What is Azure AI Search?

Azure AI Search is a fully managed, cloud-hosted service that connects your data to AI. The service unifies access to enterprise and web content so agents and LLMs can use context, chat history, and multi-source signals to produce reliable, grounded answers.

Common use cases include *classic search* and modern retrieval-augmented generation (RAG) via *agentic retrieval*. This makes Azure AI Search suitable for both enterprise and consumer scenarios, whether you're adding search functionality to a website, app, agent, or chatbot.

When you create a search service, you unlock the following capabilities:

- Two engines: [classic search](#) for single requests and [agentic retrieval](#) for parallel, iterative, LLM-assisted search.
- [Full-text](#), [vector](#), [hybrid](#), and [multimodal](#) queries over local (indexed) and remote content.
- AI enrichment to chunk, vectorize, and otherwise make raw content searchable.
- Relevance tuning to improve intent matching and result quality.
- Azure scale, security, monitoring, and compliance.
- Azure integrations with supported data platforms, Azure OpenAI, and Microsoft Foundry.

[Create a search service](#)

Why use Azure AI Search?

- Ground agents and chatbots in proprietary, enterprise, or web data for accurate, context-aware responses.
- Access data from Azure Blob Storage, Azure Cosmos DB, Microsoft SharePoint, Microsoft OneLake, and other supported data sources. Choose indexed or remote access based on your freshness, latency, and compliance needs.
- Enrich and structure content at indexing or query time with skills that perform chunking, embedding, and LLM-assisted transformations.
- Combine full-text search with vector search (hybrid search) to balance precision and recall.
- Query content containing both text and images in a single multimodal pipeline.
- Easily implement search-related features: relevance tuning, faceted navigation, filters (including geo-spatial search), synonym mapping, and autocomplete.
- Provide enterprise security, access control, and compliance through Microsoft Entra, Azure Private Link, document-level access control, and role-based access.

- Scale and operate in production with Azure reliability, monitoring and diagnostics (logs, metrics, and alerts), and REST API or SDK tooling for automation.

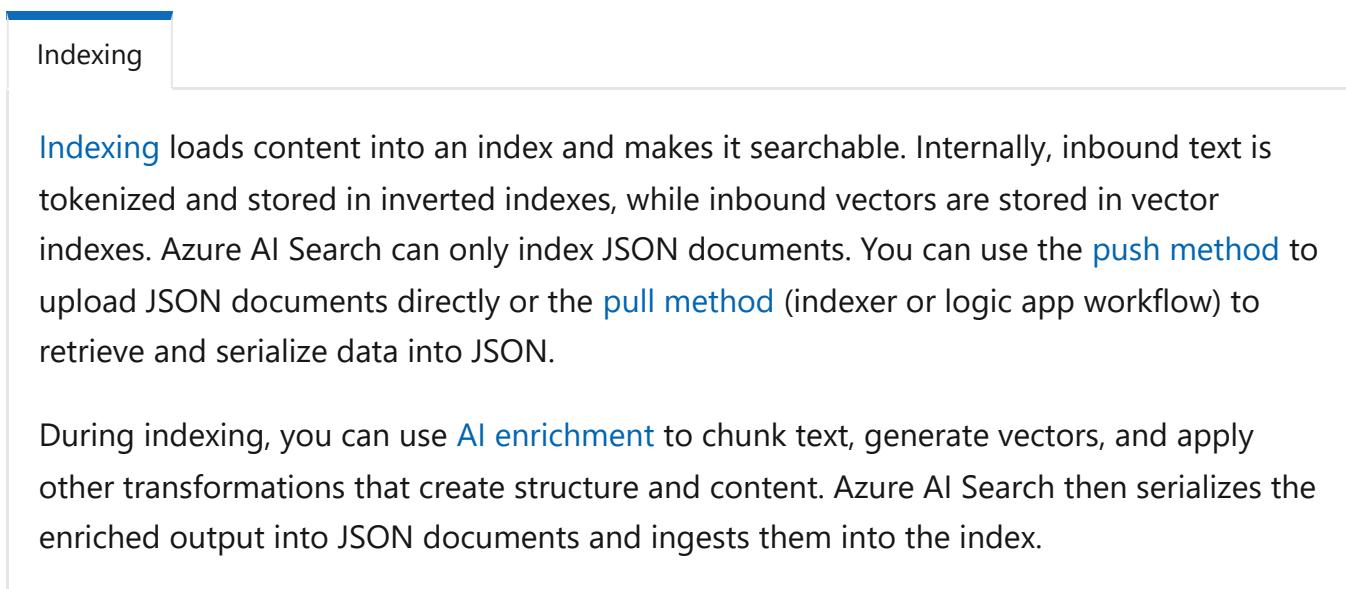

For more information about specific functionality, see [Features of Azure AI Search](#).

What is classic search?

Classic search is an index-first retrieval model for predictable, low-latency queries. Each query targets a single, predefined search index and returns ranked documents in one request-response cycle. No LLM-assisted planning, iteration, or synthesis occurs during retrieval.

In this architecture, your search service sits between the data stores that contain your unprocessed content and your client app. The app is responsible for sending query requests to your search service and handling the response.

This architecture has two primary workloads:

! Note

This diagram separates the indexing and query engines for clarity, but in Azure AI Search, they're the same component operating in read-write and read-only modes.

What is agentic retrieval?

[Agentic retrieval](#) is a multi-query pipeline designed for complex agent-to-agent workflows. Each query targets a [knowledge base](#) that represents a complete domain of knowledge. Your agent references the knowledge base for *what* to ground on, while the knowledge base handles *how* to perform grounding.

One knowledge base consists of one or more [knowledge sources](#), an optional LLM for query planning and answer synthesis, and parameters that govern retrieval behavior. Each query undergoes planning, decomposition into focused subqueries, parallel retrieval from knowledge sources, semantic reranking, and results merging. The three-pronged response is optimized for agent consumption.

Under the hood, agentic retrieval builds on the classic search architecture by adding a context layer (knowledge base) that orchestrates multi-source retrieval. Knowledge sources can be indexed or remote: indexed sources use the same indexing and query engines as classic search, while remote sources bypass indexing and are queried live.

How they compare

Classic search and agentic retrieval are complementary modes of information retrieval. Both support [full-text](#), [vector](#), [hybrid](#), and [multimodal](#) search. However, they differ in how content is ingested and queried. The following table summarizes their key differences.

Expand table

Aspect	Classic search	Agentic retrieval
Search corpus	Search index	Knowledge source
Search target	One index defined by a schema	A knowledge base pointing to one or more knowledge sources
Query plan	No plan, just a request	LLM-assisted or user-provided plan
Query request	Search documents in an index	Retrieve from knowledge sources
Response	Flattened search results based on schema	LLM-formulated answer or raw source data, activity log, references
Region restrictions	No	Yes
Status	Generally available	Public preview

How to get started

You can access Azure AI Search through the Azure portal, [REST APIs](#), and Azure SDKs for [.NET](#), [Java](#), [JavaScript](#), and [Python](#).

The portal is useful for service administration and content management, with tools for prototyping your knowledge bases, knowledge sources, indexes, indexers, skillsets, and data sources. REST APIs and SDKs are useful for production automation.

Choose your path

Before you get started, use this checklist to make key decisions:

- **Choose a search engine:** If you're not using an agent or chatbot, classic search can meet most app needs, with lower costs and complexity than LLM integration. If you want the benefits of a knowledge base and multiple knowledge sources without full LLM orchestration, consider agentic retrieval with the minimal [reasoning effort](#).
- **Choose a region:** If you're using agentic retrieval, choose a [supported region](#). For classic search, choose a region that offers the features and capacity you need.
- **Choose an ingestion method for index-bound content:** If your content is in a [supported data source](#), use the [pull method](#) to retrieve and serialize data into JSON. If you don't have a supported data source, or if your content and index must be synchronized in real time, the [push method](#) is your only option.
- **Do you need vectors?** LLMs and agents don't require vectors. Only use them if you need similarity search or if you have content that can be homogenized into vectors. Azure AI Search offers [integrated vectorization](#) for this task.
- **Do you need user-based permission inheritance?** Remote SharePoint is designed for this scenario, but you can also inherit user permissions attached to content in Azure Blob Storage or ADLS Gen2. For all other scenarios, you can use the [security filter](#) workaround.

Choose your learning resources

Quickstarts

We maintain quickstarts that span various end-to-end search scenarios:

- Quickstart: Agentic retrieval ([portal](#) or [programmatic](#))
- Quickstart: Full-text search ([portal](#) or [programmatic](#))

- Quickstart: Vector search ([portal](#) or [programmatic](#))

 Tip

For help with complex or custom solutions, [contact a partner](#) ↗ with deep expertise in Azure AI Search.

What's new in Azure AI Search

Learn about the latest updates to Azure AI Search functionality, docs, and samples.

! Note

Preview features are announced here, but we also maintain a [preview features list](#) so you can find them in one place.

