translatedFromLanguageCode	A string indicating the language code the text was translated from. Useful if you opted for the automatic language detection option as this output will give you the result of that detection.

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "translatedText": "Nous tenons ces vérités pour évidentes, que tous les hommes sont créés égaux.",
        "translatedFromLanguageCode": "en",
        "translatedToLanguageCode": "fr"
      }
    },
    {
      "recordId": "2",
      "data": {
        "translatedText": "Nous sommes très heureux d'être avec vous.",
        "translatedFromLanguageCode": "es",
        "translatedToLanguageCode": "fr"
      }
    }
  ]
}
```

Errors and warnings

If you provide an unsupported language code for either the "to" or "from" language, an error is generated, and text isn't translated. If your text is empty, a warning will be produced. If your text is larger than 50,000 characters, only the first 50,000 characters will be translated, and a warning will be issued.

Azure Content Understanding skill

The Azure Content Understanding skill uses [document analyzers](#) from [Azure Content Understanding in Foundry Tools](#) to analyze unstructured documents and other content types, generating organized, searchable outputs that can be integrated into automation workloads. This skill extracts both text and images, including location metadata that preserves each image's position within the document. Image proximity to related content is especially useful for [multimodal search](#), [agentic retrieval](#), and [retrieval-augmented generation](#) (RAG).

You can use the Azure Content Understanding skill for both content extraction and chunking. There's no need to use the Text Split skill in your skillset. This skill implements the same interface as the Document Layout skill, which uses the [Azure Document Intelligence in Foundry Tools layout model](#) when `outputFormat` is set to `text`. However, the Azure Content Understanding skill offers several advantages over the Document Layout skill:

- Tables and figures are output in Markdown format, making them easier for large language models (LLMs) to understand. In contrast, the Document Layout skill outputs tables and figures as plain text, which can result in information loss.
- For tables that span multiple pages, the Document Layout skill extracts tables page by page. The Azure Content Understanding skill can recognize and extract cross-page tables as a single unit.
- The Document Layout skill restricts chunks to a single page, but semantic units, such as cross-page tables, shouldn't be limited by page boundaries. The Azure Content Understanding skill allows chunks to span multiple pages.
- The Azure Content Understanding skill is more cost effective than the Document Layout skill because the Content Understanding API is less expensive.

The Azure Content Understanding skill is bound to a [billable Microsoft Foundry resource](#). Unlike other Azure AI resource skills, such as the [Document Layout skill](#), the Azure Content Understanding skill doesn't provide 20 free documents per indexer per day. Execution of this skill is charged at the [Azure Content Understanding price](#).

💡 Tip

You can use the Azure Content Understanding skill in a skillset that also performs image verbalization and chunk vectorization. In the following tutorials, replace the Document Layout skill with the Azure Content Understanding skill.

- [Tutorial: Verbalize images from a structured document layout](#)

- [Tutorial: Vectorize from a structured document layout](#)

Limitations

The Azure Content Understanding skill has the following limitations:

- This skill isn't suitable for large documents requiring more than five minutes of processing in the Content Understanding document analyzer. The skill times out, but charges still apply to the Foundry resource that's attached to the skillset. Ensure documents are optimized to stay within processing limits to avoid unnecessary costs.
- This skill calls the Azure Content Understanding document analyzer, so all documented [service behaviors for different document types](#) apply to its output. For example, Word (DOCX) and PDF files might produce different results due to differences in how images are handled. If consistent image behavior across DOCX and PDF is required, consider converting documents to PDF or reviewing the [multimodal search documentation](#) for alternative approaches.

Supported regions

The Azure Content Understanding skill calls the [Content Understanding 2025-05-01-preview REST API](#). Your Foundry resource must be in a supported region, which is described in [Azure Content Understanding region and language support](#).

Your search service can be in any [supported Azure AI Search region](#). When your Foundry resource and Azure AI Search service aren't in the same region, cross-region network latency impacts your indexer's performance.

Supported file formats

The Azure Content Understanding skill recognizes the following file formats:

- .PDF
- .JPEG
- .JPG
- .PNG
- .BMP
- .HEIF
- .TIFF
- .DOCX

- .XLSX
- .PPTX
- .HTML
- .TXT
- .MD
- .RTF
- .EML

Supported languages

For printed text, see [Azure Content Understanding region and language support](#).

@odata.type

Microsoft.Skills.Util.ContentUnderstandingSkill

Data limits

- Even when the file size for analyzing documents is within the 200 MB limit, as described in the [Azure Content Understanding service quotas and limits](#), indexing is still subject to the [indexer limits](#) of your search service tier.
- Image dimensions must be between 50 pixels x 50 pixels or 10,000 pixels x 10,000 pixels.
- If your PDFs are password locked, remove the lock before you run the indexer.

Skill parameters

Parameters are case sensitive.

[] Expand table

Parameter name	Allowed values	Description
extractionOptions	["images"], ["images", "locationMetadata"], ["locationMetadata"]	Identify any extra content extracted from the document. Define an array of enums that correspond to the content to be included in the output. For example, if <code>extractionOptions</code> is ["images", "locationMetadata"], the output includes images and location metadata that provides page location and visual information related to where the content was extracted.

Parameter name	Allowed values	Description
chunkingProperties	See the following table.	Options that encapsulate how to chunk text content.

[\[+\] Expand table](#)

chunkingProperties	Allowed values	Description
parameters		
unit	Characters is the only allowed value. The chunk length is measured in characters rather than words or tokens.	Controls the cardinality of the chunk unit.
maxLength	An integer between 300 and 50000.	The maximum chunk length in characters as measured by <code>String.Length</code> .
overlapLength	Integer. The value must be less than half of the <code>maxLength</code> .	The length of overlap provided between two text chunks.

Skill inputs

[\[+\] Expand table](#)

Input name	Description
file_data	The file from which content should be extracted.

The `file_data` input must be an object defined as:

JSON

```
{
  "$type": "file",
  "data": "BASE64 encoded string of the file"
}
```

Alternatively, it can be defined as:

JSON

```
{
  "$type": "file",
  "url": "URL to download the file",
  "sasToken": "OPTIONAL: SAS token for authentication if the provided URL is for a
```

```
file in blob storage"  
}
```

The file reference object can be generated in one of following ways:

- Setting the `allowSkillsetToReadFileData` parameter on your indexer definition to `true`. This setting creates a `/document/file_data` path that's an object representing the original file data downloaded from your blob data source. This parameter only applies to files in Azure Blob Storage.
- Having a custom skill returning a JSON object definition that provides `$type`, `data`, or `url` and `sastoken`. The `$type` parameter must be set to `file`, and `data` must be the base 64-encoded byte array of the file content. The `url` parameter must be a valid URL with access to download the file at that location.

Skill outputs

 Expand table

Output name	Description
<code>text_sections</code>	A collection of text chunk objects. Each chunk can span multiple pages (factoring in any more chunking configured). The text chunk object includes <code>locationMetadata</code> if applicable.
<code>normalized_images</code>	Only applies if <code>extractionOptions</code> includes <code>images</code> . A collection of images that were extracted from the document, including <code>locationMetadata</code> if applicable.

Example

This example demonstrates how to output text content in fixed-sized chunks and extract images along with location metadata from the document.

Sample definition that includes image and metadata extraction

    }
}
]
}

```

`locationMetadata` is based on the `source` property provided by Azure Content Understanding. For information about how visual position of the element in the file is encoded, see [Document analysis: Extract structured content](#).

`imagePath` represents the relative path of a stored image. If the knowledge store file projection is configured in the skillset, this path matches the relative path of the image stored in the knowledge store.

- [Indexers - Create \(REST API\)](#)

Azure OpenAI Embedding skill

The Azure OpenAI Embedding skill connects to an embedding model deployed to your [Azure OpenAI in Foundry Models](#) resource or [Microsoft Foundry](#) project to generate embeddings during indexing. Your data is processed in the [Geo ↗](#) where your model is deployed.

The [Import data \(new\) wizard](#) in the Azure portal uses the Azure OpenAI Embedding skill to vectorize content. You can run the wizard and review the generated skillset to see how the wizard builds the skill for embedding models.

!Note

This skill is bound to Azure OpenAI and is charged at the [Azure OpenAI Standard price ↗](#).

Prerequisites

- An [Azure OpenAI in Foundry Models resource](#) or [Foundry project](#).
 - Your Azure OpenAI resource must have a [custom subdomain](#), such as `https://<resource-name>.openai.azure.com`. You can find this endpoint on the **Keys and Endpoint** page in the Azure portal and use it for the `resourceUri` property in this skill.
 - The [parent resource](#) of your Foundry project provides access to multiple endpoints, including `https://<resource-name>.openai.azure.com`, `https://<resource-name>.services.ai.azure.com`, and `https://<resource-name>.cognitiveservices.azure.com`. You can find these endpoints on the **Keys and Endpoint** page in the Azure portal and use any of them for the `resourceUri` property in this skill.
- An Azure OpenAI embedding model deployed to your resource or project. For supported models, see the [Skill parameters](#) section.

@odata.type

`Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill`

Data limits

The maximum size of a text input should be 8,000 tokens. If input exceeds the maximum allowed, the model throws an invalid request error. For more information, see the [tokens](#) key concept in the Azure OpenAI documentation. Consider using the [Text Split skill](#) if you need data chunking.

Skill parameters

Parameters are case sensitive.

[] [Expand table](#)

Inputs	Description
<code>resourceUri</code>	(Required) The URI of the model provider. Supported domains are: <ul style="list-style-type: none">• <code>openai.azure.com</code>• <code>services.ai.azure.com</code>• <code>cognitiveservices.azure.com</code> This field is required if your resource is deployed behind a private endpoint or uses virtual network (VNet) integration. Azure API Management endpoints are supported with URL <code>https://<resource-name>.azure-api.net</code> . Shared private links aren't supported for API Management endpoints.
<code>apiKey</code>	The secret key used to access the model. If you provide a key, leave <code>authIdentity</code> empty. If you set both <code>apiKey</code> and <code>authIdentity</code> , the <code>apiKey</code> is used on the connection.
<code>deploymentId</code>	(Required) The ID of the deployed Azure OpenAI embedding model. This is the deployment name you specified when you deployed the model.
<code>authIdentity</code>	A user-managed identity used by the search service for the connection. You can use either a system- or user-managed identity . To use a system-managed identity, leave <code>apiKey</code> and <code>authIdentity</code> blank. The system-managed identity is used automatically. A managed identity must have Cognitive Services OpenAI User permissions to send text to Azure OpenAI.
<code>modelName</code>	(Required) The name of the Azure OpenAI model deployed at the specified <code>deploymentId</code> . Supported values are: <ul style="list-style-type: none">• <code>text-embedding-ada-002</code>• <code>text-embedding-3-large</code>• <code>text-embedding-3-small</code>
<code>dimensions</code>	(Optional) The dimensions of embeddings that you want to generate, assuming the model supports a range of dimensions . The default is the maximum dimensions for each model. For skillsets created with REST API versions prior to the 2023-10-01-preview, the

Inputs	Description
	dimensions are fixed at 1536. If you set the <code>dimensions</code> property in this skill, set the <code>dimensions</code> property on the vector field definition to the same value.

Supported dimensions by `modelName`

The supported dimensions for an Azure OpenAI Embedding skill depend on the `modelName` that is configured.

[] [Expand table](#)

<code>modelName</code>	Minimum dimensions	Maximum dimensions
text-embedding-ada-002	1536	1536
text-embedding-3-large	1	3072
text-embedding-3-small	1	1536

Skill inputs

[] [Expand table](#)

Input	Description
<code>text</code>	The input text to be vectorized. If you're using data chunking, the source might be <code>/document/pages/*</code> .

Skill outputs

[] [Expand table](#)

Output	Description
<code>embedding</code>	Vectorized embedding for the input text.

Sample definition

Consider a record that has the following fields:

JSON

```
{  
    "content": "Microsoft released Windows 10."  
}
```

Then your skill definition might look like this:

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill",  
    "description": "Connects a deployed embedding model.",  
    "resourceUri": "https://my-demo-openai-eastus.openai.azure.com/",  
    "deploymentId": "my-text-embedding-ada-002-model",  
    "modelName": "text-embedding-ada-002",  
    "dimensions": 1536,  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "embedding"  
        }  
    ]  
}
```

Sample output

For the given input text, a vectorized embedding output is produced.

JSON

```
{  
    "embedding": [  
        0.018990106880664825,  
        -0.0073809814639389515,  
        ....  
        0.021276434883475304,  
    ]  
}
```

The output resides in memory. To send this output to a field in the search index, you must define an [outputFieldMapping](#) that maps the vectorized embedding output (which is an array) to a [vector field](#). Assuming the skill output resides in the document's **embedding** node, and

`content_vector` is the field in the search index, the `outputFieldMapping` in indexer should look like:

JSON

```
"outputFieldMappings": [
  {
    "sourceFieldName": "/document/embedding/*",
    "targetFieldName": "content_vector"
  }
]
```

Best practices

The following are some best practices you need to consider when utilizing this skill:

- If you are hitting your Azure OpenAI TPM (Tokens per minute) limit, consider the [quota limits advisory](#) so you can address accordingly. Refer to the [Azure OpenAI monitoring](#) documentation for more information about your Azure OpenAI instance performance.
- The Azure OpenAI embeddings model deployment you use for this skill should be ideally separate from the deployment used for other use cases, including the [query vectorizer](#). This helps each deployment to be tailored to its specific use case, leading to optimized performance and identifying traffic from the indexer and the index embedding calls easily.
- Your Azure OpenAI instance should be in the same region or at least geographically close to the region where your AI Search service is hosted. This reduces latency and improves the speed of data transfer between the services.
- If you have a larger than default Azure OpenAI TPM (Tokens per minute) limit as published in [quotas and limits](#) documentation, open a [support case](#) with the Azure AI Search team, so this can be adjusted accordingly. This helps your indexing process not being unnecessarily slowed down by the documented default TPM limit, if you have higher limits.
- For examples and working code samples using this skill, see the following links:
 - [Integrated vectorization \(Python\)](#)
 - [Integrated vectorization \(C#\)](#)
 - [Integrated vectorization \(Java\)](#)

Errors and warnings

Condition	Result
Null or invalid URI	Error
Null or invalid deploymentID	Error
Text is empty	Warning
Text is larger than 8,000 tokens	Error

Last updated on 11/18/2025

GenAI Prompt skill

!**Note**

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

The **GenAI (Generative AI) Prompt** skill executes a *chat completion* request against a large language model (LLM) deployed in [Azure OpenAI in Foundry Models](#) or [Microsoft Foundry](#). Use this skill to create new information that can be indexed and stored as searchable content.

Here are some examples of how the GenAI prompt skill can help you create content:

- Verbalize images
- Summarize large passages of text
- Simplify complex content
- Perform any other task that you can articulate in a prompt

The GenAI Prompt skill is available in the [latest preview REST API](#). This skill supports text, image, and multimodal content, such as a PDF that contains text and images.

💡 **Tip**

It's common to use this skill combined with a data chunking skill. The following tutorials demonstrate image verbalization with two different data chunking techniques:

- [Tutorial: Verbalize images using generative AI](#)
- [Tutorial: Verbalize images from a structured document layout](#)

Supported models

- You can use any [chat completion inference model](#) deployed in Foundry, such as GPT models, Deepseek R#, Llama-4-Mavericj, and Cohere-command-r. For GPT models specifically, only the chat completions API endpoints are supported. Endpoints using the Azure OpenAI Responses API (containing `/openai/responses` in the URI) aren't currently compatible.
- For image verbalization, the model you use to analyze the image determines what image formats are supported.

- For GPT-5 models, the `temperature` parameter is not supported in the same way as previous models. If defined, it must be set to `1.0`, as other values will result in errors.
- Billing is based on the pricing of the model you use.

(!) Note

The search service connects to your model over a public endpoint, so there are no region location requirements, but if you're using an all-up Azure solution, you should check the [Azure AI Search regions](#) and the [Azure OpenAI model regions](#) to find suitable pairs, especially if you have data residency requirements.

Prerequisites

- An [Azure OpenAI in Foundry Models resource](#) or [Foundry project](#).
- A [supported model](#) deployed to your resource or project.
 - For Azure OpenAI, copy the endpoint with the `openai.azure.com` domain from the **Keys and Endpoint** page in the Azure portal. Use this endpoint for the `Uri` parameter in this skill.
 - For Foundry, copy the target URI for the deployment from the **Models** page in the Foundry portal. Use this endpoint for the `Uri` parameter in this skill.
- Authentication can be key-based with an API key from your Foundry or Azure OpenAI resource. However, we recommend role-based access using a [search service managed identity](#) assigned to a role.
 - On Azure OpenAI, assign [Cognitive Services OpenAI User](#) to the managed identity.
 - On Foundry, assign [Azure AI User](#) to the managed identity.

@odata.type

```
#Microsoft.Skills.Custom.ChatCompletionSkill
```

Data limits

[+] [Expand table](#)

Limit	Notes
<code>maxTokens</code>	Default is 1024 if omitted. Maximum value is model-dependent.
Request time-out	30 seconds (default). Override with the <code>timeout</code> property (<code>PT##S</code>).
Images	Base 64-encoded images and image URLs are supported. Size limit is model-dependent.

Skill parameters

 [Expand table](#)

Property	Type	Required	Notes
<code>uri</code>	string	Yes	Public endpoint of the deployed model. Supported domains are: <ul style="list-style-type: none"> • <code>openai.azure.com</code> • <code>services.ai.azure.com</code> • <code>cognitiveservices.azure.com</code>
<code>apiKey</code>	string	Cond.*	Secret key for the model. Leave blank when using managed identity.
<code>authIdentity</code>	string	Cond.*	User-assigned managed identity client ID (<i>Azure OpenAI only</i>). Leave blank to use the system-assigned identity.
<code>commonModelParameters</code>	object	No	Standard generation controls such as <code>temperature</code> , <code>maxTokens</code> , etc.
<code>extraParameters</code>	object	No	Open dictionary passed through to the underlying model API.
<code>extraParametersBehavior</code>	string	No	<code>"pass-through"</code> <code>"drop"</code> <code>"error"</code> (default <code>"error"</code>).
<code>responseFormat</code>	object	No	Controls whether the model returns <code>text</code> , a free-form <code>JSON object</code> , or a strongly typed <code>JSON schema</code> . <code>responseFormat</code> payload examples: { <code>responseFormat: { type: text }</code> }, { <code>responseFormat: { type: json_object }</code> }, { <code>responseFormat: { type: json_schema }</code> }

* Exactly one of `apiKey`, `authIdentity`, or the service's **system-assigned** identity must be used.

`commonModelParameters` defaults

[Expand table](#)

Parameter	Default
<code>model</code>	(deployment default)
<code>frequencyPenalty</code>	0
<code>presencePenalty</code>	0
<code>maxTokens</code>	1024
<code>temperature</code>	0.7
<code>seed</code>	<code>null</code>
<code>stop</code>	<code>null</code>

Skill inputs

[Expand table](#)

Input name	Type	Required	Description
<code>systemMessage</code>	string	Yes	System-level instruction (ex: "You are a helpful assistant.").
<code>userMessage</code>	string	Yes	User prompt.
<code>text</code>	string	No	Optional text appended to <code>userMessage</code> (text-only scenarios).
<code>image</code>	string (Base 64 data-URL)	No	Adds an image to the prompt (multimodal models only).
<code>imageDetail</code>	string (<code>low</code> <code>high</code> <code>auto</code>)	No	Fidelity hint for Azure OpenAI multimodal models.

Skill outputs

[Expand table](#)

Output name	Type	Description
<code>response</code>	string or JSON object	Model output in the format requested by <code>responseFormat.type</code> .

Output name	Type	Description
usageInformation	JSON object	Token counts and echo of model parameters.

      "prompt_tokens": 248,
      "total_tokens": 451
    }
  }
}

```

Best practices

- Chunk long documents with the **Text Split** skill to stay within the model's context window.
- For high-volume indexing, dedicate a separate model deployment to this skill so that token quotas for query-time RAG workloads remain unaffected.
- To minimize latency, co-locate the model and your Azure AI Search service in the same Azure region.
- Use `responseFormat.json_schema` with **GPT-4o** for reliable structured extraction and easier mapping to index fields.
- Monitor token usage and submit **quota-increase requests** if the indexer saturates your Tokens per Minute (TPM) limits.

Errors and warnings

[] Expand table

Condition	Result
Missing or invalid <code>uri</code>	Error
No authentication method specified	Error
Both <code>apiKey</code> and <code>authIdentity</code> supplied	Error
Unsupported model for multimodal prompt	Error
Input exceeds model token limit	Error
Model returns invalid JSON for <code>json_schema</code>	Warning – raw string returned in <code>response</code>

AML skill

Important

Support for indexer connections to the model catalog is in public preview under [supplemental terms of use](#). Preview REST APIs support this capability.

Use the AML skill to extend AI enrichment with a deployed base embedding model from the [Microsoft Foundry model catalog](#) or a custom [Azure Machine Learning \(AML\)](#) model. Your data is processed in the [Geo](#) where your model is deployed.

You specify the AML skill in a skillset, which then integrates your deployed model into an AI enrichment pipeline. The AML skill is useful for performing processing or inference not supported by built-in skills. Examples include generating embeddings with your own model and applying custom machine learning logic to enriched content.

For AML online endpoints, use a stable API version or an equivalent Azure SDK to call the AML skill. For connections to the model catalog, use a preview API version.

AML skill usage

Like other skills, the AML skill has inputs and outputs. The inputs are sent as a JSON object to a serverless deployment from the Foundry model catalog or an AML online endpoint. The output should include a success status code, JSON payload, and the parameters specified by your AML skill definition. Any other response is considered an error, and no enrichments are performed.

The indexer retries two times for the following HTTP status codes:

- 503 Service Unavailable
- 429 Too Many Requests

AML skill for models in Foundry

Azure AI Search provides the [Microsoft Foundry model catalog vectorizer](#), which is also available in the [Import data \(new\) wizard](#), for query-time connections to the model catalog. If you want to use this vectorizer for queries, the AML skill is the *indexing counterpart* for generating embeddings using a model from the model catalog.

During indexing, the AML skill can connect to the model catalog to generate vectors for the index. At query time, queries can use a vectorizer to connect to the same model to vectorize text strings. You should use the AML skill and the Microsoft Foundry model catalog vectorizer

together so that the same embedding model is used for indexing and queries. For more information, see [Use embedding models from the Foundry model catalog](#).

We recommend using the [Import data \(new\) wizard](#) to generate a skillset that includes an AML skill for deployed embedding models in Foundry. The wizard generates the AML skill definition for inputs, outputs, and mappings, providing an easy way to test a model before writing any code.

Prerequisites

- A [Foundry hub-based project](#) or an [AML workspace](#) for a custom model that you create.
- For hub-based projects only, a [serverless deployment](#) of a [supported model](#) from the Foundry model catalog.

@odata.type

Microsoft.Skills.Custom.AmlSkill

Skill parameters

Parameters are case sensitive. The parameters you use depend on what [authentication](#) your [model provider requires](#), if any.

 [Expand table](#)

Parameter name	Description
<code>uri</code>	(Required for key authentication) The target URI of the serverless deployment from the Foundry model catalog or the scoring URI of the AML online endpoint . Only the HTTPS URI scheme is allowed. Supported models from the model catalog are: <ul style="list-style-type: none">• Cohere-embed-v3-english• Cohere-embed-v3-multilingual• Cohere-embed-v4
<code>key</code>	(Required for key authentication) The API key of the model provider.
<code>resourceId</code>	(Required for token authentication) The Azure Resource Manager resource ID of the model provider. For an AML online endpoint, use the <code>subscriptions/{guid}/resourceGroups/{resource-group-}</code>

Parameter name	Description
	<code>name}/Microsoft.MachineLearningServices/workspaces/{workspace-name}/onlineendpoints/{endpoint_name}</code> format.
<code>region</code>	(Optional for token authentication) The region in which the model provider is deployed. Required if the region is different from the region of the search service.
<code>timeout</code>	(Optional) The timeout for the HTTP client making the API call. It must be formatted as an XSD "dayTimeDuration" value, which is a restricted subset of an ISO 8601 duration value. For example, <code>PT60S</code> for 60 seconds. If not set, a default value of 30 seconds is chosen. You can set the timeout to a minimum of 1 second and a maximum of 230 seconds.
<code>degreeOfParallelism</code>	(Optional) The number of calls the indexer makes in parallel to the endpoint you provide. You can decrease this value if your endpoint is failing under too high of a request load. You can raise it if your endpoint is able to accept more requests and you would like an increase in the performance of the indexer. If not set, a default value of 5 is used. You can set <code>degreeOfParallelism</code> to a minimum of 1 and a maximum of 10.

Authentication

The AML skill provides two authentication options:

- **Key-based authentication.** You provide a static key to authenticate scoring requests from the AML skill. Set the `uri` and `key` parameters for this connection.
- **Token-based authentication.** The Foundry hub-based project or AML online endpoint is deployed using token-based authentication. The Azure AI Search service must have a [managed identity](#) and a role assignment on the model provider. The AML skill then uses the search service identity to authenticate against the model provider, with no static keys required. The search service identity must have the **Owner** or **Contributor** role. Set the `resourceId` parameter, and if the search service is in a different region from the model provider, set the `region` parameter.

Skill inputs

Skill inputs are a node of the [enriched document](#) created during *document cracking*. For example, it might be the root document, a normalized image, or the content of a blob. There are no predefined inputs for this skill. For inputs, you should specify one or more nodes that are populated at the time of the AML skill's execution.

Skill outputs

Skill outputs are new nodes of an enriched document created by the skill. There are no predefined outputs for this skill. For outputs, you should provide nodes that can be populated from the JSON response of your AML skill.

Sample definition

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.AmlSkill",  
    "description": "A custom model that detects the language in a document.",  
    "uri": "https://language-model.models.contoso.com/score",  
    "context": "/document",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "detected_language_code"  
        }  
    ]  
}
```

Sample input JSON structure

This JSON structure represents the payload sent to your Foundry hub-based project or AML online endpoint. The top-level fields of the structure correspond to the "names" specified in the `inputs` section of the skill definition. The values of those fields are from the "sources" of those fields, which could be from a field in the document or another skill.

JSON

```
{  
    "text": "Este es un contrato en Inglés"  
}
```

Sample output JSON structure

The output corresponds to the response from your Foundry hub-based project or AML online endpoint. The model provider should only return a JSON payload (verified by looking at the `Content-Type` response header) and should be an object whose fields are enrichments matching the "names" in the `output` and whose value is considered the enrichment.

JSON

```
{  
    "detected_language_code": "es"  
}
```

Inline shaping sample definition

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.AmlSkill",  
    "description": "A sample model that detects the language of sentence",  
    "uri": "https://language-model.models.contoso.com/score",  
    "context": "/document",  
    "inputs": [  
        {  
            "name": "shapedText",  
            "sourceContext": "/document",  
            "inputs": [  
                {  
                    "name": "content",  
                    "source": "/document/content"  
                }  
            ]  
        }  
    ],  
    "outputs": [  
        {  
            "name": "detected_language_code"  
        }  
    ]  
}
```

Inline shaping input JSON structure

JSON

```
{  
    "shapedText": { "content": "Este es un contrato en Inglés" }  
}
```

Inline shaping sample output JSON structure

JSON

```
{  
    "detected_language_code": "es"  
}
```

Error cases

In addition to your Foundry hub-based project or AML online endpoint being unavailable or sending nonsuccessful status codes, the following cases are considered errors:

- The model provider returns a success status code, but the response indicates that it isn't `application/json`. The response is thus invalid, and no enrichments are performed.
- The model provider returns invalid JSON.

If the model provider is unavailable or returns an HTTP error, a friendly error with any available details about the HTTP error is added to the indexer execution history.

Custom Entity Lookup cognitive skill

Article • 08/28/2024

The **Custom Entity Lookup** skill is used to detect or recognize entities that you define. During skillset execution, the skill looks for text from a custom, user-defined list of words and phrases. The skill uses this list to label any matching entities found within source documents. The skill also supports a degree of fuzzy matching that can be applied to find matches that are similar but not exact.

ⓘ Note

This skill isn't bound to an Azure AI services API but requires an Azure AI services key to allow more than 20 transactions. This skill is [metered by Azure AI Search](#).

@odata.type

Microsoft.Skills.Text.CustomEntityLookupSkill

Data limits

- The maximum input record size supported is 256 MB. If you need to break up your data before sending it to the custom entity lookup skill, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.
- The maximum size of the custom entity definition is 10 MB if it's provided as an external file, specified through the "entitiesDefinitionUri" parameter.
- If the entities are defined inline using the "inlineEntitiesDefinition" parameter, the maximum size is 10 KB.

Skill parameters

Parameters are case-sensitive.

[] Expand table

Parameter name	Description
entitiesDefinitionUri	Path to an external JSON or CSV file containing all the target text to match against. This entity definition is read at the

Parameter name	Description
	beginning of an indexer run; any updates to this file mid-run won't be realized until subsequent runs. This file must be accessible over HTTPS. See Custom Entity Definition Format below for expected CSV or JSON schema.
<code>inlineEntitiesDefinition</code>	Inline JSON entity definitions. This parameter supersedes the <code>entitiesDefinitionUri</code> parameter if present. No more than 10 KB of configuration may be provided inline. See Custom Entity Definition below for expected JSON schema.
<code>defaultLanguageCode</code>	(Optional) Language code of the input text used to tokenize and delineate input text. The following languages are supported: <code>da</code> , <code>de</code> , <code>en</code> , <code>es</code> , <code>fi</code> , <code>fr</code> , <code>it</code> , <code>pt</code> . The default is English (<code>en</code>). If you pass a <code>languagecode-countrycode</code> format, only the <code>languagecode</code> part of the format is used.
<code>globalDefaultCaseSensitive</code>	(Optional) Default case sensitive value for the skill. If <code>defaultCaseSensitive</code> value of an entity isn't specified, this value will become the <code>defaultCaseSensitive</code> value for that entity.
<code>globalDefaultAccentSensitive</code>	(Optional) Default accent sensitive value for the skill. If <code>defaultAccentSensitive</code> value of an entity isn't specified, this value will become the <code>defaultAccentSensitive</code> value for that entity.
<code>globalDefaultFuzzyEditDistance</code>	(Optional) Default fuzzy edit distance value for the skill. If <code>defaultFuzzyEditDistance</code> value of an entity isn't specified, this value will become the <code>defaultFuzzyEditDistance</code> value for that entity.

Skill inputs

[] Expand table

Input name	Description
<code>text</code>	The text to analyze.
<code>languageCode</code>	Optional. Default is <code>"en"</code> .