November 2025

[] Expand table

Item	Description
Search Service 2025-11-01-preview	New preview REST API version providing programmatic access to the data plane operations described in this table.
Semantic ranker and agentic retrieval on free tiers	Both semantic ranker and agentic retrieval are now available on free tiers in select regions , subject to limits on query volume.
Knowledge agents renamed to knowledge bases	Knowledge agents are now known as knowledge bases. Knowledge sources remain unchanged. This rename introduces breaking changes to REST API routes and properties. For help with migration, see Migrate your agentic retrieval code .
Knowledge bases (preview)	After being renamed from knowledge agents, knowledge bases now support new <code>retrievalInstructions</code> and <code>outputConfiguration</code> properties for improved query planning and execution control. It also provides a new reasoning effort for control over LLM processing.
Knowledge sources (preview)	New types of knowledge sources: indexed OneLake , indexed SharePoint , remote SharePoint , and web . For indexed knowledge sources, the new <code>ingestionParameters</code> object provides properties to control content ingestion and processing, including <code>contentExtractionMode</code> for use of the Azure Content Understanding skill and <code>ingestionPermissionOptions</code> for use of ACLs in the generated indexer.
Knowledge retrieval (preview)	Execute retrieval operations with support for reasoning effort , zero-model-call mode for efficiency, and partial responses.
Portal support for knowledge sources and knowledge bases (preview)	Use the Azure portal to create and manage knowledge sources and knowledge bases, with a new chat playground for sending retrieval requests. These portal-generated objects use the 2025-08-01-preview

Item	Description
	schema and have breaking changes with the 2025-11-01-preview. For help with migration, see Migrate your agentic retrieval code .
Foundry IQ (preview)	New integration that allows agents in Foundry Agent Service to invoke knowledge bases in Azure AI Search. Foundry IQ offloads complex retrieval operations to the knowledge base, enabling the agent to provide accurate, citation-backed responses based on enterprise data and web sources.
Azure Content Understanding skill (preview)	New skill that wraps Azure Content Understanding in Foundry Tools to extract structured Markdown from text, images, PDFs, Microsoft PowerPoint, Microsoft Word, and more. This skill provides advanced document parsing with better table extraction (including cross-page tables), image descriptions, and semantic chunking. For indexed knowledge sources, this skill is available through the <code>contentExtractionMode</code> property within <code>ingestionParameters</code> .
SharePoint indexer ACL support (preview)	Extended ACL support to flow basic SharePoint permissions to indexed documents, enabling document-level access control.
Elevated read permissions for ACLs (preview)	New capability to assign elevated read permissions to administrators for investigating problems with ACL configurations used in document access control.
Document-level sensitivity label indexing (preview)	New integration with Microsoft Purview to sync document sensitivity labels to the index, honoring their labels and protection at query time for data governance.
SharePoint indexing updates (preview)	New SharePoint indexer capabilities, including improved authentication options, incremental updates, and basic handling of document permissions.
Scoring function aggregation (preview)	New capability to combine and aggregate multiple scoring functions, enabling more sophisticated relevance customization and weighted signal combination.
Facet aggregations (preview)	New facet aggregation operations, including minimum, maximum, average, and cardinality, provide enhanced analytics in faceted search experiences.
<code>azure-api.net</code> endpoint support (preview)	The Azure OpenAI Embedding skill and Azure OpenAI vectorizer now accept <code>azure-api.net</code> endpoints for Azure API Management (not custom endpoints).
<code>services.ai.azure.com</code> endpoint support	The GenAI Prompt skill , Azure OpenAI Embedding skill , Azure OpenAI vectorizer , and AI enrichment now accept <code>services.ai.azure.com</code> endpoints for Microsoft Foundry resources. When you upgrade from Azure OpenAI to Foundry , a new project is automatically created and becomes available for RAG and multimodal RAG in the Import data (new) wizard .

September 2025

 Expand table

Item	Description
Search Service 2025-09-01	New stable REST API version supports general availability for Microsoft OneLake indexer, Document Layout skill, and other APIs.
Logic app workflow integration	Generally available.
OneLake indexer	Generally available.
Document Layout skill	Generally available.
Normalizers	Generally available.
Index description	Generally available.
Rescoring of binary quantized vectors	Generally available.
Rescoring options for scalar compressed vectors	Generally available.
Scoring profiles for semantically ranked results	Generally available.
Truncate dimensions	Generally available.
Unpack @search.score to view subscores in hybrid search results	Generally available.
Updates to import wizards (Phase 1)	<p>The Azure portal is undergoing a three-phase rollout to unify the two import wizards. For Phase 1, the Import and vectorize data wizard has been renamed to Import data (new) and redeveloped to support keyword search, modernizing the legacy Import data workflow with an improved interface and user experience.</p> <p>Import data (new) isn't a direct replacement for the old wizard. For example, it supports fewer skills for keyword search and doesn't offer built-in sample data.</p> <p>Both wizards are currently available, but Import data will be deprecated in a future phase.</p>

Item	Description
Support for Azure confidential computing	<p>Configure confidential computing during service creation to process data in use on confidential VMs. This compute type isn't intended for general use, but rather for stringent regulatory, compliance, or security requirements.</p>

August 2025

[Expand table](#)

Item	Description
Search Service 2025-08-01-preview	<p>New preview REST API version providing programmatic access to the data plane operations described in this table.</p>
Knowledge agents (preview)	<p>Architectural changes to the knowledge agent definition, which now requires one or more <code>knowledgeSources</code> instead of <code>targetIndexes</code> and deprecates <code>defaultMaxDocsForReranker</code>. New <code>retrievalInstructions</code> and <code>outputConfiguration</code> properties provide greater control over query planning and execution. For help with breaking changes, see Migrate your agentic retrieval code.</p>
Knowledge sources (preview)	<p>New REST APIs for creating and managing knowledge sources, which represent content that knowledge agents use to ground and answer queries. In this preview, you can create knowledge sources for search indexes and Azure blobs.</p>
Answer synthesis (preview)	<p>New <code>answerSynthesis</code> modality for knowledge agents. When specified, an LLM generates a natural-language answer as an embedded step in the retrieval pipeline. This differs from the default <code>extractiveData</code> modality, which returns raw search results for downstream processing.</p>
"Fast path" for knowledge agents (preview)	<p>(Removed in the 2025-11-01-preview. This documentation no longer exists). The <code>attemptFastPath</code> boolean in knowledge agents enabled a shorter processing time if queries are concise and the initial response is sufficiently relevant. Replacement feature is the minimal retrieval reasoning effort.</p>
Retrieval instructions (preview)	<p>New <code>retrievalInstructions</code> property for knowledge agents guides query planning in an agentic retrieval workflow. For example, you can specify criteria for including or excluding specific knowledge sources.</p>
Improved indexer runtime tracking	<p>Applies to Standard 3 High Density (S3 HD) services only. Get Service Statistics response now provides cumulative indexer processing information for the entire</p>

Item	Description
information (preview)	service. Get Status - Indexers provides the same information, but for a specific indexer.
Strict postfiltering for vector queries (preview)	New <code>strictPostFilter</code> mode for the <code>vectorFilterMode</code> parameter. When specified, filters are applied after the global top- <code>k</code> vector results are identified, ensuring that returned documents are a subset of the unfiltered results.
Increased maximum dimensions for vector fields	The maximum dimensions per vector field are now <code>4096</code> . This update applies to all stable and preview REST API versions that support vectors and doesn't introduce breaking changes.

July 2025

[] [Expand table](#)

Item	Description
Search Management 2025-05-01	Stable release of the REST APIs for the control plane operations described in this table. For migration guidance, see Upgrade to the latest REST API in Azure AI Search .
Service upgrade	Now generally available through Upgrade Service (REST API) and the Azure portal.
Pricing tier change	Now generally available through the <code>sku</code> property in Update Service (REST API) and the Azure portal.
User-assigned managed identity assignment	Now generally available through the <code>identity</code> property that associates a user-assigned managed identity with a search service configuration. Only the assignment step, via the Update Service (REST API) or the Azure portal, is generally available. APIs used for data source or model connections that include a user-assigned managed identity are still in preview.
Network security perimeter	Now generally available through the Azure Virtual Network Manager REST APIs , which are used to join a search service, and the Search Management REST APIs , which are used to view and synchronize the configuration settings. Portal support for both steps is also generally available.

May 2025

[] [Expand table](#)

Item	Description
Agentic retrieval (preview)	Create a conversational search experience powered by large language models (LLMs) and your proprietary data. Agentic retrieval breaks down complex user queries into subqueries, runs the subqueries in parallel, and extracts grounding data from documents indexed in Azure AI Search. The output is intended for agents and custom chat solutions. A new knowledge agent object is introduced in this preview. Its response payload is designed for downstream agent and chat model consumption, with full transparency of the query plan and reference data. To get started in the portal, see Quickstart: Agentic retrieval .
Multivector support (preview)	Index multiple child vectors within a single document field. You can now use vector types in nested fields of complex collections, effectively allowing multiple vectors to be associated with a single document.
Scoring profiles with semantic ranking (preview)	Semantic ranker adds a new field, <code>@search.rerankerBoostedScore</code> , to help you maintain consistent relevance and greater control over final ranking outcomes in your search pipeline.
Azure Logic Apps integration (preview)	Create an automated indexing pipeline that retrieves content using a logic app workflow. Use the Import and vectorize data wizard in the Azure portal to build an indexing pipeline based on Azure Logic Apps integration.
Document-level access control (preview)	Flow document-level permissions from blobs in Azure Data Lake Storage (ADLS) Gen2 to searchable documents in an index. Queries can now filter results based on user identity for selected data sources.
Multimodal search (preview)	Ingest, understand, and retrieve documents that contain text and images, enabling you to perform searches that combine various modalities, such as querying with text to find information embedded in relevant complex images. See Quickstart: Search for multimodal content for portal wizard support and Azure AI Search Multimodal RAG Demo for a code-first approach.
GenAI prompt skill (preview)	A new skill that connects to a large language model (LLM) for information, using a prompt you provide. With this skill, you can populate a searchable field using content from an LLM. A primary use case for this skill is <i>image verbalization</i> , using an LLM to describe images and send the description to a searchable field in your index.
Document Layout skill (preview)	New parameters are available for this skill if you use the 2025-05-01-preview API version or later. New parameters support image offset metadata that improves the image search experience.
Import and vectorize data wizard enhancements	This wizard provides two paths for creating and populating vector indexes: Retrieval Augmented Generation (RAG) and Multimodal RAG . Logic apps integration is through the RAG path.
Index "description" support (preview)	The latest preview API adds a description to an index. Consider a Model Context Protocol (MCP) server that must pick the correct index at run time. The decision can be based on the description rather than on the index name alone. The description must be human readable and under four thousand characters.

Item	Description
2025-05-01-preview	New data plane preview REST API version providing programmatic access to the preview features announced in this release.

April 2025

[+] [Expand table](#)

Item	Description
RAG Time Journey ↗	Code and video demonstrations of Retrieval Augmented Generation (RAG) workflows that use Azure AI Search. Segments include fundamentals, patterns and use-cases, vector indexing at scale ↗ , and agentic search ↗ where you use an agent to evaluate a result and generate a better answer.

March 2025

[+] [Expand table](#)

Item	Description
Service upgrade (preview)	Upgrade your search service to higher storage limits in your region. With a one-time upgrade, you no longer need to recreate your service. Available in Upgrade Service (2025-02-01-preview) and the Azure portal.
Pricing tier change (preview)	Change the pricing tier of your search service. This provides flexibility to scale storage, increase request throughput, and decrease latency based on your needs. Initially, this preview only supported upgrades between Basic and Standard (S1, S2, and S3) tiers, but starting in July 2025, it supports upgrades <i>and</i> downgrades between these tiers. Available in Update Service (2025-02-01-preview) and the Azure portal.
Facet hierarchies, aggregations, and facet filters (preview)	New facet query parameters support nested facets. For numeric facetable fields, you can sum the values of each field. You can also specify filters on a facet to add inclusion or exclusion criteria. Available in Search Documents (2025-03-01-preview) and the Azure portal.
Rescore vector queries over binary quantization using full precision vectors (preview)	For vector indexes that contain binary quantization, you can rescore query results using a full precision vector query. The query engine uses the dot product of the binary embeddings and the vector query for rescaling, which improves the quality of search results. Set <code>enableRescoring</code> and <code>discardOriginals</code> to use this feature, and call the latest preview API version on the request.

Item	Description
Semantic ranker prerelease models (preview)	Opt in to use prerelease semantic ranker models if one happens to be available in your region. Available in Create or Update Index (2025-03-01-preview) .
Search Service REST 2025-03-01-preview	Public preview release of REST APIs for data plane operations. Adds support for multi-vector embeddings, hierarchical facets, facet aggregation, and facet filters.
Search Management 2025-02-01-preview	Public review release of REST APIs for control plane operations. Adds support for in-place upgrade to higher capacity partitions, in-place upgrade to higher tiers, and Azure Confidential Compute.

February 2025

[+] [Expand table](#)

Item	Description
Customer-managed keys support for Managed HSM	Use either Azure Key Vault or Azure Key Vault Managed HSM (Hardware Security Module) to store customer-managed keys for extra encryption of sensitive content.

2024 announcements

[+] [Expand table](#)

Month	Type	Announcement
December	Template	RAG chat with Azure AI Search + Python . An AI application template for building a RAG solution using Azure AI Search and Python.
November	Security	Network security perimeter . Join a search service to a network security perimeter to control network access to your search service. The Azure portal and the Management REST APIs in the 2024-06-01-preview can be used to view and reconcile network security perimeter configurations.
November	Security	Shared private link support for Azure AI service connections . Connections to Azure AI for built-in skills processing can now be private using a shared private link on the connection.
November	Relevance	Rescoring options for compressed vectors . You can set options to rescore with original vectors instead of compressed vectors. Applies to HNSW and exhaustive KNN vector algorithms, using binary and scalar compression.

Month	Type	Announcement
		Available in the Create or Update Index (2024-11-01-preview) , the Azure portal, and in the Azure SDK beta packages that provide this feature.
November	Vector search	<p>Store fewer vector instances. In vector compression scenarios, you can omit storage of full precision vectors if you don't need them for rescore.</p> <p>Available in the Create or Update Index (2024-11-01-preview), the Azure portal, and in the Azure SDK beta packages that provide this feature.</p>
November	Relevance	<p>Query rewrite in the semantic reranker. You can set options on a semantic query to rewrite the query input into a revised or expanded query that generates more relevant results from the L2 ranker. Available in the Search Documents (2024-11-01-preview), the Azure portal, and in the Azure SDK beta packages that provide this feature.</p>
November	Relevance	<p>New semantic ranker models. Semantic ranker runs with improved models in all supported regions. There's no change to APIs or the Azure portal experience.</p>
November	Applied AI (skills)	<p>Document Layout skill. A new skill used to analyze a document for structure and provide structure-aware (paragraph) chunking. This skill calls Azure Document Intelligence in Foundry Tools and uses the Azure Document Intelligence layout model. Available in selected regions through the Create or Update Skillset (2024-11-01-preview), the Azure portal, and in the Azure SDK beta packages that provide this feature.</p>
November	Applied AI (skills)	<p>Keyless billing for Azure AI skills processing. You can now use a managed identity and roles for a keyless connection to Foundry Tools for built-in skills processing. This capability removes restrictions for having both search and Foundry Tools in the same region. Available in the Create or Update Skillset (2024-11-01-preview), the Azure portal, and in the Azure SDK beta packages that provide this feature.</p>
November	Indexer data source	<p>Markdown parsing mode. With this parsing mode, indexers can generate one-to-one or one-to-many search documents from Markdown files in Azure Storage and Microsoft OneLake. Available in the Create or Update Indexer (2024-11-01-preview), the Azure portal, and in the Azure SDK beta packages that provide this feature.</p>
November	API	<p>2024-11-01-preview. Preview release of REST APIs for query rewrite, Document Layout skill, keyless billing for skills processing, Markdown parsing mode, and rescore options for compressed vectors.</p>
November	Feature	<p>Portal support for structured data. The Import and vectorize data wizard now supports Azure SQL, Azure Cosmos DB, and Azure Table Storage.</p>
October	Feature	<p>Lower the dimension requirements for MRL-trained text embedding models on Azure OpenAI. Text-embedding-3-small and Text-embedding-3-large are trained using Matryoshka Representation Learning (MRL). This allows you to truncate the embedding vectors to fewer dimensions, and adjust the balance</p>

Month	Type	Announcement
		between vector index size usage and retrieval quality. A new <code>truncationDimension</code> in the 2024-09-01-preview enables access to MRL compression in text embedding models. This can only be configured for new vector fields.
October	Feature	Unpack @search.score to view subscores in hybrid search results . You can investigate Reciprocal Rank Fusion (RRF) ranked results by viewing the individual query subscores of the final merged and scored result. A new <code>debug</code> property unpacks the search score. <code>QueryResultDocumentSubscores</code> , <code>QueryResultDocumentRerankerInput</code> , and <code>QueryResultDocumentSemanticField</code> provide the extra detail. These definitions are available in the 2024-09-01-preview .
October	Feature	Target filters in a hybrid search to just the vector queries . A filter on a hybrid query involves all subqueries on the request, regardless of type. You can override the global filter to scope the filter to a specific subquery. The new <code>filterOverride</code> parameter is available on hybrid queries using the 2024-09-01-preview .
October	Applied AI (skills)	Text Split skill (token chunking) . This skill has new parameters that improve data chunking for embedding models. A new <code>unit</code> parameter lets you specify token chunking. You can now chunk by token length, setting the length to a value that makes sense for your embedding model. You can also specify the tokenizer and any tokens that shouldn't be split during data chunking. The new <code>unit</code> parameter and query subscore definitions are found in the 2024-09-01-preview .
October	API	2024-09-01-preview . Preview release of REST APIs for truncated dimensions in text-embedding-3 models, targeted vector filtering for hybrid queries, RRF subscore details for debugging, and token chunking for Text Split skill.
October	Feature	Portal support for customer-managed key encryption (CMK) . When you create new objects in the Azure portal, you can now specify CMK-encryption and select an Azure Key Vault to provide the key.
August	Feature	Debug Session improvements . There are two important improvements. First, you can now debug integrated vectorization and data chunking workloads. Second, Debug Sessions is redesigned for a more streamlined presentation of skills and mappings. You can select an object in the flow, and view or edit its details in a side panel. The previous tabbed layout is fully replaced with more context-sensitive information on the page.
August	API	2024-07-01 . Stable release of REST APIs for generally available vector data types, vector compression, and integrated vectorization during indexing and queries.
August	Feature	Integrated vectorization , Announcing general availability. Skills-driven data chunking and embedding during indexing.

Month	Type	Announcement
August	Feature	Vectorizers . Announcing general availability. Text-to-vector conversion during query execution. Both Azure OpenAI vectorizer and custom Web API vectorizer are generally available.
August	Feature	AzureOpenAIEmbedding skill . Announcing general availability. A skill type that calls an Azure OpenAI embedding model to generate embeddings during indexing.
August	Feature	Index projections . Announcing general availability. A component of a skillset definition that defines the shape of a secondary index, supporting a one-to-many index pattern, where content from an enrichment pipeline can target multiple indexes.
August	Feature	Binary and Scalar quantization . Announcing general availability. Compress vector index size in memory and on disk using built-in quantization.
August	Feature	Narrow data types . Announcing general availability. Assign a smaller data type on vector fields, assuming incoming data is of that data type.
August	Feature	Import and vectorize data wizard . Announcing general availability. A wizard that creates a full indexing pipeline that includes data chunking and vectorization. The wizard creates all necessary objects and configurations. This release adds wizard support for Azure Data Lake in Azure Storage.
August	Feature	stored property . Announcing general availability. Boolean that reduces storage of vector indexes by <i>not</i> storing retrievable vectors.
August	Feature	vectorQueries.Weight property . Announcing general availability. Specify the relative weight of each vector query in a search operation.
July	Accelerator	Chat with your data . A solution accelerator for the RAG pattern running in Azure, using Azure AI Search for retrieval and Azure OpenAI large language models to create conversational search experiences. The code with sample data is available for use case scenarios such as financial advisor and contract review and summarization.
July	Accelerator	Conversational Knowledge Mining . A solution accelerator built on top of Azure AI Search, Azure Speech in Foundry Tools, and Azure OpenAI that allows customers to extract actionable insights from post-contact center conversations.
July	Accelerator	Build your own copilot . Create your own custom copilot solution that empowers Client Advisor to harness the power of generative AI across both structured and unstructured data. Help our customers to optimize daily tasks and foster better interactions with more clients.
June	Feature	Image search in the Azure portal . Search explorer now supports image search. In a vector index that contains vectorized image content, you can drop images into Search Explorer to query for a match.