Skill outputs

[] Expand table

Output name	Description
<code>entities</code>	<p>An array of complex types that contains the following fields:</p> <ul style="list-style-type: none"> • <code>"name"</code>: The top-level entity; it represents the "normalized" form. • <code>"id"</code>: A unique identifier for the entity as defined in the "Custom Entity Definition". • <code>"description"</code>: Entity description as defined by the user in the "Custom Entity Definition Format". • <code>"type"</code>: Entity type as defined by the user in the "Custom Entity Definition Format". • <code>"subtype"</code>: Entity subtype as defined by the user in the "Custom Entity Definition Format". • <code>"matches"</code>: An array of complex types that contain: <ul style="list-style-type: none"> ◦ <code>"text"</code> from the source document ◦ <code>"offset"</code> location where the match was found, ◦ <code>"length"</code> of the text measured in characters ◦ <code>"matchDistance"</code> or the number of characters that differ between the match and the entity <code>"name"</code>.

Custom entity definition format

There are three approaches for providing the list of custom entities to the Custom Entity Lookup skill:

- .CSV file (UTF-8 encoded)
- .JSON file (UTF-8 encoded)
- Inline within the skill definition

If the definition file is in a .CSV or .JSON file, provide the full path in the `"entitiesDefinitionUri"` parameter. The file is downloaded at the start of each indexer run. It must remain accessible until the indexer stops.

If you're using an inline definition, specify it under the `"inlineEntitiesDefinition"` skill parameter.

Note

Indexers support specialized parsing modes for JSON and CSV files. When using the custom entity lookup skill, keep `"parsingMode"` set to `"default"`. The skill expects JSON and CSV in an unparsed state.

CSV format

You can provide the definition of the custom entities to look for in a Comma-Separated Value (CSV) file by providing the path to the file and setting it in the "entitiesDefinitionUri" skill parameter. The path should be at an https location. The definition file can be up to 10 MB in size.

The CSV format is simple. Each line represents a unique entity, as shown below:

```
Bill Gates, BillG, William H. Gates  
Microsoft, MSFT  
Satya Nadella
```

In this case, there are three entities that can be returned (Bill Gates, Satya Nadella, Microsoft). Aliases follow after the main entity. A match on an alias is bundled under the primary entity. For example, if the string "William H. Gates" is found in a document, a match for the "Bill Gates" entity will be returned.

JSON format

You can provide the definition of the custom entities to look for in a JSON file as well. The JSON format gives you a bit more flexibility since it allows you to define matching rules per term. For instance, you can specify the fuzzy matching distance (Damerau-Levenshtein distance) for each term or whether the matching should be case-sensitive or not.

Just like with CSV files, you need to provide the path to the JSON file and set it in the "entitiesDefinitionUri" skill parameter. The path should be at an https location. The definition file can be up to 10 MB in size.

The most basic JSON custom entity list definition can be a list of entities to match:

```
JSON  
[  
  {  
    "name" : "Bill Gates"  
  },  
  {  
    "name" : "Microsoft"  
  },  
  {  
    "name" : "Satya Nadella"  
  }
```

```
        }  
    ]
```

More complex definitions can provide a user-defined ID, description, type, subtype, and aliases. If an alias term is matched, the entity will be returned as well:

JSON

```
[  
  {  
    "name" : "Bill Gates",  
    "description" : "Microsoft founder.",  
    "aliases" : [  
      { "text" : "William H. Gates", "caseSensitive" : false },  
      { "text" : "BillG", "caseSensitive" : true }  
    ]  
  },  
  {  
    "name" : "Xbox One",  
    "type": "Hardware",  
    "subtype" : "Gaming Device",  
    "id" : "4e36bf9d-5550-4396-8647-8e43d7564a76",  
    "description" : "The Xbox One product"  
  },  
  {  
    "name" : "LinkedIn" ,  
    "description" : "The LinkedIn company",  
    "id" : "differentIdentifyingScheme123",  
    "fuzzyEditDistance" : 0  
  },  
  {  
    "name" : "Microsoft" ,  
    "description" : "Microsoft Corporation",  
    "id" : "differentIdentifyingScheme987",  
    "defaultCaseSensitive" : false,  
    "defaultFuzzyEditDistance" : 1,  
    "aliases" : [  
      { "text" : "MSFT", "caseSensitive" : true }  
    ]  
  }  
]
```

The tables below describe the configuration parameters you can set when defining custom entities:

[\[\] Expand table](#)

Field name	Description
name	The top-level entity descriptor. Matches in the skill output will be grouped by this name, and it should represent the "normalized" form of the text being found.
description	(Optional) This field can be used as a passthrough for custom metadata about the matched text(s). The value of this field will appear with every match of its entity in the skill output.
type	(Optional) This field can be used as a passthrough for custom metadata about the matched text(s). The value of this field will appear with every match of its entity in the skill output.
subtype	(Optional) This field can be used as a passthrough for custom metadata about the matched text(s). The value of this field will appear with every match of its entity in the skill output.
id	(Optional) This field can be used as a passthrough for custom metadata about the matched text(s). The value of this field will appear with every match of its entity in the skill output.
caseSensitive	(Optional) Defaults to false. Boolean value denoting whether comparisons with the entity name should be sensitive to character casing. Sample case insensitive matches of "Microsoft" could be: microsoft, microSoft, MICROSOFT
accentSensitive	(Optional) Defaults to false. Boolean value denoting whether accented and unaccented letters such as 'é' and 'e' should be identical.
fuzzyEditDistance	(Optional) Defaults to 0. Maximum value of 5. Denotes the acceptable number of divergent characters that would still constitute a match with the entity name. The smallest possible fuzziness for any given match is returned. For instance, if the edit distance is set to 3, "Windows 10" would still match "Windows", "Windows10" and "windows 7". When case sensitivity is set to false, case differences do NOT count towards fuzziness tolerance, but otherwise do.
defaultCaseSensitive	(Optional) Changes the default case sensitivity value for this entity. It can be used to change the default value of all aliases caseSensitive values.
defaultAccentSensitive	(Optional) Changes the default accent sensitivity value for this entity. It can be used to change the default value of all aliases accentSensitive values.
defaultFuzzyEditDistance	(Optional) Changes the default fuzzy edit distance value for this entity. It can be used to change the default value of all aliases fuzzyEditDistance values.

Field name	Description
aliases	(Optional) An array of complex objects that can be used to specify alternative spellings or synonyms to the root entity name.

[\[\] Expand table](#)

Alias properties	Description
text	The alternative spelling or representation of some target entity name.
caseSensitive	(Optional) Acts the same as root entity "caseSensitive" parameter above, but applies to only this one alias.
accentSensitive	(Optional) Acts the same as root entity "accentSensitive" parameter above, but applies to only this one alias.
fuzzyEditDistance	(Optional) Acts the same as root entity "fuzzyEditDistance" parameter above, but applies to only this one alias.

Inline format

In some cases, it may be more convenient to embed the custom entity definition so that its inline with the skill definition. You can use the same JSON format as the one described above, except that it's included within the skill definition. Only configurations that are less than 10 KB in size (serialized size) can be defined inline.

Sample skill definition

A sample skill definition using an inline format is shown below:

```
JSON

{
  "@odata.type": "#Microsoft.Skills.Text.CustomEntityLookupSkill",
  "context": "/document",
  "inlineEntitiesDefinition": [
    {
      "name" : "Bill Gates",
      "description" : "Microsoft founder." ,
      "aliases" : [
        { "text" : "William H. Gates", "caseSensitive" : false },
        { "text" : "BillG", "caseSensitive" : true }
      ]
    },
    {
      "name" : "Steve Jobs",
      "description" : "Apple founder." ,
      "aliases" : [
        { "text" : "Stephen Jobs", "caseSensitive" : false },
        { "text" : "SteveJ", "caseSensitive" : true }
      ]
    }
  ]
}
```

```

        "name" : "Xbox One",
        "type": "Hardware",
        "subtype" : "Gaming Device",
        "id" : "4e36bf9d-5550-4396-8647-8e43d7564a76",
        "description" : "The Xbox One product"
    }
],
"inputs": [
{
    "name": "text",
    "source": "/document/content"
}
],
"outputs": [
{
    "name": "entities",
    "targetName": "matchedEntities"
}
]
}

```

Alternatively, you can point to an external entities definition file. A sample skill definition using the `entitiesDefinitionUri` format is shown below:

JSON

```
{
"@odata.type": "#Microsoft.Skills.Text.CustomEntityLookupSkill",
"context": "/document",
"entitiesDefinitionUri": "https://myblobhost.net/keyWordsConfig.csv",
"inputs": [
{
    "name": "text",
    "source": "/document/content"
}
],
"outputs": [
{
    "name": "entities",
    "targetName": "matchedEntities"
}
]
}
```

Sample index definition

This section provides a sample index definition. Both "entities" and "matches" are arrays of complex types. You can have multiple entities per document, and multiple matches for each entity.

JSON

```
{  
  "name": "entities",  
  "type": "Collection(Edm.ComplexType)",  
  "fields": [  
    {  
      "name": "name",  
      "type": "Edm.String",  
      "facetable": false,  
      "filterable": false,  
      "retrievable": true,  
      "searchable": true,  
      "sortable": false,  
    },  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "facetable": false,  
      "filterable": false,  
      "retrievable": true,  
      "searchable": false,  
      "sortable": false,  
    },  
    {  
      "name": "description",  
      "type": "Edm.String",  
      "facetable": false,  
      "filterable": false,  
      "retrievable": true,  
      "searchable": true,  
      "sortable": false,  
    },  
    {  
      "name": "type",  
      "type": "Edm.String",  
      "facetable": true,  
      "filterable": true,  
      "retrievable": true,  
      "searchable": false,  
      "sortable": false,  
    },  
    {  
      "name": "subtype",  
      "type": "Edm.String",  
      "facetable": true,  
      "filterable": true,  
      "retrievable": true,  
      "searchable": false,  
      "sortable": false,  
    },  
    {  
      "name": "matches",  
      "type": "Collection(Edm.ComplexType)",  
    }  
  ]  
}
```

```

"fields": [
  {
    "name": "text",
    "type": "Edm.String",
    "facetable": false,
    "filterable": false,
    "retrievable": true,
    "searchable": true,
    "sortable": false,
  },
  {
    "name": "offset",
    "type": "Edm.Int32",
    "facetable": true,
    "filterable": true,
    "retrievable": true,
    "sortable": false,
  },
  {
    "name": "length",
    "type": "Edm.Int32",
    "facetable": true,
    "filterable": true,
    "retrievable": true,
    "sortable": false,
  },
  {
    "name": "matchDistance",
    "type": "Edm.Double",
    "facetable": true,
    "filterable": true,
    "retrievable": true,
    "sortable": false,
  }
]
}
]
}

```

Sample input data

JSON

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "text": "The company, Microsoft, was founded by Bill Gates.  
Microsoft's gaming console is called Xbox",
        "languageCode": "en"
      }
    }
  ]
}
```

```
        }
    ]
}
```

Sample output

JSON

```
{
  "values" :
  [
    {
      "recordId": "1",
      "data" : {
        "entities": [
          {
            "name" : "Microsoft",
            "description" : "This document refers to Microsoft the company",
            "id" : "differentIdentifyingScheme987",
            "matches" : [
              {
                "text" : "microsoft",
                "offset" : 13,
                "length" : 9,
                "matchDistance" : 0
              },
              {
                "text" : "Microsoft",
                "offset" : 49,
                "length" : 9,
                "matchDistance" : 0
              }
            ]
          },
          {
            "name" : "Bill Gates",
            "description" : "William Henry Gates III, founder of Microsoft.",
            "matches" : [
              {
                "text" : "Bill Gates",
                "offset" : 37,
                "length" : 10,
                "matchDistance" : 0
              }
            ]
          }
        ]
      }
    }
}
```

```
]  
}
```

Warnings

```
"Reached maximum capacity for matches, skipping all further duplicate matches."
```

This warning will be emitted if the number of matches detected is greater than the maximum allowed. No more duplicate matches will be returned. If you need a higher threshold, you can file a [support ticket](#) for assistance with your individual use case.

Custom Web API skill in an Azure AI Search enrichment pipeline

Article • 04/14/2025

The **Custom Web API** skill allows you to extend AI enrichment by calling out to a Web API endpoint providing custom operations. Similar to built-in skills, a **Custom Web API** skill has inputs and outputs. Depending on the inputs, your Web API receives a JSON payload when the indexer runs, and outputs a JSON payload as a response, along with a success status code. The response is expected to have the outputs specified by your custom skill. Any other response is considered an error and no enrichments are performed. The structure of the JSON payload is described further down in this document.

The **Custom Web API** skill is also used in the implementation of [Azure OpenAI On Your Data](#) feature. If Azure OpenAI is [configured for role-based access](#) and you get `403 Forbidden` calls when creating the vector index, verify that Azure AI Search has a [system assigned identity](#) and runs as a [trusted service](#) on Azure OpenAI.

ⓘ Note

The indexer retries twice for certain standard HTTP status codes returned from the Web API. These HTTP status codes are:

- `502 Bad Gateway`
- `503 Service Unavailable`
- `429 Too Many Requests`

@odata.type

Microsoft.Skills.Custom.WebApiSkill

Skill parameters

Parameters are case-sensitive.

[+] [Expand table](#)

Parameter name	Description
<code>uri</code>	The URI of the Web API to which the JSON payload is sent. Only the <code>https</code> URI scheme is allowed.

Parameter name	Description
<code>authResourceId</code>	(Optional) A string that if set, indicates that this skill should use a system managed identity on the connection to the function or app hosting the code. This property takes an application (client) ID or app's registration in Microsoft Entra ID, in any of these formats: <code>api://<appId></code> , <code><appId>/default</code> , <code>api://<appId>/default</code> . This value is used to scope the authentication token retrieved by the indexer, and is sent along with the custom Web skill API request to the function or app. Setting this property requires that your search service is configured for managed identity and your Azure function app is configured for a Microsoft Entra sign in . To use this parameter, call the API with <code>api-version=2023-10-01-Preview</code> .
<code>authIdentity</code>	(Optional) A user-managed identity used by the search service for connecting to the function or app hosting the code. You can use either a system or user managed identity . To use a system manged identity, leave <code>authIdentity</code> blank.
<code>httpMethod</code>	The method to use while sending the payload. Allowed methods are <code>PUT</code> or <code>POST</code>
<code>httpHeaders</code>	A collection of key-value pairs where the keys represent header names and values represent header values that are sent to your Web API along with the payload. The following headers are prohibited from being in this collection: <code>Accept</code> , <code>Accept-Charset</code> , <code>Accept-Encoding</code> , <code>Content-Length</code> , <code>Content-Type</code> , <code>Cookie</code> , <code>Host</code> , <code>TE</code> , <code>Upgrade</code> , <code>Via</code> .
<code>timeout</code>	(Optional) When specified, indicates the timeout for the http client making the API call. It must be formatted as an XSD "dayTimeDuration" value (a restricted subset of an ISO 8601 duration value). For example, <code>PT60S</code> for 60 seconds. If not set, a default value of 30 seconds is chosen. The timeout can be set to a maximum of 230 seconds and a minimum of 1 second.
<code>batchSize</code>	(Optional) Indicates how many "data records" (see JSON payload structure below) is sent per API call. If not set, a default of 1000 is chosen. We recommend that you make use of this parameter to achieve a suitable tradeoff between indexing throughput and load on your API.
<code>degreeOfParallelism</code>	(Optional) When specified, indicates the number of calls the indexer makes in parallel to the endpoint you provide. You can decrease this value if your endpoint is failing under pressure, or raise it if your endpoint can handle the load. If not set, a default value of 5 is used. The <code>degreeOfParallelism</code> can be set to a maximum of 10 and a minimum of 1.

Skill inputs

There are no predefined inputs for this skill. The inputs are any existing field, or any [node in the enrichment tree](#) that you want to pass to your custom skill.

Skill outputs

There are no predefined outputs for this skill. Be sure to [define an output field mapping](#) in the indexer if the skill's output should be sent to a field in the search index.

Sample definition