Month	Type	Announcement
May	Service limits	<p>Higher capacity and more vector quota at every tier (same billing rate). For most regions, partition sizes are now even larger for Standard 2 (S2), Standard 3 (S3), and Standard 3 High Density (S3 HD) for services created after April 3, 2024. To get the larger partitions, create a new service in a region that provides newer infrastructure.</p> <p>Storage Optimized tiers (L1 and L2) also have more capacity. L1 and L2 customers must create a new service to benefit from the higher capacity. There's no in-place upgrade at this time.</p> <p>Extra capacity is now available in more regions: Germany North, Germany West Central, South Africa North, Switzerland West, and Azure Government (Texas, Arizona, and Virginia).</p>
May	Feature	<p>OneLake integration (preview). New indexer for OneLake files and OneLake shortcuts. If you use Microsoft OneLake for data access to Amazon Web Services (AWS) and Google data sources, use this indexer to import external data into a search index. This indexer is available through the Azure portal, the 2024-05-01-preview REST API, and Azure SDK beta packages.</p>
May	Feature	<p>Vector relevance</p> <p>hybrid query relevance. Four enhancements improve vector and hybrid search relevance.</p> <p>First, you can now set thresholds on vector search results to exclude low-scoring results.</p> <p>Second, changes in the query architecture apply scoring profiles at the end of the query pipeline for every query type. Document boosting is a common scoring profile, and it now works as expected on vector and hybrid queries.</p> <p>Third, you can set MaxTextRecallSize and countAndFacetMode in hybrid queries to control the quantity of BM25-ranked search results that flow into the hybrid ranking model.</p> <p>Fourth, for vector and hybrid search, you can weight a vector query to have boost or diminish its importance in a multiquery request.</p>
May	Feature	<p>Binary vectors support. <code>Collection(Edm.Byte)</code> is a new supported data type. This data type opens up integration with the Cohere v3 binary embedding models and custom binary quantization. Narrow data types lower the cost of large vector datasets. See Index binary data for vector search for more information.</p>
May	Skill	<p>Azure Vision multimodal embeddings skill (preview). New skill that's bound to the multimodal embeddings API of Azure Vision. You can generate embeddings for text or images during indexing. This skill is available through the Azure portal and the 2024-05-01-preview REST API.</p>

Month	Type	Announcement
May	Vectorizer	Azure Vision vectorizer (preview). New vectorizer connects to an Azure Vision resource using the multimodal embeddings API to generate embeddings at query time. This vectorizer is available through the Azure portal and the 2024-05-01-preview REST API .
May	Vectorizer	Microsoft Foundry model catalog vectorizer (preview). New vectorizer connects to an embedding model deployed from the Foundry model catalog . This vectorizer is available through the Azure portal and the 2024-05-01-preview REST API .
		How to implement integrated vectorization using models from Foundry.
May	Skill	AzureOpenAIEmbedding skill (preview) supports more models on Azure OpenAI. Now supports text-embedding-3-large and text-embedding-3-small, along with text-embedding-ada-002 from the previous update. New <code>dimensions</code> and <code>modelName</code> properties make it possible to specify the various embedding models on Azure OpenAI. Previously, the dimensions limits were fixed at 1,536 dimensions, applicable to text-embedding-ada-002 only. The updated skill is available through the Azure portal and the 2024-05-01-preview REST API .
May	Portal	Import and vectorize data wizard now supports OneLake indexers as a data source. For embeddings, it also supports connections to Azure Vision multimodal, Foundry model catalog, and more embedding models on Azure OpenAI. When adding a field to an index, you can choose a binary data type . Search explorer now defaults to 2024-05-01-preview and supports the new preview features for vector and hybrid queries.
May	API	2024-05-01-preview . New preview version of the Search REST APIs provides new skills and vectorizers, new binary data type, OneLake files indexer, and new query parameters for more relevant results. See Upgrade REST APIs if you have existing code written against the 2023-07-01-preview and need to migrate to this version.
May	API	Azure SDK beta packages. Review the changelogs of the following Azure SDK beta packages for new feature support: Azure SDK for Python , Azure SDK for .NET , Azure SDK for Java
May	Samples	Python code samples . New end-to-end samples demonstrate integration with Cohere Embed v3 , integration with OneLake and cloud data platforms on Google and AWS , and integration with Azure Vision multimodal APIs .
April	API	Security update addressing information disclosure . GET responses no longer return connection strings or keys. Applies to GET Skillset, GET Index,

Month	Type	Announcement
		and GET Indexer. This change helps protect your Azure assets integrated with AI Search from unauthorized access.
April	API	2024-03-01-preview Search REST API
April	API	2024-03-01-preview Management REST API
April	API	2023-07-01-preview deprecation announcement . This version is no longer supported as of July 8, 2024. Newer API versions have a different vector configuration. You should migrate to a newer version as soon as possible.
April	Service limits	Basic and Standard tiers offer more storage per partition, at the same per-partition billing rate. Extra capacity is subject to regional availability and applies to new search services created after April 3, 2024. Basic now supports up to three partitions and three replicas.
April	Service limits	Vector quotas are higher on new services created after April 3, 2024 in selected regions.
April	Feature	Vector quantization, narrow vector data types, and a new stored property (preview) . Collectively, these three features minimize storage and costs.
February	Feature	New dimension limits on vector fields. Maximum dimension limits are now 3072 , up from 2048 .

Previous year's announcements

- [2023 announcements](#)
- [2022 announcements](#)
- [2021 announcements](#)
- [2020 announcements](#)
- [2019 announcements](#)

Service rebrand

This service has had multiple names over the years. Here they are in reverse chronological order:

- **Azure AI Search** (November 2023) Renamed to align with Foundry Tools and customer expectations.
- **Azure Cognitive Search** (October 2019) Renamed to reflect the expanded (yet optional) use of cognitive skills and AI processing in service operations.
- **Azure Search** (March 2015) The original name.

Service updates

You can find [service update announcements](#) for Azure AI Search on the Azure website.

Feature rename

Semantic search was renamed to [semantic ranker](#) in November 2023 to better describe the feature, which provides L2 ranking of an existing result set.

Last updated on 11/18/2025

Features of Azure AI Search

08/13/2025

Azure AI Search provides information retrieval and uses optional AI integration to extract more value from text and vector content.

The following table summarizes features by category. There's feature parity in all Azure public, private, and sovereign clouds, but some features aren't supported in [specific regions](#) or [specific tiers](#).

ⓘ Note

Looking for preview features? See the [preview features list](#).

[+] Expand table

Category	Features
Data sources	<p>Search indexes can accept text from any source, provided it's submitted as a JSON document.</p> <p>Indexers are a feature that automates data import from supported data sources to extract searchable content in primary data stores. Indexers handle JSON serialization for you and most support some form of change and deletion detection. You can connect to a variety of data sources, including OneLake (preview), Azure SQL Database, Azure Cosmos DB, or Azure Blob storage.</p> <p>Logic Apps connectors (preview) give you access to a broader range of data sources, including data on other cloud platforms. This indexing and enrichment pipeline is created in Azure AI Search but managed in Azure Logic Apps.</p>
Hierarchical and nested data structures	<p>Complex types and collections allow you to model virtually any type of JSON structure within a search index. One-to-many and many-to-many cardinality can be expressed natively through collections, complex types, and collections of complex types.</p>
Linguistic analysis	Analyzers are components used for text processing during indexing and search operations. By default, you can use the general-purpose Standard Lucene analyzer, or override the default with a language analyzer, a custom analyzer that you configure, or another predefined analyzer that

Category	Features
	<p>produces tokens in the format you require.</p> <p>Language analyzers from Lucene or Microsoft are used to intelligently handle language-specific linguistics including verb tenses, gender, irregular plural nouns (for example, 'mouse' vs. 'mice'), word decompounding, word-breaking (for languages with no spaces), and more.</p> <p>Custom lexical analyzers are used for complex query forms such as phonetic matching and regular expressions.</p>

Chat model and agent integration

[] [Expand table](#)

Category	Features
Chat completion models used during indexing	<p>GenAI prompt skill (preview) is a skill that calls a large language model during indexing and provides a prompt that determines the task. You decide what the task is. It might describing an image, summarizing or manipulating content, or any task the model can perform. Output is added as a new field in a searchable index.</p>
Chat completion models used at query time	<p>Agentic retrieval (preview) uses a large language model for query planning, decomposing and paraphrasing complex queries for better query coverage over your index. Responses from agentic retrieval are designed for agent-to-agent workflows. You can pass search results as single large string, which simplifies agent consumption of your proprietary content. The response also includes citations and query execution information.</p>
	<p>RAG patterns can be implemented using existing capabilities. The ability to tune for relevance and construct hybrid queries improve the quality of the content sent to chat bots for answer generation.</p>

Applied AI and AI enriched content

[] [Expand table](#)

Category	Features
AI processing during indexing	<p>AI enrichment refers to embedded image and natural language processing in an indexer pipeline that extracts text and information</p>

Category	Features
	<p>from content that can't otherwise be indexed for full text search. AI processing is achieved by adding and combining skills in a skillset, which is then attached to an indexer. AI can be either built-in skills from Microsoft, such as text translation or Optical Character Recognition (OCR), or custom skills that you provide.</p> <p>Integrated data chunking and vectorization splits up larger passages into smaller chunks that can be vectorized, with vectors routed to dedicated fields in an index for vector and hybrid search.</p>
AI processing during query execution	<p>Vectorizers are used to encode user query strings into vectors for vector search. You can use the same embedding models for queries that you used for indexing.</p>
Storing enriched content for analysis and consumption in non-search scenarios	<p>Knowledge store is persistent storage of AI enriched or AI generated content, intended for non-search scenarios like knowledge mining and data science workloads. A knowledge store is defined in a skillset, but created in Azure Storage as objects or tabular rowsets.</p>
Cached enrichments	<p>Enrichment caching (preview) refers to cached enrichments that can be reused during skillset execution. Caching is valuable in skillsets that include OCR and image analysis, which are expensive to process.</p>

Vector and hybrid retrieval

[] [Expand table](#)

Category	Features
Vector indexing	<p>Within a search index, add vector fields to support vector search scenarios. Vector fields can coexist with nonvector fields in the same search document.</p>
Vector queries	<p>Formulate single and multiple vector queries.</p>
Vector search algorithms	<p>Use Hierarchical Navigable Small World (HNSW) or exhaustive K-Nearest Neighbors (KNN) to find similar vectors in a search index.</p>
Vector filters	<p>Apply filters before or after query execution for greater precision during information retrieval.</p>
Hybrid information retrieval	<p>Search for concepts and keywords in a single hybrid query request.</p> <p>Hybrid search consolidates vector and text search, with optional semantic ranking and relevance tuning for best results.</p>

Category	Features
Integrated data chunking and vectorization	<p>Native data chunking through Text Split skill. Native vectorization through vectorizers and embedding skills such as AzureOpenAIEmbeddingModel, Azure AI Vision multimodal, and the AML skill that you can use to connect to endpoints in the Azure AI Foundry model catalog.</p> <p>Integrated vectorization provides an end-to-end indexing pipeline from source files to queries.</p>
Integrated vector compression and quantization	<p>Use built-in scalar and binary quantization to reduce vector index size in memory and on disk. You can also forego storage of vectors you don't need, or assign narrow data types to vector fields for reduced storage requirements.</p>

Full text and other query forms

[] [Expand table](#)

Category	Features
Free-form text search	<p>Full-text search is a primary use case for most search-based apps. Queries can be formulated using a supported syntax.</p> <p>Simple query syntax provides logical operators, phrase search operators, suffix operators, precedence operators.</p> <p>Full Lucene query syntax includes all operations in simple syntax, with extensions for fuzzy search, proximity search, term boosting, and regular expressions.</p>
Relevance	<p>Simple scoring is a key benefit of Azure AI Search. Scoring profiles are used to model relevance as a function of values in the documents themselves. For example, you might want newer products or discounted products to appear higher in the search results. You can also build scoring profiles using tags for personalized scoring based on customer search preferences you've tracked and stored separately.</p> <p>Semantic ranker is premium feature that reranks results based on semantic relevance to the query. Depending on your content and scenario, it can significantly improve search relevance with almost minimal configuration or effort.</p>
Geospatial search	<p>Geospatial functions filter over and match on geographic coordinates. You can match on distance or by inclusion in a polygon shape.</p>

Category	Features
Filters and facets	<p>Faceted navigation is enabled through a single query parameter. Azure AI Search returns a faceted navigation structure you can use as the code behind a categories list, for self-directed filtering (for example, to filter catalog items by price-range or brand).</p> <p>Filters can be used to incorporate faceted navigation into your application's UI, enhance query formulation, and filter based on user- or developer-specified criteria. Create filters using the OData syntax.</p>
User experience	<p>Autocomplete can be enabled for type-ahead queries in a search bar.</p> <p>Search suggestions also works off of partial text inputs in a search bar, but the results are actual documents in your index rather than query terms.</p> <p>Synonyms associates equivalent terms that implicitly expand the scope of a query, without the user having to provide the alternate terms.</p> <p>Hit highlighting applies text formatting to a matching keyword in search results. You can choose which fields return highlighted snippets.</p> <p>Sorting is offered for multiple fields via the index schema and then toggled at query-time with a single search parameter.</p> <p>Paging and throttling your search results is straightforward with the finely tuned control that Azure AI Search offers over your search results.</p>

Security features

 Expand table

Category	Features
Network security	<p>IP rules for inbound firewall support allows you to set up IP ranges over which the search service accepts requests.</p> <p>Create a private endpoint using Azure Private Link to force all requests through a virtual network.</p> <p>Network security perimeter support allows you to join Azure AI Search to a network security perimeter that includes other Azure resources so that you can manage network access holistically.</p>
Data encryption	<p>Microsoft-managed encryption-at-rest is built into the internal storage layer and is irrevocable.</p>

Category	Features
	<p>Customer-managed encryption keys (CMK) that you create and manage in Azure Key Vault can be used for supplemental encryption of indexes and synonym maps. For services created after August 1 2020, CMK encryption extends to data on temporary disks, for full double encryption of indexed content.</p>
Inbound access	<p>Role-based access control assigns roles to users and groups in Microsoft Entra ID for controlled access to search content and operations. You can also use key-based authentication if you don't want to use role assignments.</p> <p>Document-level access control (preview) filters out search results that a user isn't authorized to see. For several data sources, if the data source provides an access control model, you can configure an index to inherit the user permission metadata.</p>
Outbound security (indexers)	<p>Data connections through private endpoints allows an indexer to connect to Azure resources that are protected through Azure Private Link.</p> <p>Data connections through managed identities authenticates connections to Azure resources using a Microsoft Entra security principal, which eliminates storage and passing of hardcoded API keys.</p> <p>Data access using a trusted identity means that connection strings to external data sources can omit user names and passwords. When an indexer connects to the data source, the resource allows the connection if the search service was previously registered as a trusted service (applies to Azure Storage only).</p>

Portal features

[] Expand table

Category	Features
Tools for prototyping and inspection	<p>Add index is an index designer in the Azure portal that you can use to create a basic schema consisting of attributed fields and a few other settings. After saving the index, you can populate it using an SDK or the REST API to provide the data.</p> <p>Import data wizard creates indexes, indexers, skillsets, and data source definitions. If your data exists in Azure, this wizard can save you significant time and effort, especially for proof-of-concept investigation and exploration.</p> <p>Import and vectorize data wizard creates a full indexing pipeline that</p>

Category	Features
	<p>includes data chunking and vectorization. The wizard creates all of the objects and configuration settings.</p> <p>Search explorer is used to test queries and refine scoring profiles.</p> <p>Create demo app is used to generate an HTML page that can be used to test the search experience.</p> <p>Debug Sessions is a visual editor that lets you debug a skillset interactively. It shows you dependencies, output, and transformations.</p>
Monitoring and diagnostics	<p>Enable monitoring features to go beyond the metrics-at-a-glance that are always visible in the Azure portal. Metrics on queries per second, latency, and throttling are captured and reported in portal pages with no extra configuration required.</p>

Programmability

 [Expand table](#)

Category	Features
REST	<p>Service REST API is for data plane operations, including all operations related to indexing, queries, and AI enrichment. You can also use this client library to retrieve system information and statistics.</p> <p>Management REST API is for service creation and provisioning through Azure Resource Manager. You can also use this API to manage keys and capacity.</p>
Azure SDK for .NET	<p>Azure.Search.Documents is for data plane operations, including all operations related to indexing, queries, and AI enrichment. You can also use this client library to retrieve system information and statistics.</p> <p>Microsoft.Azure.Management.Search is for service creation and provisioning through Azure Resource Manager. You can also use this API to manage keys and capacity.</p>
Azure SDK for Java	<p>com.azure.search.documents is for data plane operations, including all operations related to indexing, queries, and AI enrichment. You can also use this client library to retrieve system information and statistics.</p> <p>com.microsoft.azure.management.search is for service creation and provisioning through Azure Resource Manager. You can also use this API to manage keys and capacity.</p>

Category	Features
Azure SDK for Python	<p>azure-search-documents is for data plane operations, including all operations related to indexing, queries, and AI enrichment. You can also use this client library to retrieve system information and statistics.</p> <p>azure-mgmt-search is for service creation and provisioning through Azure Resource Manager. You can also use this API to manage keys and capacity.</p>
Azure SDK for JavaScript/TypeScript	<p>azure/search-documents is for data plane operations, including all operations related to indexing, queries, and AI enrichment. You can also use this client library to retrieve system information and statistics.</p> <p>azure/arm-search is for service creation and provisioning through Azure Resource Manager. You can also use this API to manage keys and capacity.</p>

Try Azure AI Search for free

If you're new to Azure, you can set up an Azure free account to explore Azure AI Search and other services at no charge. Information retrieval over your own content is useful for many scenarios including AI generative search.

This article explains how to get the most value from your Azure free account so that you can complete your evaluation of Azure AI Search quickly and efficiently.

Step one: Sign up for an Azure free account

To try Azure AI Search for free, [sign up for an Azure free account](#). The free account is active for 30 days, and comes with free credits so that you can create billable services at no charge.

Currently, the credit is equivalent to USD 200. The exact amount is subject to change, and you can verify the credit on the Azure sign-up page.

[Try Azure for free](#)

After you sign up, you can immediately use either of these links to access Azure resources and experiences:

- [Sign in to Azure portal](#) to view, manage, and create more resources. You can also use the Azure portal to track your credits and projected costs.
- [Sign in to the Microsoft Foundry portal](#) for a no-code approach to deploying models on Azure OpenAI and using Azure AI Search for information retrieval. **We recommend you start here first.**

Step two: "Day One" tasks

In the Foundry (new) portal, you can create an end-to-end solution that integrates Azure AI Search and Foundry Agent Service for knowledge retrieval.

The portal supports creating *knowledge sources* that map to your indexed content in Azure AI Search and *knowledge bases* that orchestrate retrieval operations, including query decomposition, hybrid search, and result reranking. You can then configure a Foundry agent to use this knowledge base as a Model Context Protocol (MCP) tool, allowing the agent to retrieve relevant information and provide grounded, citation-backed responses.

For more information about the programmatic experience, see [Connect a Foundry IQ knowledge base to Foundry Agent Service](#).

Step three: Have a plan for next steps

The trial period can go by quick. Having a plan of action can help you get the most out of your trial subscription. For Azure AI Search, most newer customers and developers are exploring RAG patterns.

For a next step evaluation of [RAG scenarios](#), you should have three or five Azure resources for:

- Storing data
- Deploying embedding and chat models ([Azure OpenAI](#))
- Applying Foundry Tools for creating AI-generated content during indexing (optional)
- Adding information retrieval ([Azure AI Search](#))
- Adding a frontend app (optional)

Many of our quickstarts and tutorials use Azure Storage, so we recommend creating an Azure Storage account for getting started.

Generative search requires embedding and chat models. The Azure cloud provides Azure OpenAI, but you can also use Azure Vision in Foundry Tools for multimodal embeddings (but not chat). Another model provider is Foundry and deploying chat and embedding models into the model catalog. However, for initial exploration, we recommend Azure OpenAI for its familiarity and mainstream offerings.

Application frontends are useful if you're prototyping a solution for a wider audience. You can use Azure Web apps or build an ASP.NET MVC application for this task. Otherwise, if you're working locally, you can view output in Jupyter notebooks in Visual Studio Code or another IDE. Or view results in console apps or other apps that run on localhost.

Check regions

Azure AI Search offers integrated operations with applied AI in the Azure cloud. For data residency and efficient operations, integration typically depends on services running within the same region.

Note

The same-region requirement doesn't apply to Azure OpenAI and Foundry for interoperability with Azure AI Search. However, using the same region can improve performance and reduce latency.

For [AI enrichment](#), [integrated vectorization](#), and [multimodal search](#) powered by Foundry Tools, you must create Azure AI Search and Foundry in the same region. This is required for [billing](#)

purposes.

Before you create these resources:

- Check [Azure AI Search regions](#). The **AI enrichment** column indicates whether Azure AI Search and Foundry are in the same region.
- Check [Azure Vision regions](#). The **Multimodal embeddings** column indicates regional support for the multimodal APIs that enable text and image vectorization. Azure Vision provides these APIs, which you access through a Foundry resource. Ensure that your search service and Foundry resource are in the same region as the multimodal APIs.