```
JSON

{
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",
    "description": "A custom skill that can identify positions of different phrases in the source text",
    "uri": "https://contoso.count-things.com",
    "batchSize": 4,
    "context": "/document",
    "inputs": [
        {
            "name": "text",
            "source": "/document/content"
        },
        {
            "name": "language",
            "source": "/document/languageCode"
        },
        {
            "name": "phraseList",
            "source": "/document/keyphrases"
        }
    ],
    "outputs": [
        {
            "name": "hitPositions"
        }
    ]
}
```

Sample input JSON structure

This JSON structure represents the payload that is sent to your Web API. It always follows these constraints:

- The top-level entity is called `values` and is an array of objects. The number of such objects are at most the `batchSize`.
- Each object in the `values` array has:
 - A `recordId` property that is a **unique** string, used to identify that record.

- A `data` property that is a JSON object. The fields of the `data` property correspond to the "names" specified in the `inputs` section of the skill definition. The values of those fields are from the `source` of those fields (which could be from a field in the document, or potentially from another skill).

JSON

```
{
  "values": [
    {
      "recordId": "0",
      "data": {
        "text": "Este es un contrato en Inglés",
        "language": "es",
        "phraseList": ["Este", "Inglés"]
      }
    },
    {
      "recordId": "1",
      "data": {
        "text": "Hello world",
        "language": "en",
        "phraseList": ["Hi"]
      }
    },
    {
      "recordId": "2",
      "data": {
        "text": "Hello world, Hi world",
        "language": "en",
        "phraseList": ["world"]
      }
    },
    {
      "recordId": "3",
      "data": {
        "text": "Test",
        "language": "es",
        "phraseList": []
      }
    }
  ]
}
```

Sample output JSON structure

The "output" corresponds to the response returned from your Web API. The Web API should only return a JSON payload (verified by looking at the `Content-Type` response header) and should satisfy the following constraints:

- There should be a top-level entity called `values`, which should be an array of objects.
- The number of objects in the array should be the same as the number of objects sent to the Web API.
- Each object should have:
 - A `recordId` property.
 - A `data` property, which is an object where the fields are enrichments matching the "names" in the `output` and whose value is considered the enrichment.
 - An `errors` property, an array listing any errors encountered that is added to the indexer execution history. This property is required, but can have a `null` value.
 - A `warnings` property, an array listing any warnings encountered that is added to the indexer execution history. This property is required, but can have a `null` value.
- The ordering of objects in the `values` in either the request or response isn't important. However, the `recordId` is used for correlation so any record in the response containing a `recordId`, which wasn't part of the original request to the Web API is discarded.

JSON

```
{  
  "values": [  
    {  
      "recordId": "3",  
      "data": {},  
      "errors": [  
        {  
          "message" : "'phraseList' should not be null or empty"  
        }  
      ],  
      "warnings": null  
    },  
    {  
      "recordId": "2",  
      "data": {  
        "hitPositions": [6, 16]  
      },  
      "errors": null,  
      "warnings": null  
    }  
  ]  
}
```

```
        },
        {
            "recordId": "0",
            "data": {
                "hitPositions": [0, 23]
            },
            "errors": null,
            "warnings": null
        },
        {
            "recordId": "1",
            "data": {
                "hitPositions": []
            },
            "errors": null,
            "warnings": [
                {
                    "message": "No occurrences of 'Hi' were found in the input text"
                }
            ]
        },
    ],
}
}
```

Error cases

In addition to your Web API being unavailable, or sending out non-successful status codes the following are considered erroneous cases:

- If the Web API returns a success status code but the response indicates that it isn't `application/json` then the response is considered invalid and no enrichments are performed.
- If there are invalid records (for example, `recordId` is missing or duplicated) in the response `values` array, no enrichment is performed for the invalid records. It's important to adhere to the Web API skill contract when developing custom skills. You can refer to [this example ↗](#) provided in the [Power Skill repository ↗](#) that follows the expected contract.

For cases when the Web API is unavailable or returns an HTTP error, a friendly error with any available details about the HTTP error is added to the indexer execution history.

Conditional cognitive skill

Article • 08/28/2024

The **Conditional** skill enables Azure AI Search scenarios that require a Boolean operation to determine the data to assign to an output. These scenarios include filtering, assigning a default value, and merging data based on a condition.

The following pseudocode demonstrates what the conditional skill accomplishes:

```
if (condition)
    { output = whenTrue }
else
    { output = whenFalse }
```

ⓘ Note

This skill isn't bound to Azure AI services. It is non-billable and has no Azure AI services key requirement.

@odata.type

Microsoft.Skills.Util.ConditionalSkill

Evaluated fields

This skill is special because its inputs are evaluated fields.

The following items are valid values of an expression:

- Annotation paths (paths in expressions must be delimited by "\$(" and ")"")
Examples:

```
"= $(/document)"
 "= $(/document/content)"
```

- Literals (strings, numbers, true, false, null)
Examples:

```
"= 'this is a string'"    // string (note the single quotation marks)
 "= 34"                  // number
 "= true"                // Boolean
 "= null"                // null value
```

- Expressions that use comparison operators (==, !=, >=, >, <=, <)

Examples:

```
"= $(/document/language) == 'en'"
 "= $(/document/sentiment) >= 0.5"
```

- Expressions that use Boolean operators (&&, ||, !, ^)

Examples:

```
"= $(/document/language) == 'en' && $(/document/sentiment) > 0.5"
 "= !true"
```

- Expressions that use numeric operators (+, -, *, /, %)

Examples:

```
"= $(/document/sentiment) + 0.5"           // addition
 "= $(/document/totalValue) * 1.10"          // multiplication
 "= $(/document/lengthInMeters) / 0.3049"     // division
```

Because the conditional skill supports evaluation, you can use it in minor-transformation scenarios. For example, see [skill definition 4](#).

Skill inputs

Inputs are case-sensitive.

 Expand table

Input	Description
condition	<p>This input is an evaluated field that represents the condition to evaluate. This condition should evaluate to a Boolean value (<i>true</i> or <i>false</i>).</p> <p>Examples:</p> <pre>= true = \$(/document/language) =='fr' = \$(/document/pages/*/language) == \$(/document/expectedLanguage)"</pre>
whenTrue	<p>This input is an evaluated field that represents the value to return if the condition is evaluated to <i>true</i>. Constants strings should be returned in single quotation marks (' and ').</p> <p>Sample values:</p> <pre>= 'contract' = \$(/document/contractType)" = \$(/document/entities/*)"</pre>
whenFalse	<p>This input is an evaluated field that represents the value to return if the condition is evaluated to <i>false</i>.</p> <p>Sample values:</p> <pre>= 'contract" = \$(/document/contractType)" = \$(/document/entities/*)"</pre>

Skill outputs

There's a single output that's simply called "output." It returns the value *whenFalse* if the condition is false or *whenTrue* if the condition is true.

Examples

Sample skill definition 1: Filter documents to return only French documents

The following output returns an array of sentences ("\$/document/frenchSentences") if the language of the document is French. If the language isn't French, the value is set to *null*.

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill",
  "context": "/document",
  "inputs": [
    { "name": "condition", "source": "= $(/document/language) == 'fr'" }
},
```

```

        { "name": "whenTrue", "source": "/document/sentences" },
        { "name": "whenFalse", "source": "= null" }
    ],
    "outputs": [ { "name": "output", "targetName": "frenchSentences" } ]
}

```

If "/document/frenchSentences" is used as the *context* of another skill, that skill only runs if "/document/frenchSentences" isn't set to *null*.

Sample skill definition 2: Set a default value for a value that doesn't exist

The following output creates an annotation (""/document/languageWithDefault") that's set to the language of the document or to "es" if the language isn't set.

JSON

```

{
    "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill",
    "context": "/document",
    "inputs": [
        { "name": "condition", "source": "= $(/document/language) == null" }
    ],
    { "name": "whenTrue", "source": "= 'es'" },
    { "name": "whenFalse", "source": "= $(/document/language)" }
],
    "outputs": [ { "name": "output", "targetName": "languageWithDefault" } ]
}

```

Sample skill definition 3: Merge values from two fields into one

In this example, some sentences have a *frenchSentiment* property. Whenever the *frenchSentiment* property is null, we want to use the *englishSentiment* value. We assign the output to a member that's called *sentiment* (""/document/sentences/*/sentiment").

JSON

```

{
    "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill",
    "context": "/document/sentences/*",
    "inputs": [
        { "name": "condition", "source": "= $(/document/sentences/*/frenchSentiment) == null" },
        { "name": "whenTrue", "source": "/document/sentences/*/englishSentiment" },

```

```
        { "name": "whenFalse", "source":  
  "/document/sentences/*/frenchSentiment" }  
    ],  
    "outputs": [ { "name": "output", "targetName": "sentiment" } ]  
}
```

Transformation example

Sample skill definition 4: Data transformation on a single field

In this example, we receive a *sentiment* that's between 0 and 1. We want to transform it to be between -1 and 1. We can use the conditional skill to do this minor transformation.

In this example, we don't use the conditional aspect of the skill because the condition is always *true*.

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill",  
  "context": "/document/sentences/*",  
  "inputs": [  
    { "name": "condition", "source": "= true" },  
    { "name": "whenTrue", "source": "=  
$(/document/sentences/*/sentiment) * 2 - 1" },  
    { "name": "whenFalse", "source": "= 0" }  
  ],  
  "outputs": [ { "name": "output", "targetName": "normalizedSentiment" } ]  
}
```

Special considerations

Some parameters are evaluated, so you need to be especially careful to follow the documented pattern. Expressions must start with an equals sign. A path must be delimited by "\$(" and ")". Make sure to put strings in single quotation marks. That helps the evaluator distinguish between strings and actual paths and operators. Also, make sure to put white space around operators (for instance, a "*" in a path means something different than multiply).

Document Extraction cognitive skill

07/29/2025

The **Document Extraction** skill extracts content from a file within the enrichment pipeline. By default, content extraction or retrieval is built into the indexer pipeline. However, by using the Document Extraction skill, you can control how parameters are set, and how extracted content is named in the enrichment tree.

For [vector](#) and [multimodal search](#), Document Extraction combined with the [Text Split skill](#) is more affordable than other [data chunking approaches](#). The following tutorials demonstrate skill usage for different scenarios:

- [Tutorial: Vectorize images and text](#)
- [Tutorial: Verbalize images using generative AI](#)

!**Note**

This skill isn't bound to Azure AI services and has no Azure AI services key requirement.

This skill extracts text and images. Text extraction is free. Image extraction is [billable by Azure AI Search](#). On a free search service, the cost of 20 transactions per indexer per day is absorbed so that you can complete quickstarts, tutorials, and small projects at no charge. For basic and higher tiers, image extraction is billable.

@odata.type

Microsoft.Skills.Util.DocumentExtractionSkill

Supported document formats

The DocumentExtractionSkill can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)

- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Skill parameters

Parameters are case-sensitive.

 [Expand table](#)

Inputs	Allowed Values	Description
<code>parsingMode</code>	<code>default</code> <code>text</code> <code>json</code>	<p>Set to <code>default</code> for document extraction from files that aren't pure text or json. For source files that contain mark up (such as PDF, HTML, RTF, and Microsoft Office files), use the default to extract just the text, minus any markup language or tags. If <code>parsingMode</code> isn't defined explicitly, it will be set to <code>default</code>.</p> <p>Set to <code>text</code> if source files are TXT. This parsing mode improves performance on plain text files. If files include markup, this mode will preserve the tags in the final output.</p> <p>Set to <code>json</code> to extract structured content from json files.</p>
<code>dataToExtract</code>	<code>contentAndMetadata</code> <code>allMetadata</code>	<p>Set to <code>contentAndMetadata</code> to extract all metadata and textual content from each file. If <code>dataToExtract</code> isn't defined explicitly, it will be set to <code>contentAndMetadata</code>.</p> <p>Set to <code>allMetadata</code> to extract only the metadata properties for the content type (for example, metadata unique to just .png files).</p>
<code>configuration</code>	See below.	A dictionary of optional parameters that adjust how the document extraction is performed. See the below table for descriptions of supported configuration properties.

 [Expand table](#)

Configuration Parameter	Allowed Values	Description
<code>imageAction</code>	<code>none</code> <code>generateNormalizedImages</code> <code>generateNormalizedImagePerPage</code>	<p>Set to <code>none</code> to ignore embedded images or image files in the data set, or if the source data doesn't include image files. This is the default.</p> <p>For OCR and image analysis, set to <code>generateNormalizedImages</code> to have the skill create an array of normalized images as part of document cracking. This action requires that <code>parsingMode</code> is set to <code>default</code> and <code>dataToExtract</code> is set to <code>contentAndMetadata</code>. A normalized image refers to extra processing resulting in uniform image output, sized and rotated to promote consistent rendering when you include images in visual search results (for example, same-size photographs in a graph control as seen in the JFK demo). This information is generated for each image when you use this option.</p> <p>If you set to <code>generateNormalizedImagePerPage</code>, PDF files are treated differently in that instead of extracting embedded images, each page is rendered as an image and normalized accordingly. Non-PDF file types are treated the same as if <code>generateNormalizedImages</code> was set.</p>
<code>normalizedImageMaxWidth</code>	Any integer between 50-10000	The maximum width (in pixels) for normalized images generated. The default is 2000.
<code>normalizedImageMaxHeight</code>	Any integer between 50-10000	The maximum height (in pixels) for normalized images generated. The default is 2000.

(!) Note

The default of 2000 pixels for the normalized images maximum width and height is based on the maximum sizes supported by the [OCR skill](#) and the [image analysis skill](#). The [OCR skill](#) supports a maximum width and height of 4200 for non-English languages, and 10000

for English. If you increase the maximum limits, processing could fail on larger images depending on your skillset definition and the language of the documents.

Skill inputs

[Expand table](#)

Input name	Description
file_data	The file that content should be extracted from.

The "file_data" input must be an object defined as:

JSON

```
{  
  "$type": "file",  
  "data": "BASE64 encoded string of the file"  
}
```

Alternatively, it can be defined as:

JSON

```
{  
  "$type": "file",  
  "url": "URL to download file",  
  "sasToken": "OPTIONAL: SAS token for authentication if the URL provided is for a  
file in blob storage"  
}
```

The file reference object can be generated one of three ways:

- Setting the `allowSkillsetToReadFileData` parameter on your indexer definition to "true". This creates a path `/document/file_data` that is an object representing the original file data downloaded from your blob data source. This parameter only applies to files in Blob storage.
- Setting the `imageAction` parameter on your indexer definition to a value other than `none`. This creates an array of images that follows the required convention for input to this skill if passed individually (that is, `/document/normalized_images/*`).

- Having a custom skill return a json object defined EXACTLY as above. The `$type` parameter must be set to exactly `file` and the `data` parameter must be the base 64 encoded byte array data of the file content, or the `url` parameter must be a correctly formatted URL with access to download the file at that location.

Skill outputs

[] [Expand table](#)

Output name	Description
<code>content</code>	The textual content of the document.
<code>normalized_images</code>	When the <code>imageAction</code> is set to a value other than <code>none</code> , the new <code>normalized_images</code> field contains an array of images. See Extract text and information from images for more details on the output format.

Sample definition

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Util.DocumentExtractionSkill",
  "parsingMode": "default",
  "dataToExtract": "contentAndMetadata",
  "configuration": {
    "imageAction": "generateNormalizedImages",
    "normalizedImageMaxWidth": 2000,
    "normalizedImageMaxHeight": 2000
  },
  "context": "/document",
  "inputs": [
    {
      "name": "file_data",
      "source": "/document/file_data"
    }
  ],
  "outputs": [
    {
      "name": "content",
      "targetName": "extracted_content"
    },
    {
      "name": "normalized_images",
      "targetName": "extracted_normalized_images"
    }
  ]
}
```

```
    ]  
}
```