Create services

1. [Create a search service](#) if you don't have one already. Choose the Basic tier and, if applicable, the same region as Foundry. Most Azure AI Search regions provide higher capacity storage limits. There are just a few that have older and lower limits. For the Basic tier, as you install, confirm that you have a 15-GB partition.
[Create a search service](#)
2. [Create an Azure Storage account](#). Choose a general purpose account and use default settings.
3. [Create an Azure OpenAI resource](#).
4. [Create a Foundry resource](#) to use applied AI in your indexing workloads and Azure Vision multimodal APIs as an embedding model provider. You can create and transform content during indexing if applied AI can be attached. For multimodal APIs, make sure you choose a region that provides those APIs. Look for this tile in Azure Marketplace:

Try the quickstarts

Try the Azure portal quickstarts for Azure AI Search or quickstarts that use Visual Studio Code with REST or Python extensions. It's the fastest approach creating searchable content, and you don't need coding skills to complete the tasks.

- [Quickstart: Vector search in the Azure portal](#)
- [Quickstart: Image search in the Azure portal](#)
- [Quickstart: Keyword in the Azure portal](#)
- [Quickstart: Generative search \(RAG\) using a Python client](#)
- [Quickstart: Vector search using a REST client](#)

Foundry supports connecting to content in Azure AI Search.

- [Quickstart: Chat using your own data with Azure OpenAI](#)
- [Tutorial: Build a custom chat app with the prompt flow SDK](#)

Developers should review [azure-search-vector-samples](#) repository or the solution accelerators. You can deploy and run any of these samples using the Azure trial subscription.

Many samples and [accelerators](#) come with bicep scripts that deploy all Azure resources and dependencies, so you can skip installation steps and explore an operational solution as soon as the development completes.

Step four: Track your credits

During the trial period, you want to stay under the USD 200 credit allocation. Most services are Standard, so you won't be charged while they're not in use, but an Azure AI Search service on the Basic tier is provisioned on dedicated clusters and it can only be used by you. It's billable during its lifetime. If you provision a basic search service, expect Azure AI Search to consume about one third of your available credits during the trial period.

During the trial period, the Azure portal provides a notification on the top right that tells you how many credits are used up and what remains.

You can also monitor billing by searching for *subscriptions* in the Azure portal to view subscription information at any time. The Overview page gives you spending rates, forecasts, and cost management. For more information, see [Check usage of free services included with your Azure free account](#).

Consider the free tier

You can create a search service that doesn't consume credits. Here are some points about the free tier to keep in mind:

- You can have one free search service per Azure subscription.
- You can complete all of the quickstarts and most tutorials, except for those featuring semantic ranking and managed identities for Microsoft Entra ID authentication and authorization.
- Storage is capped at 50 MB.
- You can have up to three indexes, indexers, data sources, and skillset at one time.

Review the [service limits](#) for other constraints that apply to the free tier.

 Note

Free services that remain inactive for an extended period of time might be deleted to free up capacity if the region is under capacity constraints.

Next steps

Sign up for an Azure free account:

[Try Azure for free](#)

When you're ready, add Azure AI Search as your first resource:

[Create a search service](#)

Last updated on 11/18/2025

Azure AI Search Frequently Asked Questions

Find answers to commonly asked questions about Azure AI Search.

General

What is Azure AI Search?

Azure AI Search provides a dedicated search engine and persistent storage of your searchable content for agentic, full-text, and vector search scenarios. It also includes optional integrated AI to extract text and structure from raw content and to chunk and vectorize content for vector search.

How do I work with Azure AI Search?

The primary workflow is create, load, and query an index. Although you can use the Azure portal for most tasks, Azure AI Search is intended to be used programmatically, handling requests from client code. Programmatic support is provided through REST APIs and client libraries in .NET, Python, Java, and JavaScript SDKs for Azure.

Are "Azure Search," "Azure Cognitive Search," and "Azure AI Search" the same product?

Yes. They're all the same product, with rebranding occurring in October 2019 and again in October 2023. You might occasionally see evidence of the former names at the programmatic level.

What languages are supported?

For vectors, the embedding models you use determines the linguistic experience.

For nonvector strings and numbers, the default analyzer used for tokenization is standard Lucene, which is language agnostic. Otherwise, language support is expressed through [language analyzers](#) that apply linguistic rules to inbound (indexing) and outbound (queries) content. Some features, such as [speller](#) and [query rewrite](#), are limited to a subset of languages.

How do I integrate search into my solution?

Client code should call the Azure SDK client libraries or REST APIs to connect to a search index, formulate queries, and handle responses. You can also write code that builds and refreshes an index, or that runs indexers programmatically or via script.

Can I pause the service and stop billing?

You can't pause a search service. In Azure AI Search, computing resources are allocated when the service is created. It's not possible to release and reclaim those resources on demand.

Can I upgrade or downgrade the service?

Services created before April 2024 in select regions can be [upgraded to higher-capacity clusters](#). Downgrading your service isn't supported.

To get more or less capacity, you can also [switch to a different pricing tier](#). Scaling is blocked if your current service configuration exceeds the [limits of the target tier](#) or if your region has [capacity constraints on the target tier](#). Currently, you can only switch between Basic and Standard (S1, S2, and S3) tiers.

Can I rename or move the service?

Service name and region are fixed for the lifetime of the service.

If I migrate my search service to another subscription or resource group, should I expect any downtime?

As long as you follow the [checklist before moving resources](#) and make sure each step is completed, there shouldn't be any downtime.

Why do I see different storage limits for same-tier search services?

Storage limits can vary by service creation date. In most supported regions, [newer services have higher storage limits than older services](#), even if they're on the same tier. However, you might be able to [upgrade your old service](#) to access the new limits.

Indexing

What does "indexing" mean in Azure AI Search?

It refers to the ingestion, parsing, and storing of textual content and tokens that populate a search index. Indexing creates inverted indexes and other physical data structures that support information retrieval.

It creates vector indexes if the schema includes vector fields.

Can I move, backup, and restore indexes?

There's no native support for porting indexes. Search indexes are considered downstream data structures, accepting content from other data sources that collect operational data. Therefore, there's no built-in support for backing up and restoring indexes. The expectation is that you would rebuild an index from source data if it was deleted or needed to be moved.

However, if you want to move an index between search services, you can try the backup and restore code sample for [.NET ↗](#) or [Python ↗](#).

Can I restore my index or service after it's deleted?

No. If you delete an Azure AI Search index or service, it can't be recovered. When you delete a search service, all indexes in the service are permanently deleted.

Can I index from SQL Database replicas?

If you're using the search indexer for Azure SQL Database, there are no restrictions on the use of primary or secondary replicas as a data source when building an index from scratch. However, refreshing an index with incremental updates (based on changed records) requires the primary replica. This requirement comes from SQL Database, which guarantees change tracking on primary replicas only. If you try using secondary replicas for an index refresh workload, there's no guarantee you get all of the data.

Vectors

What is vector search?

Vector search is a technique that finds the most similar documents by comparing their vector representations. Because the goal of a vector representation is to capture the essential characteristics of an item in a numerical format, vector queries can identify similar content, even if there are no explicit matches based on keywords or tags.

When a user performs a search, the query is summarized into a vector representation, and the vector search engine identifies the most similar documents. To improve efficiency on large databases, vector search often provides the Approximate Nearest Neighbors (ANN) for a query vector. For more information, see [Vector search in Azure AI Search](#).

Does Azure AI Search support vector search?

Azure AI Search supports vector indexing and retrieval. It can chunk and vectorize query strings and content if you use [integrated vectorization](#), which takes a dependency on indexers and skillsets.

How does vector search work in Azure AI Search?

With standalone vector search, you first use an embedding model to transform content into a vector representation within an embedding space. You can then provide these vectors in a document payload to the search index for indexing. To serve search requests, you use the same embedding model to transform the search query into a vector representation, and vector search finds the most similar vectors and return the corresponding documents.

In Azure AI Search, you can index vector data as fields in documents alongside textual and other types of content. There are [multiple data types](#) for vector fields.

Vector queries can be issued standalone or in combination with other query types, including term queries and filters in the same search request.

Can Azure AI Search vectorize my content or queries?

[Built-in integrated vectorization](#) is now generally available.

Does my search service support vector search?

Most existing services support vector search. If you're using a package or API that supports vector search and index creation fails, the underlying search service doesn't support vector search, and a new service must be created. This can occur for a small subset of services created prior to January 1, 2019.

Can I add vector search to an existing index?

If your search service supports vector search, both existing and new indexes can accommodate vector fields.

Why do I see different vector index size limits between my new search services and existing search services?

Azure AI Search rolled out improved vector index size limits worldwide for new search services, but [some regions experience capacity constraints](#), and some regions don't have the required infrastructure. New search services created after May 2024 in supported regions should see increased vector index size limits. Alternatively, if you have an existing service in a supported region, you might be able to [upgrade your service](#) to access the new limits.

Why does my vector index show zero storage?

Only vector indexes that use the Hierarchical Navigable Small World (HNSW) algorithm report on vector index size in the Azure portal. If your index uses exhaustive KNN, vector index size is reported as zero, even though the index contains vectors.

How do I enable vector search on a search index?

To enable vector search in an index:

- Add one or more vector fields to a field collection.
- Add a "vectorSearch" section to the index schema specifying the configuration used by vector search fields, including the parameters of the ANN algorithm used, like HNSW.
- Use the latest stable version, [2025-09-01](#), or an Azure SDK to create or update the index, load documents, and issue queries. For more information, see [Create a vector index](#).

Queries

Where does query execution occur?

Queries execute over a single search index that's hosted on your search service. You can't join multiple indexes to search content in two or more indexes, but you can [query same-name indexes in multiple search services](#).

Why are there zero matches on terms I know to be valid?

The most common case isn't knowing that each query type supports different search behaviors and levels of linguistic analyses. Full-text search, which is the predominant workload, includes a language analysis phase that breaks down terms to root forms. This aspect of query parsing casts a broader net over possible matches, because the tokenized term matches a greater number of variants.

However, wildcard, fuzzy, and regex queries aren't analyzed like regular term or phrase queries and can lead to poor recall if the query doesn't match the analyzed form of the word in the search index. For more information about query parsing and analysis, see [Full-text search in Azure AI Search](#).

Why are my wildcard searches slow?

Most wildcard search queries, like prefix, fuzzy, and regex, are rewritten internally with matching terms in the search index. This extra processing adds to latency. Additionally, broad search queries like `a*` are likely to be rewritten with many terms, which can be slow. For performant wildcard searches, consider defining a [custom analyzer](#).

Can I search across multiple indexes?

No. A query is always scoped to a single index.

Why is the search score a constant 1.0 for every match?

Search scores are generated for full-text search queries based on the [statistical properties of matching terms](#) and are ordered from high to low in the result set. Query types that aren't full-text search (wildcard, prefix, regex) aren't ranked by a relevance score. A constant score allows matches found through query expansion to be included in the results without affecting the ranking.

For example, suppose an input of "tour*" in a wildcard search produces matches on "tours", "tourettes", and "tourmaline". Given the nature of these results, there's no way to reasonably infer which terms are more valuable than others. For this reason, term frequencies are ignored when scoring results in queries of types wildcard, prefix, and regex. Search results based on a partial input are given a constant score to avoid bias towards potentially unexpected matches.

Security

Where does Azure AI Search store customer data?

It stores your data in the [geography \(Geo\)](#) where your service is deployed. Microsoft might replicate your data within the same geo for high availability and durability. For more information, see [Data residency in Azure](#).

Does Azure AI Search send customer data to other services for processing?

Yes. Skills and vectorizers make [outbound calls from Azure AI Search](#) to other Azure resources or external models that you specify for embedding or chat. Calls to those APIs typically contain raw content to be processed or queries that are vectorized by an embedding model. For Azure-to-Azure connections, the service sends requests over the internal network. If you add a custom skill or vectorizer, the indexer sends content to the URI provided in the custom skill over the public network unless you configure a [shared private link](#).

Does Azure AI Search process customer data in other regions?

Processing (vectorization or applied AI transformations) is performed in the Geo that hosts the Foundry Tools subservice used by skills, the Azure apps or functions hosting custom skills, or the Azure OpenAI or Microsoft Foundry region that hosts your deployed models. These resources are specified by you, so you can choose whether to deploy them in the same Geo as your search service or not.

If you send data to external (non-Azure) models or services, the processing location is determined by the external service.

Can I control access to search results based on user identity?

You can if you implement a solution that associates documents with a user identity. Typically, users who are authorized to run your application are also authorized to see all search results. Azure AI Search doesn't have built-in support for row-level or document-level permissions, but you can implement [security filters](#) as a workaround. For steps and script, see [Get started: Chat using your own data \(Python sample\)](#).

Can I control access to operations based on user identity?

Yes. You can use [role-based authorization](#) for data plane operations over content.

Can I use the Azure portal to view and manage search content if my search service is behind an IP firewall or private endpoint?

You can use the Azure portal on a network-protected search service if you create a network exception that allows client and portal access. For more information, see [Connect through an IP firewall](#) or [Connect through a private endpoint](#).

[What is Azure AI Search?](#)

Data import in Azure AI Search

09/23/2025

In Azure AI Search, queries execute over your content that's loaded into a [search index](#). This article describes the two basic workflows for populating an index: *push* your data into the index programmatically, or *pull* in the data using a [search indexer](#).

Both approaches load documents from an external data source. Although you can create an empty index, it's not queryable until you add the content.

(!) Note

If [AI enrichment](#) or [integrated vectorization](#) are solution requirements, you must use the pull model (indexers) to load an index. Skillsets are attached to indexers and don't run independently.

Pushing data to an index

Push model is an approach that uses APIs to upload documents into an existing search index. You can upload documents individually or in batches up to 1000 per batch, or 16 MB per batch, whichever limit comes first.

Key benefits include:

- No restrictions on data source type. The payload must be composed of JSON documents that map to your index schema, but the data can be sourced from anywhere.
- No restrictions on frequency of execution. You can push changes to an index as often as you like. For applications having low latency requirements (for example, when the index needs to be in sync with product inventory fluctuations), the push model is your only option.
- Connectivity and the secure retrieval of documents are fully under your control. In contrast, indexer connections are authenticated using the security features provided in Azure AI Search.

How to push data to an Azure AI Search index

Use the following APIs to load single or multiple documents into an index:

- [Index Documents \(REST API\)](#)

- [IndexDocumentsAsync](#) (Azure SDK for .NET) or [SearchIndexingBufferedSender](#)
- [IndexDocumentsBatch](#) (Azure SDK for Python) or [SearchIndexingBufferedSender](#)
- [IndexDocumentsBatch](#) (Azure SDK for Java) or [SearchIndexingBufferedSender](#)
- [IndexDocumentsBatch](#) (Azure SDK for JavaScript) or [SearchIndexingBufferedSender](#)

There's no support for pushing data via the Azure portal.

For an introduction to the push APIs, see:

- [Quickstart: Full-text search](#)
- [C# Tutorial: Optimize indexing with the push API](#)
- [REST Quickstart: Create an Azure AI Search index using PowerShell](#)

Indexing actions: upload, merge, mergeOrUpload, delete

You can control the type of indexing action on a per-document basis, specifying whether the document should be uploaded in full, merged with existing document content, or deleted.

Whether you use the REST API or an Azure SDK, the following document operations are supported for data import:

- **Upload**, similar to an "upsert" where the document is inserted if it's new, and updated or replaced if it exists. If the document is missing values that the index requires, the document field's value is set to null.
- **merge** updates a document that already exists, and fails a document that can't be found. Merge replaces existing values. For this reason, be sure to check for collection fields that contain multiple values, such as fields of type `Collection(Edm.String)`. For example, if a `tags` field starts with a value of `["budget"]` and you execute a merge with `["economy", "pool"]`, the final value of the `tags` field is `["economy", "pool"]`. It won't be `["budget", "economy", "pool"]`.
- **mergeOrUpload** behaves like **merge** if the document exists, and **upload** if the document is new.
- **delete** removes the entire document from the index. If you want to remove an individual field, use **merge** instead, setting the field in question to null.

Pulling data into an index

The pull model uses *indexers* connecting to a supported data source, automatically uploading the data into your index. Indexers from Microsoft are available for these platforms:

- Azure Blob storage
- Azure Table storage
- Azure Data Lake Storage Gen2
- Azure Files (preview)
- Azure Cosmos DB
- Azure SQL Database, SQL Managed Instance, and SQL Server on Azure VMs
- Microsoft OneLake files and shortcuts
- SharePoint Online (preview)

You can use third-party connectors, developed and maintained by Microsoft partners. For more information and links, see [Data source gallery](#).

Indexers connect an index to a data source (usually a table, view, or equivalent structure), and map source fields to equivalent fields in the index. During execution, the rowset is automatically transformed to JSON and loaded into the specified index. All indexers support schedules so that you can specify how frequently the data is to be refreshed. Most indexers provide change tracking if the data source supports it. By tracking changes and deletes to existing documents in addition to recognizing new documents, indexers remove the need to actively manage the data in your index.

How to pull data into an Azure AI Search index

Use the following tools and APIs for indexer-based indexing:

- Azure portal: [Import wizards](#)
- REST APIs: [Create Indexer \(REST\)](#), [Create Data Source \(REST\)](#), [Create Index \(REST\)](#)
- Azure SDK for .NET: [SearchIndexer](#), [SearchIndexerDataSourceConnection](#), [SearchIndex](#),
- Azure SDK for Python: [SearchIndexer](#), [SearchIndexerDataSourceConnection](#), [SearchIndex](#),
- Azure SDK for Java: [SearchIndexer](#), [SearchIndexerDataSourceConnection](#), [SearchIndex](#),
- Azure SDK for JavaScript: [SearchIndexer](#), [SearchIndexerDataSourceConnection](#),
[SearchIndex](#),

Indexer functionality is exposed in the Azure portal, the [REST API](#), and the [.NET SDK](#).

An advantage to using the Azure portal is that Azure AI Search can usually generate a default index schema by reading the metadata of the source dataset.

Verify data import with Search explorer

A quick way to perform a preliminary check on the document upload is to use [Search explorer](#) in the Azure portal.

The explorer lets you query an index without having to write any code. The search experience is based on default settings, such as the [simple syntax](#) and default [searchMode query parameter](#). Results are returned in JSON so that you can inspect the entire document.

Here's an example query that you can run in Search Explorer in JSON view. The "HotelId" is the document key of the hotels-sample-index. The filter provides the document ID of a specific document:

```
JSON

{
  "search": "*",
  "filter": "HotelId eq '50'"
}
```

If you're using REST, this [Look up query](#) achieves the same purpose.

Search indexes in Azure AI Search

In Azure AI Search, a *search index* is your searchable content, available to the search engine for indexing, agentic search, full-text search, vector search, hybrid search, and filtered queries. An index is defined by a schema and saved to the search service, with data ingestion following as a second step. Indexed content exists within your search service, apart from your primary external data stores, which is necessary for the millisecond response times expected in modern search applications. Except for indexer-driven indexing scenarios, the search service never connects to or queries your external source data.

This article covers the key concepts for creating and managing a search index, including:

- Content (documents and schema)
- Physical data structure
- Basic operations

💡 Tip

Want to get started right away? See [Create a search index](#).

Schema of a search index

In Azure AI Search, indexes contain *search documents*. Conceptually, a document is a single unit of searchable data in your index. For example, a retailer might have a document for each product, a university might have a document for each class, a travel site might have a document for each hotel and destination, and so forth. Mapping these concepts to more familiar database equivalents: a *search index* equates to a *table*, and *documents* are roughly equivalent to *rows* in a table.

The structure of a document is determined by the *index schema*, as illustrated in the following example. The "fields" collection is typically the largest part of an index, where each field is named, assigned a [data type](#), and attributed with allowable behaviors that determine how it's used.