Sample input

JSON

```

Shaper cognitive skill

Article • 08/28/2024

The **Shaper** skill is used to reshape or modify the structure of the [in-memory enrichment tree](#) created by a skillset. If skill outputs can't be mapped directly to search fields, you can add a **Shaper** skill to create the data shape you need for your search index or knowledge store.

Primary use-cases for this skill include:

- You're populating a knowledge store. The physical structure of the tables and objects of a knowledge store are defined through projections. A **Shaper** skill adds granularity by creating data shapes that can be pushed to the projections.
- You want to map multiple skill outputs into a single structure in your search index, usually a [complex type](#), as described in [scenario 1](#).
- Skills produce multiple outputs, but you want to combine into a single field (it doesn't have to be a complex type), as described in [scenario 2](#). For example, combining titles and authors into a single field.
- Skills produce multiple outputs with child elements, and you want to combine them. This use-case is illustrated in [scenario 3](#).

The output name of a **Shaper** skill is always "output". Internally, the pipeline can map a different name, such as "analyzedText" as shown in the examples below, but the **Shaper** skill itself returns "output" in the response. This might be important if you are debugging enriched documents and notice the naming discrepancy, or if you build a custom skill and are structuring the response yourself.

ⓘ Note

This skill isn't bound to Azure AI services. It is non-billable and has no Azure AI services key requirement.

@odata.type

Microsoft.Skills.Util.ShaperSkill

Scenario 1: complex types

Consider a scenario where you want to create a structure called *analyzedText* that has two members: *text* and *sentiment*, respectively. In an index, a multi-part searchable field is called a *complex type* and it's often created when source data has a corresponding complex structure that maps to it.

However, another approach for creating complex types is through the **Shaper** skill. By including this skill in a skillset, the in-memory operations during skillset processing can output data shapes with nested structures, which can then be mapped to a complex type in your index.

The following example skill definition provides the member names as the input.

JSON

```
{  
  "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",  
  "context": "/document/content/phrases/*",  
  "inputs": [  
    {  
      "name": "text",  
      "source": "/document/content/phrases/*"  
    },  
    {  
      "name": "sentiment",  
      "source": "/document/content/phrases/*/sentiment"  
    }  
  ],  
  "outputs": [  
    {  
      "name": "output",  
      "targetName": "analyzedText"  
    }  
  ]  
}
```

Sample index

A skillset is invoked by an indexer, and an indexer requires an index. A complex field representation in your index might look like the following example.

JSON

```
"name": "my-index",  
"fields": [  
  { "name": "myId", "type": "Edm.String", "key": true, "filterable": true },  
  { "name": "analyzedText", "type": "Edm.ComplexType",  
    "fields": [  
      {
```

```
        "name": "text",
        "type": "Edm.String",
        "facetable": false,
        "filterable": false,
        "searchable": true,
        "sortable": false },
    {
        "name": "sentiment",
        "type": "Edm.Double",
        "facetable": true,
        "filterable": true,
        "searchable": true,
        "sortable": true }
}
```

Skill input

An incoming JSON document providing usable input for this **Shaper** skill could be:

JSON

```
{
    "values": [
        {
            "recordId": "1",
            "data": {
                "text": "this movie is awesome",
                "sentiment": 0.9
            }
        }
    ]
}
```

Skill output

The **Shaper** skill generates a new element called *analyzedText* with the combined elements of *text* and *sentiment*. This output conforms to the index schema. It will be imported and indexed in an Azure AI Search index.

JSON

```
{
    "values": [
        {
            "recordId": "1",
            "data": {
                "analyzedText":
```

```

        {
            "text": "this movie is awesome" ,
            "sentiment": 0.9
        }
    }
]
}

```

Scenario 2: input consolidation

In another example, imagine that at different stages of pipeline processing, you have extracted the title of a book, and chapter titles on different pages of the book. You could now create a single structure composed of these various outputs.

The **Shaper** skill definition for this scenario might look like the following example:

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
    "context": "/document",
    "inputs": [
        {
            "name": "title",
            "source": "/document/content/title"
        },
        {
            "name": "chapterTitles",
            "source": "/document/content/pages/*/chapterTitles/*/title"
        }
    ],
    "outputs": [
        {
            "name": "output",
            "targetName": "titlesAndChapters"
        }
    ]
}
```

Skill output

In this case, the **Shaper** flattens all chapter titles to create a single array.

JSON

```
{
    "values": [

```

```

{
    "recordId": "1",
    "data": {
        "titlesAndChapters": {
            "title": "How to be happy",
            "chapterTitles": [
                "Start young",
                "Laugh often",
                "Eat, sleep and exercise"
            ]
        }
    }
}
]
}

```

Scenario 3: input consolidation from nested contexts

Imagine you have chapter titles and chapter numbers of a book and have run entity recognition and key phrases on the contents and now need to aggregate results from the different skills into a single shape with the chapter name, entities, and key phrases.

This example adds an optional `sourceContext` property to the "chapterTitles" input. The `source` and `sourceContext` properties are mutually exclusive. If the input is at the context of the skill, you can use `source`. If the input is at a *different* context than the skill context, use `sourceContext`. The `sourceContext` requires you to define a nested input, where each input has a `source` that identifies the specific element used to populate the named node.

The **Shaper** skill definition for this scenario might look like the following example:

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
    "context": "/document",
    "inputs": [
        {
            "name": "title",
            "source": "/document/content/title"
        },
        {
            "name": "chapterTitles",
            "sourceContext": "/document/content/pages/*/chapterTitles/*",
            "inputs": [
                {

```

```

        "name": "title",
        "source": "/document/content/pages/*/chapterTitles/*/title"
    },
    {
        "name": "number",
        "source": "/document/content/pages/*/chapterTitles/*/number"
    }
]
}
],
"outputs": [
{
    "name": "output",
    "targetName": "titlesAndChapters"
}
]
}

```

Skill output

In this case, the **Shaper** creates a complex type. This structure exists in-memory. If you want to save it to a [knowledge store](#), you should create a projection in your skillset that defines storage characteristics.

JSON

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "titlesAndChapters": {
          "title": "How to be happy",
          "chapterTitles": [
            { "title": "Start young", "number": 1},
            { "title": "Laugh often", "number": 2},
            { "title": "Eat, sleep and exercise", "number": 3}
          ]
        }
      }
    }
  ]
}
```

Text Merge cognitive skill

The Text Merge skill consolidates text from an array of strings into a single field.

! Note

This skill isn't bound to Foundry Tools. It's nonbillable and has no Foundry Tools key requirement.

@odata.type

Microsoft.Skills.Text.MergeSkill

Skill parameters

Parameters are case sensitive.

[\[+\] Expand table](#)

Parameter	Description
<code>name</code>	
<code>insertPreTag</code>	String to be included before every insertion. The default value is <code>" "</code> . To omit the space, set the value to <code>""</code> .
<code>insertPostTag</code>	String to be included after every insertion. The default value is <code>" "</code> . To omit the space, set the value to <code>""</code> .

Skill inputs

[\[+\] Expand table](#)

Input name	Description
<code>itemsToInsert</code>	Array of strings to be merged.
<code>text</code>	(optional) Main text body to be inserted into. If <code>text</code> is not provided, elements of <code>itemsToInsert</code> will be concatenated.
<code>offsets</code>	(optional) Array of positions within <code>text</code> where <code>itemsToInsert</code> should be inserted. If provided, the number of elements of <code>text</code> must equal the number of elements of <code>textToInsert</code> . Otherwise all items will be appended at the end of <code>text</code> .

Skill outputs

 Expand table

Output name	Description
mergedText	The resulting merged text.
mergedOffsets	Array of positions within mergedText where elements of itemsToInsert were inserted.

Sample input

A JSON document providing usable input for this skill could be:

JSON

```
{  
  "values": [  
    {  
      "recordId": "1",  
      "data":  
        {  
          "text": "The brown fox jumps over the dog",  
          "itemsToInsert": ["quick", "lazy"],  
          "offsets": [3, 28]  
        }  
    }  
  ]  
}
```

Sample output

This example shows the output of the previous input, assuming that the *insertPreTag* is set to `" "`, and *insertPostTag* is set to `""`.

JSON

```
{  
  "values": [  
    {  
      "recordId": "1",  
      "data":  
        {  
          "mergedText": "The quick brown fox jumps over the lazy dog"  
        }  
    }  
  ]  
}
```

```
]  
}
```

Extended sample skillset definition

A common scenario for using Text Merge is to merge the textual representation of images (text from an OCR skill, or the caption of an image) into the content field of a document.

The following example skillset uses the OCR skill to extract text from images embedded in the document. Next, it creates a *merged_text* field to contain both original and OCRed text from each image. You can learn more about the OCR skill [here](#).

JSON

```
{  
  "description": "Extract text from images and merge with content text to produce  
  merged_text",  
  "skills":  
  [  
    {  
      "description": "Extract text (plain and structured) from image.",  
      "@odata.type": "#Microsoft.Skills.Vision.OcrSkill",  
      "context": "/document/normalized_images/*",  
      "defaultLanguageCode": "en",  
      "detectOrientation": true,  
      "inputs": [  
        {  
          "name": "image",  
          "source": "/document/normalized_images/*"  
        }  
      ],  
      "outputs": [  
        {  
          "name": "text"  
        }  
      ]  
    },  
    {  
      "@odata.type": "#Microsoft.Skills.Text.MergeSkill",  
      "description": "Create merged_text, which includes all the textual  
      representation of each image inserted at the right location in the content field.",  
      "context": "/document",  
      "insertPreTag": " ",  
      "insertPostTag": " ",  
      "inputs": [  
        {  
          "name": "text",  
          "source": "/document/content"  
        },  
        {  
          "name": "itemsToInsert",  
          "source": "/document/normalized_images/*"  
        }  
      ]  
    }  
  ]  
}
```

```
        "source": "/document/normalized_images/*/text"
    },
    {
        "name": "offsets",
        "source": "/document/normalized_images/*/contentOffset"
    }
],
{
    "outputs": [
        {
            "name": "mergedText",
            "targetName": "merged_text"
        }
    ]
}
]
```

The example above assumes that a normalized-images field exists. To get normalized-images field, set the *imageAction* configuration in your indexer definition to *generateNormalizedImages* as shown below:

JSON

```
{  
    //...rest of your indexer definition goes here ...  
    "parameters": {  
        "configuration": {  
            "dataToExtract": "contentAndMetadata",  
            "imageAction": "generateNormalizedImages"  
        }  
    }  
}
```

Text split cognitive skill

09/19/2025

ⓘ Important

Some parameters are in public preview under [Supplemental Terms of Use](#). The [preview REST API](#) supports these parameters.

The **Text Split** skill breaks text into chunks of text. You can specify whether you want to break the text into sentences or into pages of a particular length. Positional metadata like offset and ordinal position are also available as outputs. This skill is useful if there are maximum text length requirements in other skills downstream, such as embedding skills that pass data chunks to embedding models on Azure OpenAI and other model providers. For more information about this scenario, see [Chunk documents for vector search](#).

Several parameters are version-specific. The skills parameter table notes the API version in which a parameter was introduced so that you know whether a [version upgrade](#) is required. To use version-specific features such as *token chunking* in **2024-09-01-preview**, you can use the Azure portal, or target a REST API version, or check an Azure SDK change log to see if it supports the feature.

The Azure portal supports most preview features and can be used to create or update a skillset. For updates to the Text Split skill, edit the skillset JSON definition to add new preview parameters.

! Note

This skill isn't bound to Azure AI services. It's non-billable and has no Azure AI services key requirement.

@odata.type

Microsoft.Skills.Text.SplitSkill

Skill Parameters

Parameters are case-sensitive.

Parameter name	Description
<code>textSplitMode</code>	Either <code>pages</code> or <code>sentences</code> . Pages have a configurable maximum length, but the skill attempts to avoid truncating a sentence so the actual length might be smaller. Sentences are a string that terminates at sentence-ending punctuation, such as a period, question mark, or exclamation point, assuming the language has sentence-ending punctuation.
<code>maximumPageLength</code>	Only applies if <code>textSplitMode</code> is set to <code>pages</code> . For <code>unit</code> set to <code>characters</code> , this parameter refers to the maximum page length in characters as measured by <code>String.Length</code> . The minimum value is 300, the maximum is 50000, and the default value is 5000. The algorithm does its best to break the text on sentence boundaries, so the size of each chunk might be slightly less than <code>maximumPageLength</code> .
	For <code>unit</code> set to <code>azureOpenAITokens</code> , the maximum page length is the token length limit of the model. For text embedding models, a general recommendation for page length is 512 tokens.
<code>defaultLanguageCode</code>	(optional) One of the following language codes: <code>am</code> , <code>bs</code> , <code>cs</code> , <code>da</code> , <code>de</code> , <code>en</code> , <code>es</code> , <code>et</code> , <code>fr</code> , <code>he</code> , <code>hi</code> , <code>hr</code> , <code>hu</code> , <code>fi</code> , <code>id</code> , <code>is</code> , <code>it</code> , <code>ja</code> , <code>ko</code> , <code>lv</code> , <code>no</code> , <code>nl</code> , <code>pl</code> , <code>pt-PT</code> , <code>pt-BR</code> , <code>ru</code> , <code>sk</code> , <code>sl</code> , <code>sr</code> , <code>sv</code> , <code>tr</code> , <code>ur</code> , <code>zh-Hans</code> . Default is English (<code>en</code>). A few things to consider: <ul style="list-style-type: none"> • Providing a language code is useful to avoid cutting a word in half for nonwhitespace languages such as Chinese, Japanese, and Korean. • If you don't know the language in advance (for example, if you're using the LanguageDetectionSkill to detect language), we recommend the <code>en</code> default.
<code>pageOverlapLength</code>	Only applies if <code>textSplitMode</code> is set to <code>pages</code> . Each page starts with this number of characters or tokens from the end of the

Parameter name	Description
	previous page. If this parameter is set to 0, there's no overlapping text on successive pages. This example includes the parameter.
<code>maximumPagesToTake</code>	Only applies if <code>textSplitMode</code> is set to <code>pages</code> . Number of pages to return. The default is 0, which means to return all pages. You should set this value if only a subset of pages are needed. This example includes the parameter.
<code>unit</code>	Only applies if <code>textSplitMode</code> is set to <code>pages</code> . Specifies whether to chunk by <code>characters</code> (default) or <code>azureOpenAITokens</code> . Setting the unit affects <code>maximumPageLength</code> and <code>pageOverlapLength</code> .
<code>azureOpenAITokenizerParameters</code>	An object providing extra parameters for the <code>azureOpenAITokens</code> unit.
	<p><code>encoderModelName</code> is a designated tokenizer used for converting text into tokens, essential for natural language processing (NLP) tasks. Different models use different tokenizers. Valid values include <code>cl100k_base</code> (default) used by GPT-35-Turbo and GPT-4. Other valid values are <code>r50k_base</code>, <code>p50k_base</code>, and <code>p50k_edit</code>. The skill implements the <code>tiktoken</code> library by way of SharpToken and <code>Microsoft.ML.Tokenizers</code> but doesn't support every encoder. For example, there's currently no support for <code>o200k_base</code> encoding used by GPT-4o.</p>
	<p><code>allowedSpecialTokens</code> defines a collection of special tokens that are permitted within the tokenization process. Special tokens are string that you want to treat uniquely, ensuring they aren't split during tokenization. For example <code>["[START]", "[END]"]</code>. If the <code>tiktoken</code> library doesn't perform tokenization as expected, either due to language-specific limitations or other unexpected behaviors, it's recommended to use text splitting instead.</p>

Skill Inputs

 [Expand table](#)

Parameter	Description
<code>name</code>	
<code>text</code>	The text to split into substring.
<code>languageCode</code>	(Optional) Language code for the document. If you don't know the language of the text inputs (for example, if you're using LanguageDetectionSkill to detect the language), you can omit this parameter. If you set <code>languageCode</code> to a language isn't in the supported list for the <code>defaultLanguageCode</code> , a warning is emitted and the text isn't split.

Skill Outputs

[\[\]](#) Expand table

Parameter name	Description
<code>textItems</code>	<p>Output is an array of substrings that were extracted. <code>textItems</code> is the default name of the output.</p> <p><code>targetName</code> is optional, but if you have multiple Text Split skills, make sure to set <code>targetName</code> so that you don't overwrite the data from the first skill with the second one. If <code>targetName</code> is set, use it in output field mappings or in downstream skills that consume the skill output, such as an embedding skill.</p>
<code>offsets</code>	<p>Output is an array of offsets that were extracted. The value at each index is an object containing the offset of the text item at that index in three encodings: UTF-8, UTF-16, and CodePoint. <code>offsets</code> is the default name of the output.</p> <p><code>targetName</code> is optional, but if you have multiple Text Split skills, make sure to set <code>targetName</code> so that you don't overwrite the data from the first skill with the second one. If <code>targetName</code> is set, use it in output field mappings or in downstream skills that consume the skill output, such as an embedding skill.</p>
<code>lengths</code>	<p>Output is an array of lengths that were extracted. The value at each index is an object containing the offset of the text item at that index in three encodings: UTF-8, UTF-16, and CodePoint. <code>lengths</code> is the default name of the output.</p> <p><code>targetName</code> is optional, but if you have multiple Text Split skills, make sure to set <code>targetName</code> so that you don't overwrite the data from the first skill with the second one. If <code>targetName</code> is set, use it in output field mappings or in downstream skills that consume the skill output, such as an embedding skill.</p>
<code>ordinalPositions</code>	<p>Output is an array of ordinal positions corresponding to the position of the text item within the source text. <code>ordinalPositions</code> is the default name of the output.</p> <p><code>targetName</code> is optional, but if you have multiple Text Split skills, make sure to set <code>targetName</code> so that you don't overwrite the data from the first skill with the second one.</p>

Parameter name	Description
	one. If <code>targetName</code> is set, use it in output field mappings or in downstream skills that consume the skill output, such as an embedding skill.

Sample definition

JSON

```
{
  "name": "SplitSkill",
  "@odata.type": "#Microsoft.Skills.Text.SplitSkill",

                    },
                    {
                        "utf8": 211,
                        "utf16": 211,
                        "codePoint": 211
                    }
                ]
            }
        }
    ]
}
```

```

        "utf16": 211,
        "codePoint": 211
    }
],
"ordinalPositions" : [
    1,
    2
]
}
},
{
"recordId": "2",
"data": {
"pages": [
    "This is the second document...",
    "In the next section of the second doc..."
],
"offsets": [
    {
        "utf8": 0,
        "utf16": 0,
        "codePoint": 0
    },
    {
        "utf8": 115,
        "utf16": 115,
        "codePoint": 115
    }
],
"lengths": [
    {
        "utf8": 115,
        "utf16": 115,
        "codePoint": 115
    },
    {
        "utf8": 209,
        "utf16": 209,
        "codePoint": 209
    }
],
"ordinalPositions" : [
    1,
    2
]
}
]
}
}

```

 **Note**

This example sets `textItems` to `pages` through `targetName`. Because `targetName` is set, `pages` is the value you should use to select the output from the Text Split skill. Use `/document/pages/*` in downstream skills, indexer [output field mappings](#), [knowledge store projections](#), and [index projections](#). This example doesn't set `offsets`, `lengths`, or `ordinalPosition` to any other name, so the value you should use in downstream skills would be unchanged. `offsets` and `lengths` are complex types rather than primitives, because they contain the values for multiple encoding types. The value you should use to obtain a specific encoding, for example UTF-8, would look like this:

```
/document/offsets/*/utf8.
```

Example for chunking and vectorization

This example is for integrated vectorization.

- `pageOverlapLength`: Overlapping text is useful in [data chunking](#) scenarios because it preserves continuity between chunks generated from the same document.
- `maximumPagesToTake`: Limits on page intake are useful in [vectorization](#) scenarios because it helps you stay under the maximum input limits of the embedding models providing the vectorization.

Sample definition

This definition adds `pageOverlapLength` of 100 characters and `maximumPagesToTake` of one.

Assuming the `maximumPageLength` is 5,000 characters (the default), then `"maximumPagesToTake": 1` processes the first 5,000 characters of each source document.

This example sets `textItems` to `myPages` through `targetName`. Because `targetName` is set, `myPages` is the value you should use to select the output from the Text Split skill. Use `/document/myPages/*` in downstream skills, indexer [output field mappings](#), [knowledge store projections](#), and [index projections](#).

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.SplitSkill",  
    "textSplitMode" : "pages",  
    "maximumPageLength": 1000,  
    "pageOverlapLength": 100,  
    "maximumPagesToTake": 1,  
    "defaultLanguageCode": "en",
```

```

"inputs": [
    {
        "name": "text",
        "source": "/document/content"
    },
    {
        "name": "languageCode",
        "source": "/document/language"
    }
],
"outputs": [
    {
        "name": "textItems",
        "targetName": "myPages"
    }
]
}

```

Sample input (same as previous example)

JSON

```

{
    "values": [
        {
            "recordId": "1",
            "data": {
                "text": "This is the loan application for Joe Romero, a Microsoft employee who was born in Chile and who then moved to Australia...",
                "languageCode": "en"
            }
        },
        {
            "recordId": "2",
            "data": {
                "text": "This is the second document, which will be broken into several sections...",
                "languageCode": "en"
            }
        }
    ]
}

```

Sample output (notice the overlap)

Within each "textItems" array, trailing text from the first item is copied into the beginning of the second item.

JSON

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "myPages": [
          "This is the loan...Here is the overlap part",
          "Here is the overlap part...In the next section, we
continue..."
        ]
      }
    },
    {
      "recordId": "2",
      "data": {
        "myPages": [
          "This is the second document...Here is the overlap part...",
          "Here is the overlap part...In the next section of the second
doc..."
        ]
      }
    }
  ]
}
```

Error cases

If a language isn't supported, a warning is generated.

Deprecated Cognitive Skills in Azure AI Search

Article • 08/28/2024

This document describes cognitive skills that are considered deprecated (retired). Use the following guide for the contents:

- Skill Name: The name of the skill that will be deprecated; it maps to the @odata.type attribute.
- Last available api version: The last version of the Azure AI Search public API through which skillsets containing the corresponding deprecated skill can be created/updated. Indexers with attached skillsets with these skills will continue to run even in future API versions until the "End of support" date, at which point they start failing.
- End of support: The day after which the corresponding skill is considered unsupported and stops working. Previously created skillsets should still continue to function, but users are recommended to migrate away from a deprecated skill.
- Recommendations: Migration path forward to use a supported skill. Users are advised to follow the recommendations to continue to receive support.

If you're using the [Microsoft.Skills.Text.EntityRecognitionSkill](#) (Entity Recognition cognitive skill (v2)), this article helps you upgrade your skillset to use the [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#) which is generally available and introduces new features.

If you're using the [Microsoft.Skills.Text.SentimentSkill](#) (Sentiment cognitive skill (v2)), this article helps you upgrade your skillset to use the [Microsoft.Skills.Text.V3.SentimentSkill](#) which is generally available and introduces new features.

If you're using the [Microsoft.Skills.Text.NamedEntityRecognitionSkill](#) (Named Entity Recognition cognitive skill (v2)), this article helps you upgrade your skillset to use the [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#) which is generally available and introduces new features.

Microsoft.Skills.Text.EntityRecognitionSkill

Last available api version

2021-04-30-Preview

End of support

August 31, 2024

Recommendations

Use [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#) instead. It provides most of the functionality of the EntityRecognitionSkill at a higher quality. It also has richer information in its complex output fields.

To migrate to the [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#), make one or more of the following changes to your skill definition. You can update the skill definition using the [Update Skillset API](#).

1. *(Required)* Change the `@odata.type` from

```
"#Microsoft.Skills.Text.EntityRecognitionSkill" to  
"#Microsoft.Skills.Text.V3.EntityRecognitionSkill".
```

2. *(Optional)* The `includeTypelessEntities` parameter is no longer supported as the new skill only returns entities with known types, so if your previous skill definition referenced it, it should now be removed.

3. *(Optional)* If you're making use of the `namedEntities` output, there are a few minor changes to the property names.

- a. `value` is renamed to `text`
- b. `confidence` is renamed to `confidenceScore`

If you need to generate the exact same property names, add a [ShaperSkill](#) to reshape the output with the required names. For example, this ShaperSkill renames the properties to their old values.

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",  
    "name": "NamedEntitiesShaper",  
    "description": "NamedEntitiesShaper",  
    "context": "/document/namedEntitiesV3",  
    "inputs": [  
        {  
            "name": "old_format",  
            "sourceContext": "/document/namedEntitiesV3/*",  
            "inputs": [  
                {  
                    "name": "value",  
                    "source": "/document/namedEntitiesV3/*/text"  
                }  
            ]  
        }  
    ]  
}
```

```

        },
        {
            "name": "offset",
            "source": "/document/namedEntitiesV3/*/offset"
        },
        {
            "name": "category",
            "source": "/document/namedEntitiesV3/*/category"
        },
        {
            "name": "confidence",
            "source":
                "/document/namedEntitiesV3/*/confidenceScore"
        }
    ]
}
],
"outputs": [
{
    "name": "output",
    "targetName": "namedEntities"
}
]
}

```

4. *(Optional)* If you're making use of the `entities` output to link entities to well-known entities, this feature is now a new skill, the [Microsoft.Skills.Text.V3.EntityLinkingSkill](#). Add the entity linking skill to your skillset to generate the linked entities. There are also a few minor changes to the property names of the `entities` output between the `EntityRecognitionSkill` and the new `EntityLinkingSkill`.

- a. `wikipediaId` is renamed to `id`
- b. `wikipediaLanguage` is renamed to `language`
- c. `wikipediaUrl` is renamed to `url`
- d. The `type` and `subtype` properties are no longer returned.

If you need to generate the exact same property names, add a [ShaperSkill](#) to reshape the output with the required names. For example, this ShaperSkill renames the properties to their old values.

JSON

```
{
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
    "name": "LinkedEntitiesShaper",
    "description": "LinkedEntitiesShaper",
    "context": "/document/linkedEntitiesV3",
    "inputs": [

```

```

    {
        "name": "old_format",
        "sourceContext": "/document/linkedEntitiesV3/*",
        "inputs": [
            {
                "name": "name",
                "source": "/document/linkedEntitiesV3/*/name"
            },
            {
                "name": "wikipediaId",
                "source": "/document/linkedEntitiesV3/*/id"
            },
            {
                "name": "wikipediaLanguage",
                "source": "/document/linkedEntitiesV3/*/language"
            },
            {
                "name": "wikipediaUrl",
                "source": "/document/linkedEntitiesV3/*/url"
            },
            {
                "name": "bingId",
                "source": "/document/linkedEntitiesV3/*/bingId"
            },
            {
                "name": "matches",
                "source": "/document/linkedEntitiesV3/*/matches"
            }
        ]
    },
    "outputs": [
        {
            "name": "output",
            "targetName": "entities"
        }
    ]
}

```

5. (Optional) If you don't explicitly specify the `categories`, the

`EntityRecognitionSkill V3` can return different type of categories besides those that were supported by the `EntityRecognitionSkill`. If this behavior is undesirable, make sure to explicitly set the `categories` parameter to `["Person", "Location", "Organization", "Quantity", "Datetime", "URL", "Email"]`.

Sample Migration Definitions

- Simple migration

(Before) EntityRecognition skill definition

JSON

```
{  
    "@odata.type":  
        "#Microsoft.Skills.Text.EntityRecognitionSkill",  
    "categories": [ "Person" ],  
    "defaultLanguageCode": "en",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "persons",  
            "targetName": "people"  
        }  
    ]  
}
```

(After) EntityRecognition skill V3 definition

JSON

```
{  
    "@odata.type":  
        "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",  
    "categories": [ "Person" ],  
    "defaultLanguageCode": "en",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "persons",  
            "targetName": "people"  
        }  
    ]  
}
```

- Complicated migration

(Before) EntityRecognition skill definition

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Text.EntityRecognitionSkill",
  "categories": [ "Person", "Location", "Organization" ],
  "defaultLanguageCode": "en",
  "minimumPrecision": 0.1,
  "includeTypelessEntities": true,
  "inputs": [
    {
      "name": "text",
      "source": "/document/content"
    }
  ],
  "outputs": [
    {
      "name": "persons",
      "targetName": "people"
    },
    {
      "name": "namedEntities",
      "targetName": "namedEntities"
    },
    {
      "name": "entities",
      "targetName": "entities"
    }
  ]
}
```

(After) EntityRecognition skill V3 definition

JSON

```
{

Microsoft.Skills.Text.SentimentSkill

Last available api version

2021-04-30-Preview

End of support

August 31, 2024

Recommendations

Use [Microsoft.Skills.Text.V3.SentimentSkill](#) instead. It provides an improved model and includes the option to add opinion mining or aspect-based sentiment. As the skill is significantly more complex, the outputs are also very different.

To migrate to the [Microsoft.Skills.Text.V3.SentimentSkill](#), make one or more of the following changes to your skill definition. You can update the skill definition using the [Update Skillset API](#).

Note

The skill outputs for the Sentiment Skill V3 are not compatible with the index definition based on the SentimentSkill. You will have to make changes to the index definition, skillset (later skill inputs and/or knowledge store projections) and indexer output field mappings to replace the sentiment skill with the new version.

1. *(Required)* Change the `@odata.type` from
"`#Microsoft.Skills.Text.SentimentSkill`" to
"`#Microsoft.Skills.Text.V3.SentimentSkill`".

2. *(Required)* The Sentiment Skill V3 provides a `positive`, `neutral`, and `negative` score for the overall text and the same scores for each sentence in the overall text, whereas the previous SentimentSkill only provided a single double that ranged from 0.0 (negative) to 1.0 (positive) for the overall text. You will need to update your index definition to accept the three double values in place of a single score, and make sure all of your downstream skill inputs, knowledge store projections, and output field mappings are consistent with the naming changes.

It's recommended to replace the old SentimentSkill with the SentimentSkill V3 entirely, update your downstream skill inputs, knowledge store projections, indexer output field mappings, and index definition to match the new output format, and reset your indexer so that all of your documents have consistent sentiment results going forward.

ⓘ Note

If you need any additional help updating your enrichment pipeline to use the latest version of the sentiment skill or if resetting your indexer is not an option for you, please open a [new support request](#) where we can work with you directly.

Microsoft.Skills.Text.NamedEntityRecognitionSkill

Last available api version

2017-11-11-Preview

End of support

August 31, 2024

Recommendations

Use [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#) instead. It provides most of the functionality of the NamedEntityRecognitionSkill at a higher quality. It also has richer information in its complex output fields.

To migrate to the [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#), make one or more of the following changes to your skill definition. You can update the skill definition using the [Update Skillset API](#).

1. *(Required)* Change the `@odata.type` from

```
"#Microsoft.Skills.Text.NamedEntityRecognitionSkill" to  
"#Microsoft.Skills.Text.V3.EntityRecognitionSkill".
```

2. *(Optional)* If you're making use of the `entities` output, use the `namedEntities` complex collection output from the `EntityRecognitionSkill v3` instead. There are a few minor changes to the property names of the new `namedEntities` complex output:
 - a. `value` is renamed to `text`

- b. `confidence` is renamed to `confidenceScore`

If you need to generate the exact same property names, add a [ShaperSkill](#) to reshape the output with the required names. For example, this ShaperSkill renames the properties to their old values.

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",  
    "name": "NamedEntitiesShaper",  
    "description": "NamedEntitiesShaper",  
    "context": "/document/namedEntities",  
    "inputs": [  
        {  
            "name": "old_format",  
            "sourceContext": "/document/namedEntities/*",  
            "inputs": [  
                {  
                    "name": "value",  
                    "source": "/document/namedEntities/*/text"  
                },  
                {  
                    "name": "offset",  
                    "source": "/document/namedEntities/*/offset"  
                },  
                {  
                    "name": "category",  
                    "source": "/document/namedEntities/*/category"  
                },  
                {  
                    "name": "confidence",  
                    "source":  
                        "/document/namedEntities/*/confidenceScore"  
                }  
            ]  
        }  
    ],  
    "outputs": [  
        {  
            "name": "output",  
            "targetName": "entities"  
        }  
    ]  
}
```

3. (Optional) If you don't explicitly specify the `categories`, the `EntityRecognitionSkill v3` can return different type of categories besides those that were supported by the `NamedEntityRecognitionSkill`. If this behavior is

undesirable, make sure to explicitly set the `categories` parameter to `["Person", "Location", "Organization"]`.

Sample Migration Definitions

- Simple migration

(Before) NamedEntityRecognition skill definition

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.NamedEntityRecognitionSkill",  
    "categories": [ "Person" ],  
    "defaultLanguageCode": "en",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "persons",  
            "targetName": "people"  
        }  
    ]  
}
```

(After) EntityRecognition skill V3 definition

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",  
    "categories": [ "Person" ],  
    "defaultLanguageCode": "en",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "persons",  
            "targetName": "people"  
        }  
    ]  
}
```

```
    ]  
}
```

- Slightly complicated migration

(Before) NamedEntityRecognition skill definition

JSON

```
{  
  "@odata.type":  
  "#Microsoft.Skills.Text.NamedEntityRecognitionSkill",  
  "defaultLanguageCode": "en",  
  "minimumPrecision": 0.1,  
  "inputs": [  
    {  
      "name": "text",  
      "source": "/document/content"  
    }  
  ],  
  "outputs": [  
    {  
      "name": "persons",  
      "targetName": "people"  
    },  
    {  
      "name": "entities"  
    }  
  ]  
}
```

(After) EntityRecognition skill V3 definition

JSON

```
{  
  "@odata.type":  
  "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",  
  "categories": [ "Person", "Location", "Organization" ],  
  "defaultLanguageCode": "en",  
  "minimumPrecision": 0.1,  
  "inputs": [  
    {  
      "name": "text",  
      "source": "/document/content"  
    }  
  ],  
  "outputs": [  
    {  
      "name": "persons",  
      "targetName": "people"  
    }  
  ]  
}
```

```

        },
        {
            "name": "namedEntities"
        }
    ]
},
{
    "@odata.type": "#Microsoft.Skills.Util.ShaperSkill",
    "name": "NamedEntitiesShaper",
    "description": "NamedEntitiesShaper",
    "context": "/document/namedEntities",
    "inputs": [
        {
            "name": "old_format",
            "sourceContext": "/document/namedEntities/*",
            "inputs": [
                {
                    "name": "value",
                    "source": "/document/namedEntities/*/text"
                },
                {
                    "name": "offset",
                    "source": "/document/namedEntities/*/offset"
                },
                {
                    "name": "category",
                    "source": "/document/namedEntities/*/category"
                },
                {
                    "name": "confidence",
                    "source":
                        "/document/namedEntities/*/confidenceScore"
                }
            ]
        }
    ],
    "outputs": [
        {
            "name": "output",
            "targetName": "entities"
        }
    ]
}

```

[Provide product feedback ↗](#) | [Get help at Microsoft Q&A](#)

Named Entity Recognition cognitive skill (v2)

The Named Entity Recognition skill (v2) extracts named entities from text. Available entities include the types `person`, `location` and `organization`.

Important

Named entity recognition skill (v2) (`Microsoft.Skills.Text.NamedEntityRecognitionSkill`) is now discontinued replaced by [Microsoft.Skills.Text.V3.EntityRecognitionSkill](#). Follow the recommendations in [Deprecated Azure AI Search skills](#) to migrate to a supported skill.

Note

As you expand scope by increasing the frequency of processing, adding more documents, or adding more AI algorithms, you will need to [attach a billable Microsoft Foundry resource](#). Charges accrue when calling APIs in Foundry Tools, and for image extraction as part of the document-cracking stage in Azure AI Search. There are no charges for text extraction from documents. Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#).

Image extraction is an extra charge metered by Azure AI Search, as described on the [pricing page](#). Text extraction is free.

@odata.type

`Microsoft.Skills.Text.NamedEntityRecognitionSkill`

Data limits

The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the key phrase extractor, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameters are case sensitive.

[Expand table](#)

Parameter name	Description
categories	Array of categories that should be extracted. Possible category types: "Person", "Location", "Organization". If no category is provided, all types are returned.
defaultLanguageCode	Language code of the input text. The following languages are supported: de, en, es, fr, it
minimumPrecision	A number between 0 and 1. If the precision is lower than this value, the entity is not returned. The default is 0.

Skill inputs

[Expand table](#)

Input name	Description
languageCode	Optional. Default is "en".
text	The text to analyze.

Skill outputs

[Expand table](#)

Output name	Description
persons	An array of strings where each string represents the name of a person.
locations	An array of strings where each string represents a location.
organizations	An array of strings where each string represents an organization.
entities	An array of complex types. Each complex type includes the following fields: <ul style="list-style-type: none">• category ("person", "organization", or "location")• value (the actual entity name)• offset (The location where it was found in the text)• confidence (A value between 0 and 1 that represents that confidence that the value is an actual entity)

Sample definition

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.NamedEntityRecognitionSkill",  
    "categories": [ "Person", "Location", "Organization"],

Entity Recognition cognitive skill (v2)

The Entity Recognition skill (v2) extracts entities of different types from text. This skill uses the machine learning models provided by [Text Analytics](#) in Foundry Tools.

Important

The Entity Recognition skill (v2) (`Microsoft.Skills.Text.EntityRecognitionSkill`) is now discontinued replaced by [`Microsoft.Skills.Text.V3.EntityRecognitionSkill`](#). Follow the recommendations in [Deprecated skills](#) to migrate to a supported skill.

Note

As you expand scope by increasing the frequency of processing, adding more documents, or adding more AI algorithms, you will need to [attach a billable Microsoft Foundry resource](#). Charges accrue when calling APIs in Foundry Tools, and for image extraction as part of the document-cracking stage in Azure AI Search. There are no charges for text extraction from documents.

Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#). Image extraction pricing is described on the [Azure AI Search pricing page](#).

@odata.type

`Microsoft.Skills.Text.EntityRecognitionSkill`

Data limits

The maximum size of a record should be 50,000 characters as measured by [`String.Length`](#). If you need to break up your data before sending it to the key phrase extractor, consider using the [Text Split skill](#). If you do use a text split skill, set the page length to 5000 for the best performance.

Skill parameters

Parameters are case sensitive and are all optional.

 Expand table

Parameter name	Description
categories	Array of categories that should be extracted. Possible category types: "Person", "Location", "Organization", "Quantity", "Datetime", "URL", "Email". If no category is provided, all types are returned.
defaultLanguageCode	Language code of the input text. The following languages are supported: ar, cs, da, de, en, es, fi, fr, hu, it, ja, ko, nl, no, pl, pt-BR, pt-PT, ru, sv, tr, zh-hans. Not all entity categories are supported for all languages; see note below.
minimumPrecision	A value between 0 and 1. If the confidence score (in the <code>namedEntities</code> output) is lower than this value, the entity is not returned. The default is 0.
includeTypelessEntities	Set to <code>true</code> if you want to recognize well-known entities that don't fit the current categories. Recognized entities are returned in the <code>entities</code> complex output field. For example, "Windows 10" is a well-known entity (a product), but since "Products" is not a supported category, this entity would be included in the <code>entities</code> output field. Default is <code>false</code> .

Skill inputs

[+] Expand table

Input name	Description
languageCode	Optional. Default is "en".
text	The text to analyze.

Skill outputs

! Note

Not all entity categories are supported for all languages. The "Person", "Location", and "Organization" entity category types are supported for the full list of languages above. Only *de*, *en*, *es*, *fr*, and *zh-hans* support extraction of "Quantity", "Datetime", "URL", and "Email" types. For more information, see [Language and region support for the Text Analytics API](#).

[+] Expand table

Output name	Description
persons	An array of strings where each string represents the name of a person.
locations	An array of strings where each string represents a location.
organizations	An array of strings where each string represents an organization.
quantities	An array of strings where each string represents a quantity.
dateTimes	An array of strings where each string represents a DateTime (as it appears in the text) value.
urls	An array of strings where each string represents a URL
emails	An array of strings where each string represents an email
namedEntities	An array of complex types that contains the following fields: <ul style="list-style-type: none"> category value (The actual entity name) offset (The location where it was found in the text) confidence (Higher value means it's more to be a real entity)
entities	An array of complex types that contains rich information about the entities extracted from text, with the following fields <ul style="list-style-type: none"> name (the actual entity name. This represents a "normalized" form) wikipediaId wikipediaLanguage wikipediaUrl (a link to Wikipedia page for the entity) bingId type (the category of the entity recognized) subType (available only for certain categories, this gives a more granular view of the entity type) matches (a complex collection that contains) <ul style="list-style-type: none"> text (the raw text for the entity) offset (the location where it was found) length (the length of the raw entity text)

            "length": 7
```

```
        }]
    ]
}
]
}
```

Note that the offsets returned for entities in the output of this skill are directly returned from the [Text Analytics API](#), which means if you are using them to index into the original string, you should use the [StringInfo](#) class in .NET in order to extract the correct content. [More details can be found here.](#)

Warning cases

If the language code for the document is unsupported, a warning is returned and no entities are extracted.

Last updated on 11/18/2025

Sentiment cognitive skill (v2)

The Sentiment skill (v2) evaluates unstructured text along a positive-negative continuum, and for each record, returns a numeric score between 0 and 1. Scores close to 1 indicate positive sentiment, and scores close to 0 indicate negative sentiment. This skill uses the machine learning models provided by [Text Analytics](#) in Foundry Tools.

Important

The Sentiment skill (v2) (`Microsoft.Skills.Text.SentimentSkill`) is now discontinued replaced by [`Microsoft.Skills.Text.V3.SentimentSkill`](#). Follow the recommendations in [Deprecated Azure AI Search skills](#) to migrate to a supported skill.

Note

As you expand scope by increasing the frequency of processing, adding more documents, or adding more AI algorithms, you will need to [attach a billable Microsoft Foundry resource](#). Charges accrue when calling APIs in Foundry Tools, and for image extraction as part of the document-cracking stage in Azure AI Search. There are no charges for text extraction from documents.

Execution of built-in skills is charged at the existing [Foundry Tools Standard price](#). Image extraction pricing is described on the [Azure AI Search pricing page](#).

@odata.type

`Microsoft.Skills.Text.SentimentSkill`

Data limits

The maximum size of a record should be 5000 characters as measured by [`String.Length`](#). If you need to break up your data before sending it to the sentiment analyzer, use the [`Text Split` skill](#).

Skill parameters

Parameters are case sensitive.

 Expand table

Parameter Name	Description
defaultLanguageCode	(optional) The language code to apply to documents that don't specify language explicitly. See the full list of supported languages .

Skill inputs

[] [Expand table](#)

Input Name	Description
text	The text to be analyzed.
languageCode	(Optional) A string indicating the language of the records. If this parameter is not specified, the default value is "en". See the full list of supported languages .

Skill outputs

[] [Expand table](#)

Output Name	Description
score	A value between 0 and 1 that represents the sentiment of the analyzed text. Values close to 0 have negative sentiment, close to 0.5 have neutral sentiment, and values close to 1 have positive sentiment.

Sample definition

JSON

```
{
  "@odata.type": "#Microsoft.Skills.Text.SentimentSkill",
  "inputs": [
    {
      "name": "text",
      "source": "/document/content"
    },
    {
      "name": "languageCode",
      "source": "/document/languagecode"
    }
  ],
}
```

```
"outputs": [
  {
    "name": "score",
    "targetName": "mySentiment"
  }
]
```

Sample input

JSON

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "text": "I had a terrible time at the hotel. The staff was rude and
the food was awful.",
        "languageCode": "en"
      }
    }
  ]
}
```

Sample output

JSON

```
{
  "values": [
    {
      "recordId": "1",
      "data": {
        "score": 0.01
      }
    }
  ]
}
```

Warning cases

If your text is empty, a warning is generated and no sentiment score is returned. If a language is not supported, a warning is generated and no sentiment score is returned.

Microsoft Foundry model catalog vectorizer

ⓘ Important

This vectorizer is in public preview under [Supplemental Terms of Use](#). To use this feature, we recommend the latest preview version of [Indexes - Create Or Update \(REST API\)](#).

The Microsoft Foundry model catalog vectorizer connects to an embedding model deployed from the [Foundry model catalog](#) or an [Azure Machine Learning](#) (AML) endpoint. Your data is processed in the [Geo](#) where your model is deployed.

If you're using integrated vectorization to create the vector arrays, the skillset should include an [AML skill](#) that points to the same model specified in the vectorizer.

Prerequisites

- A [Foundry hub-based project](#) or an [AML workspace](#) for a custom model that you create.
- For hub-based projects only, a [serverless deployment](#) of a [supported model](#) from the Foundry model catalog.

Vectorizer parameters

Parameters are case sensitive. The parameters you use depend on what [authentication](#) your model provider requires, if any.

[+] [Expand table](#)

Parameter	Description
name	
<code>uri</code>	(Required for key authentication) The target URI of the serverless deployment from the Foundry model catalog or the scoring URI of the AML online endpoint . Only the HTTPS URI scheme is allowed.
<code>key</code>	(Required for key authentication) The API key of the model provider.
<code>resourceId</code>	(Required for token authentication) The Azure Resource Manager resource ID of the model provider. For an AML online endpoint, use the <code>subscriptions/{guid}/resourceGroups/{resource-group-}</code>

Parameter	Description
<code>name</code>	
	<code>name}/Microsoft.MachineLearningServices/workspaces/{workspace-name}/onlineendpoints/{endpoint_name}</code> format.
<code>modelName</code>	The name of the embedding model from the Foundry model catalog deployed at the specified <code>uri</code> . Supported models are: <ul style="list-style-type: none"> • Cohere-embed-v3-english • Cohere-embed-v3-multilingual • Cohere-embed-v4
<code>region</code>	(Optional for token authentication) The region in which the model provider is deployed. Required if the region is different from the region of the search service.
<code>timeout</code>	(Optional) The timeout for the HTTP client making the API call. It must be formatted as an XSD "dayTimeDuration" value (a restricted subset of an ISO 8601 duration value). For example, <code>PT60S</code> for 60 seconds. If not set, a default value of 30 seconds is chosen. The timeout can be set to a maximum of 230 seconds and a minimum of 1 second.

What authentication parameters to use

The Microsoft Foundry model catalog vectorizer provides two authentication options:

- **Key-based authentication.** You provide a static key to authenticate scoring requests from the vectorizer. Set the `uri` and `key` parameters for this connection.
- **Token-based authentication.** The Foundry hub-based project or AML online endpoint is deployed using token-based authentication. The Azure AI Search service must have a [managed identity](#) and a role assignment on the model provider. The vectorizer then uses the search service identity to authenticate against the model provider, with no static keys required. The search service identity must have the **Owner** or **Contributor** role. Set the `resourceId` parameter, and if the search service is in a different region from the model provider, set the `region` parameter.

Supported vector query types

Which vector query types are supported by the Microsoft Foundry model catalog vectorizer depends on the `modelName` that is configured.

[] [Expand table](#)

Embedding model	Supports <code>text</code> query	Supports <code>imageUrl</code> query	Supports <code>imageBinary</code> query
Cohere-embed-v3-english	X		X
Cohere-embed-v3-multilingual	X		X
Cohere-embed-v4	X		X

Expected field dimensions

The expected field dimensions for a vector field configured with a Microsoft Foundry model catalog vectorizer depend on the `modelName` that is configured.

[Expand table](#)

<code>modelName</code>	Expected dimensions
Cohere-embed-v3-english	1024
Cohere-embed-v3-multilingual	1024
Cohere-embed-v4	256–1536

Sample definition

Suggested model names in the Foundry model catalog consist of the base model plus a random three-letter suffix. The name of your model will be different from the one shown in this example.

JSON

```
"vectorizers": [
  {
    "name": "my-model-catalog-vectorizer",
    "kind": "aml",
    "amlParameters": {
      "uri": "https://Cohere-embed-v3-multilingual-
hin.eastus.models.ai.azure.com",
      "key": "aaaaaaaa-0b0b-1c1c-2d2d-333333333333",
      "timeout": "PT60S",
      "modelName": "Cohere-embed-v3-multilingual-hin",
      "resourceId": null,
      "region": null,
    },
  },
]
```

```
    }  
]

Azure OpenAI vectorizer

The Azure OpenAI vectorizer connects to an embedding model deployed to your [Azure OpenAI in Foundry Models](#) resource or [Microsoft Foundry](#) project to generate embeddings at query time. Your data is processed in the [Geo ↗](#) where your model is deployed.

Although vectorizers are used at query time, you specify them in index definitions and reference them on vector fields through a vector profile. For more information, see [Configure a vectorizer in a search index](#).

The Azure OpenAI vectorizer is called `AzureOpenAIVectorizer` in the REST API. Use the latest stable version of [Indexes - Create \(REST API\)](#) or an Azure SDK package that provides the feature.

(!) Note

This vectorizer is bound to Azure OpenAI and is charged at the [Azure OpenAI Standard price ↗](#).

Prerequisites

- An [Azure OpenAI in Foundry Models resource](#) or Foundry project.
 - Your Azure OpenAI resource must have a [custom subdomain](#), such as `https://<resource-name>.openai.azure.com`. You can find this endpoint on the **Keys and Endpoint** page in the Azure portal and use it for the `resourceUri` property in this skill.
 - The [parent resource](#) of your Foundry project provides access to multiple endpoints, including `https://<resource-name>.openai.azure.com`, `https://<resource-name>.services.ai.azure.com`, and `https://<resource-name>.cognitiveservices.azure.com`. You can find these endpoints on the **Keys and Endpoint** page in the Azure portal and use any of them for the `resourceUri` property in this skill.
- An Azure OpenAI embedding model deployed to your resource or project. For supported models, see the next section.

Vectorizer parameters

Parameters are case sensitive.

Parameter	Description
name	
<code>resourceUri</code>	(Required) The URI of the model provider. Supported domains are: <ul style="list-style-type: none"> • <code>openai.azure.com</code> • <code>services.ai.azure.com</code> • <code>cognitiveservices.azure.com</code> <p>Azure API Management endpoints are supported with URL <code>https://<resource-name>.azure-api.net</code>. Shared private links aren't supported for API Management endpoints.</p>
<code>apiKey</code>	The secret key used to access the model. If you provide a key, leave <code>authIdentity</code> empty. If you set both <code>apiKey</code> and <code>authIdentity</code> , the <code>apiKey</code> is used on the connection.
<code>deploymentId</code>	(Required) The ID of the deployed Azure OpenAI embedding model. This is the deployment name you specified when you deployed the model.
<code>authIdentity</code>	A user-managed identity used by the search service for the connection. You can use either a system- or user-managed identity . To use a system-managed identity, leave <code>apiKey</code> and <code>authIdentity</code> blank. The system-managed identity is used automatically. A managed identity must have Cognitive Services OpenAI User permissions to send text to Azure OpenAI.
<code>modelName</code>	(Required) The name of the Azure OpenAI model deployed at the specified <code>deploymentId</code> . Supported values are: <ul style="list-style-type: none"> • <code>text-embedding-ada-002</code> • <code>text-embedding-3-large</code> • <code>text-embedding-3-small</code>

Supported vector query types

The Azure OpenAI vectorizer only supports `text` vector queries.

Expected field dimensions

The expected field dimensions for a field configured with an Azure OpenAI vectorizer depend on the `modelName` that is configured.

modelName	Minimum dimensions	Maximum dimensions
text-embedding-ada-002	1536	1536
text-embedding-3-large	1	3072
text-embedding-3-small	1	1536

Sample definition

Azure Vision vectorizer

Important

This vectorizer is in public preview under [Supplemental Terms of Use](#). The [2024-05-01-Preview REST API](#) and newer preview APIs support this feature.

The **Azure Vision** vectorizer connects to Azure Vision in Foundry Tools via a [Microsoft Foundry resource](#). At query time, the vectorizer uses the [multimodal embeddings API](#) to generate embeddings.

To determine where this model is accessible, see the [region availability for multimodal embeddings](#). Your data is processed in the [Geo](#) where your model is deployed.

Note

This vectorizer is bound to Foundry Tools. Execution of the vectorizer is charged at the [Foundry Tools Standard price](#).

Vectorizer parameters

Parameters are case sensitive.

 [Expand table](#)

Parameter	Description
<code>name</code>	
<code>resourceUri</code>	The endpoint of the Foundry resource, which must have the the <code>https://<resource-name>.services.ai.azure.com</code> or <code>https://<resource-name>.cognitiveservices.azure.com</code> format. You can find this endpoint on the Keys and Endpoint page in the Azure portal.
<code>apiKey</code>	The API key of the Foundry resource.
<code>modelVersion</code>	(Required) The model version to be passed to the Azure Vision API for generating embeddings. It's important that all embeddings stored in a given index field are generated using the same <code>modelVersion</code> . For information about version support for this model refer to multimodal embeddings .
<code>authIdentity</code>	A user-managed identity used by the search service for connecting to Foundry. You can use either a system- or user-managed identity . To use a system-managed identity, leave <code>apiKey</code> and <code>authIdentity</code> blank. The system-managed identity is used automatically. A managed identity must have Cognitive Services User permissions to use this vectorizer.

Supported vector query types

The Azure Vision vectorizer supports `text`, `imageUrl`, and `imageBinary` vector queries.

Expected field dimensions

A vector field configured with the Azure Vision vectorizer should have a `dimensions` value of 1024.

Sample definition

JSON

```
"vectorizers": [
  {
    "name": "my-ai-services-vision-vectorizer",
    "kind": "aiServicesVision",
    "aiServicesVisionParameters": {
      "resourceUri": "https://westus.api.cognitive.microsoft.com/",
      "apiKey": "00000000000000000000000000000000",
      "authIdentity": null,
      "modelVersion": "2023-04-15"
    }
  }
]
```

Custom Web API vectorizer

09/12/2025

The **custom web API vectorizer** allows you to configure your search queries to call out to a Web API endpoint to generate embeddings at query time. The structure of the JSON payload required to be implemented in the provided endpoint is described further down in this document. Your data is processed in the [Geo](#) where your model is deployed.

Although vectorizers are used at query time, you specify them in index definitions and reference them on vector fields through a vector profile. For more information, see [Configure a vectorizer in a search index](#).

The custom web API vectorizer is called `WebApiVectorizer` in the REST API. Use the latest stable version of [Indexes - Create \(REST API\)](#) or an Azure SDK package that provides the feature.

Vectorizer parameters

Parameters are case-sensitive.

 Expand table

Parameter	Description
<code>name</code>	
<code>uri</code>	The URI of the Web API to which the JSON payload is sent. Only the <code>https</code> URI scheme is allowed.
<code>httpMethod</code>	The method to use while sending the payload. Allowed methods are <code>PUT</code> or <code>POST</code>
<code>httpHeaders</code>	A collection of key-value pairs where the keys represent header names and values represent header values that are sent to your Web API along with the payload. The following headers are prohibited from being in this collection: <code>Accept</code> , <code>Accept-Charset</code> , <code>Accept-Encoding</code> , <code>Content-Length</code> , <code>Content-Type</code> , <code>Cookie</code> , <code>Host</code> , <code>TE</code> , <code>Upgrade</code> , <code>Via</code> .
<code>authResourceId</code>	(Optional) A string that if set, indicates that this vectorizer should use a managed identity on the connection to the function or app hosting the code. This property takes an application (client) ID or app's registration in Microsoft Entra ID, in any of these formats: <code>api://<appId></code> , <code><appId>/.default</code> , <code>api://<appId>/.default</code> . This value is used to scope the authentication token retrieved by the indexer, and is sent along with the custom Web API request to the function or app. Setting this property requires that your search service is configured for managed identity and your Azure function app is configured for a Microsoft Entra sign in .
<code>authIdentity</code>	(Optional) A user-managed identity used by the search service for connecting to the function or app hosting the code. You can use either a system or user managed

Parameter	Description
<code>name</code>	
<code>timeout</code>	(Optional) When specified, indicates the timeout for the http client making the API call. It must be formatted as an XSD "dayTimeDuration" value (a restricted subset of an ISO 8601 duration value). For example, <code>PT60S</code> for 60 seconds. If not set, a default value of 30 seconds is chosen. The timeout can be set to a maximum of 230 seconds and a minimum of 1 second.

Supported vector query types

The Custom Web API vectorizer supports `text`, `imageUrl`, and `imageBinary` vector queries.

Sample definition

JSON

```
"vectorizers": [
  {
    "name": "my-custom-web-api-vectorizer",
    "kind": "customWebApi",
    "customWebApiParameters": {
      "uri": "https://contoso.embeddings.com",
      "httpMethod": "POST",
      "httpHeaders": {
        "api-key": "00000000000000000000000000000000"
      },
      "timeout": "PT60S",
      "authResourceId": null,
      "authIdentity": null
    }
  }
]
```

JSON payload structure

The required JSON payload structure that is expected for an endpoint when using it with the custom web API vectorizer is the same as that of the custom web API skill, which is discussed in more detail in [the documentation for the skill](#).

There are the following other considerations to make when implementing a web API endpoint to use with the custom web API vectorizer.

- The vectorizer sends only one record at a time in the `values` array when making a request to the endpoint.
- The vectorizer passes the data to be vectorized in a specific key in the `data` JSON object in the request payload. That key is `text`, `imageUrl`, or `imageBinary`, depending on which type of vector query was requested.
- The vectorizer expects the resulting embedding to be under the `vector` key in the `data` JSON object in the response payload.
- Any errors or warnings returned by the endpoint are ignored by the vectorizer and not obtainable for debugging purposes at query time.
- If an `imageBinary` vector query was requested, the request payload sent to the endpoint is the following:

```
JSON

{
  "values": [
    {
      "recordId": "0",
      "data": {
        "imageBinary": {
          "data": "<base 64 encoded image binary data>"
        }
      }
    }
  ]
}
```

Productivity tools and accelerators for Azure AI Search

07/28/2025

Microsoft engineers build productivity tools that aren't part of the Azure AI Search service and aren't covered by service-level agreements (SLAs). You can download, modify, and build these tools to create an app that helps you develop or maintain a search solution.

Accelerators

 Expand table

Accelerator	Description
RAG Experiment Accelerator	Conduct experiments and evaluations using Azure AI Search and the RAG pattern. This accelerator has code for loading multiple data sources, using a variety of models, and creating a variety of search indexes and queries.
Build your own copilot solution accelerator	Code and docs to build a copilot for specific use cases.
Chat with your data solution accelerator	Code and docs to create interactive search solution in production environments.
Document knowledge mining solution accelerator	Code and docs built on Azure OpenAI in Azure AI Foundry Models and Azure AI Document Intelligence. It processes and extracts summaries, entities, and metadata from unstructured, multimodal documents to enable searching and chatting over this data.

Tools

 Expand table

Tool name	Description
Azure AI Search Lab	Learning and experimentation lab to try out AI-enabled search scenarios in Azure. It provides a web application front end that uses Azure AI Search and Azure OpenAI to execute searches with various options. These options range from simple keyword search to semantic ranking, vector and hybrid search, and using generative AI to answer search queries.
Back up and restore (C#)	Download the retrievable fields of an index to your local device and then upload the index and its content to a new search service.

Tool name	Description
Back up and restore (Python)	Download the retrievable fields of an index to your local device and then upload the index and its content to a new search service.
Performance testing solution	This solution helps you load test Azure AI Search. It uses Apache JMeter as an open source load and performance testing tool and Terraform to dynamically provision and destroy the required infrastructure on Azure.
Visual Studio Code extension	Although the extension is no longer available on the Visual Studio Code Marketplace, the code is open source. You can clone and modify the tool for your own use.

Training - Azure AI Search

Training modules deliver an end-to-end experience that helps you build skills and develop insights while working through a progression of exercises. Visit the following links to begin learning with prepared lessons from Microsoft and other training providers.

Learning paths

Learning paths are a collection of training modules that are organized around specific roles (like developer) or technologies (like Azure AI Search). Azure AI Search is covered in two learning paths.

- [Microsoft Azure AI Fundamentals: Azure Document Intelligence in Foundry Tools and Knowledge Mining](#) includes two modules: [Fundamentals of Azure AI Search](#) and [knowledge mining](#) and [Fundamentals of Azure Document Intelligence](#). Choose this learning path to broaden your understanding of when to use each technology.
- [Implement knowledge mining with Azure AI Search](#) includes eight modules that teach important skills. Choose this learning path to gain expertise in Azure AI Search.

Modules

 Expand table

Module	Learning path
Fundamentals of Knowledge Mining and Azure AI Search	Microsoft Azure AI Fundamentals
Create an Azure AI Search solution	Implement knowledge mining
Create a custom skill for Azure AI Search	Implement knowledge mining
Enrich your data with Azure Language in Foundry Tools	
Create a knowledge store with Azure AI Search	Implement knowledge mining
Implement advanced search features in Azure AI Search	Implement knowledge mining
Search data outside the Azure platform in Azure AI Search using Azure Data Factory	Implement knowledge mining
Perform vector search and retrieval in Azure AI Search	Implement knowledge mining
Perform search reranking with semantic ranking in Azure AI Search	Implement knowledge mining

Module	Learning path
Maintain an Azure AI Search solution	Implement knowledge mining

RAG-centric modules

- [Build a RAG-based copilot solution with your own data using Microsoft Foundry](#)
- [Implement Retrieval Augmented Generation \(RAG\) with Azure OpenAI in Foundry Models](#)

Pluralsight training

- [Add search to apps \(Pluralsight\)](#)
- [Developer course \(Pluralsight\)](#)