JSON

```
{  
  "name": "name_of_index, unique across the service",  
  "description" : "Health plan coverage for standard and premium plans for Northwind  
  and Contoso employees."  
  "fields": [  
    {  
      "name": "name_of_field",  
      "type": "string",  
      "filterable": true,  
      "selectable": true,  
      " sortable": true,  
      "analyzer": "standard",  
      "normalizer": "lowercase"  
    }  
  ]  
}
```

```

    "type": "Edm.String | Collection(Edm.String) | Collection(Edm.Single) | Edm.Int32 | Edm.Int64 | Edm.Double | Edm.Boolean | Edm.DateTimeOffset | Edm.GeographyPoint",
        "searchable": true (default where applicable) | false (only Edm.String and Collection(Edm.String) fields can be searchable),
        "filterable": true (default) | false,
        "sortable": true (default where applicable) | false (Collection(Edm.String) fields cannot be sortable),
        "facetable": true (default where applicable) | false (Edm.GeographyPoint fields cannot be facetable),
        "key": true | false (default, only Edm.String fields can be keys),
        "retrievable": true (default) | false,
        "analyzer": "name_of_analyzer_for_search_and_indexing", (only if 'searchAnalyzer' and 'indexAnalyzer' are not set)
            "searchAnalyzer": "name_of_search_analyzer", (only if 'indexAnalyzer' is set and 'analyzer' is not set)
            "indexAnalyzer": "name_of_indexing_analyzer", (only if 'searchAnalyzer' is set and 'analyzer' is not set)
            "normalizer": "name_of_normalizer", (applies to fields that are filterable)
            "synonymMaps": "name_of_synonym_map", (optional, only one synonym map per field is currently supported)
        "dimensions": "number of dimensions used by an embedding models", (applies to vector fields only, of type Collection(Edm.Single))
        "vectorSearchProfile": "name_of_vector_profile" (indexes can have many configurations, a field can use just one)
    }
],
"suggesters": [ ],
"scoringProfiles": [ ],
"analyzers":(optional)[ ... ],
"charFilters":(optional)[ ... ],
"tokenizers":(optional)[ ... ],
"tokenFilters":(optional)[ ... ],
"defaultScoringProfile": (optional) "...",
"corsOptions": (optional) { },
"encryptionKey":(optional){ },
"semantic":(optional){ },
"vectorSearch":(optional){ }
}

```

Other elements are collapsed for brevity, but the following links provide details:

- [suggesters](#) support type-ahead queries like autocomplete.
- [scoringProfiles](#) are used for relevance tuning.
- [analyzers](#) are used to process strings into tokens according to linguistic rules or other characteristics supported by the analyzer.
- [corsOptions](#), or Cross-origin remote scripting (CORS), is used for apps that issues requests from different domains.
- [encryptionKey](#) configures double-encryption of sensitive content in the index.
- [semantic](#) configures semantic reranking in full text and hybrid search.
- [vectorSearch](#) configures vector fields and queries.

Field definitions

A search document is defined by the "fields" collection in the body of [Create Index request](#). You need fields for document identification (keys), storing searchable text, and fields for supporting filters, facets, and sorting. You might also need fields for data that a user never sees. For example, you might want fields for profit margins or marketing promotions that you can use in a scoring profile to boost a search score.

If incoming data is hierarchical in nature, you can represent it within an index as a [complex type](#), used for nested structures. The sample data set, [Hotels](#), illustrates complex types using an Address (contains multiple subfields) that has a one-to-one relationship with each hotel, and a Rooms complex collection, where multiple rooms are associated with each hotel.

Field attributes

Field attributes determine how a field is used, such as whether it's used in full text search, faceted navigation, sort operations, and so forth.

String fields are often marked as "searchable" and " retrievable". Fields used to narrow search results include "sortable", "filterable", and "facetable".

[\[+\] Expand table](#)

Attribute	Description
"searchable"	Full-text or vector searchable. Text fields are subject to lexical analysis such as word-breaking during indexing. If you set a searchable field to a value like "sunny day", internally it's split into the individual tokens "sunny" and "day". For details, see How full text search works .
"filterable"	Referenced in \$filter queries. Filterable fields of type <code>Edm.String</code> or <code>Collection(Edm.String)</code> don't undergo word-breaking, so comparisons are for exact matches only. For example, if you set such a field f to "sunny day", <code>\$filter=f eq 'sunny'</code> finds no matches, but <code>\$filter=f eq 'sunny day'</code> will.
"sortable"	By default the system sorts results by score, but you can configure sort based on fields in the documents. Fields of type <code>Collection(Edm.String)</code> can't be "sortable".
"facetable"	Typically used in a presentation of search results that includes a hit count by category (for example, hotels in a specific city). This option can't be used with fields of type <code>Edm.GeographyPoint</code> . Fields of type <code>Edm.String</code> that are filterable, "sortable", or "facetable" can be at most 32 kilobytes in length. For details, see Create Index (REST API) .
"key"	Unique identifier for documents within the index. Exactly one field must be chosen as the key field and it must be of type <code>Edm.String</code> .

Attribute	Description
"retrievable"	Determines whether the field can be returned in a search result. This is useful when you want to use a field (such as <i>profit margin</i>) as a filter, sorting, or scoring mechanism, but don't want the field to be visible to the end user. This attribute must be <code>true</code> for key fields.

Although you can add new fields at any time, existing field definitions are locked in for the lifetime of the index. For this reason, developers typically use the Azure portal for creating simple indexes, testing ideas, or using the Azure portal pages to look up a setting. Frequent iteration over an index design is more efficient if you follow a code-based approach so that you can rebuild the index easily.

(!) Note

The APIs you use to build an index have varying default behaviors. For the [REST APIs](#), most attributes are enabled by default (for example, "searchable" and "retrievable" are true for string fields) and you often only need to set them if you want to turn them off. For the .NET SDK, the opposite is true. On any property you do not explicitly set, the default is to disable the corresponding search behavior unless you specifically enable it.

Physical structure and size

In Azure AI Search, the physical structure of an index is largely an internal implementation. You can access its schema, load and query its content, monitor its size, and manage its capacity. However, Microsoft manages the infrastructure and physical data structures stored with your search service.

You can monitor index size on the [Search management > Indexes](#) page in the Azure portal. Alternatively, you can issue a [GET INDEX request](#) against your search service or a [Service Statistics request](#) to check the value of storage size.

The size of an index is determined by the:

- Quantity and composition of your documents.
- Attributes on individual fields: "retrievable" doesn't bloat your index, but "filterable", "sortable", "facetable" consume more storage for storing non-tokenized text.
- Index configuration. Specifically, whether you include suggesters or specialized [analyzers](#). If you use the edgeNgram tokenizer to store verbatim sequences of characters (`a`, `ab`, `abc`, `abcd`), the index is larger than if you use the standard analyzer.

Document composition and quantity are determined by what you choose to import.

Remember that a search index should only contain content that's useful for your search application. If source data includes binary fields, omit those fields unless you're using AI enrichment to crack and analyze the content to create text-searchable information.

Field attributes determine behaviors. To support those behaviors, the indexing process creates the necessary data structures. For example, for a field of type `Edm.String`, "searchable" invokes [full-text search](#), which scans inverted indexes for the tokenized term. In contrast, a "filterable" or "sortable" attribute supports iteration over unmodified strings.

Suggesters are constructs that support type-ahead or autocomplete queries. When you include a suggester, the indexing process creates the data structures necessary for verbatim character matches. Suggesters are implemented at the field level, so choose only those fields that are reasonable for type-ahead.

Basic operations and interaction

Now that you have a better idea of what an index is, this section introduces index runtime operations, including connecting to and securing a single index.

Note

There's no portal or API support for moving or copying an index. Typically, you either point your application deployment to a different search service (using the same index name) or revise the name to create a copy on your current search service and then build it.

Index isolation

In Azure AI Search, you work with one index at a time. All index-related operations target a single index. There's no concept of related indexes or the joining of independent indexes for either indexing or querying.

Continuously available

An index is immediately available for queries as soon as the first document is indexed, but it's not fully operational until all documents are indexed. Internally, an index is [distributed across partitions and executes on replicas](#). The physical index is managed internally. You manage the logical index.

An index is continuously available and can't be paused or taken offline. Because it's designed for continuous operation, updates to its content and additions to the index itself happen in real time. If a request coincides with a document update, queries might temporarily return incomplete results.

Query continuity exists for document operations, such as refreshing or deleting, and for modifications that don't affect the existing structure or integrity of an index, such as adding new fields. Structural updates, such as changing existing fields, are typically managed using a drop-and-rebuild workflow in a development environment or by creating a new version of the index on the production service.

To avoid an [index rebuild](#), some customers who are making small changes "version" a field by creating a new one that coexists with a previous version. Over time, this leads to orphaned content by way of obsolete fields and obsolete custom analyzer definitions, especially in a production index that's expensive to replicate. You can address these issues during planned updates to the index as part of index lifecycle management.

Endpoint connection and security

All indexing and query requests target an index. Endpoints are usually one of the following:

[] [Expand table](#)

Endpoint	Connection and access control
<code><your-service>.search.windows.net/indexes</code>	Targets the indexes collection. Used when creating, listing, or deleting an index. Admin rights are required for these operations and available through admin API keys or a Search Contributor role .
<code><your-service>.search.windows.net/indexes/<your-index>/docs</code>	Targets the documents collection of a single index. Used when querying an index or data refresh. For queries, read rights are sufficient and available through query API keys or a data reader role. For data refresh, admin rights are required.

How to connect to Azure AI Search

1. [Start with the Azure portal](#). Azure subscribers, or the person who created the search service, can manage the search service in the Azure portal. An Azure subscription requires Contributor or above permissions to create or delete services. This permission level is sufficient for fully managing a search service in the Azure portal.
2. Try other clients for programmatic access. We recommend the quickstarts for first steps:

- [Quickstart: REST](#)
- [Quickstart: Full-text search](#)
- [Quickstart: RAG \(using Visual Studio Code and a Jupyter notebook\)](#)

Next steps

You can get hands-on experience creating an index using almost any sample or walkthrough for Azure AI Search. For starters, you could choose any of the quickstarts from the table of contents.

But you'll also want to become familiar with methodologies for loading an index with data. Index definition and data import strategies are defined in tandem. The following articles provide more information about creating and loading an index.

- [Create a search index](#)
- [Update an index](#)
- [Create a vector store](#)
- [Create an index alias](#)
- [Data import overview](#)
- [Load an index](#)

Last updated on 12/05/2025

Vector indexes in Azure AI Search

08/28/2025

Vectors are high-dimensional embeddings that represent text, images, and other content mathematically. Azure AI Search stores vectors at the field level, allowing vector and nonvector content to coexist within the same [search index](#).

A search index becomes a *vector index* when you define vector fields and a vector configuration. To populate vector fields, you can push [precomputed embeddings](#) into them or use [integrated vectorization](#), a built-in Azure AI Search capability that generates embeddings during indexing.

At query time, the vector fields in your index enable similarity search, where the system retrieves documents whose vectors are most similar to the vector query. You can use [vector search](#) for similarity matching alone or [hybrid search](#) for a combination of similarity and keyword matching.

This article covers the key concepts for creating and managing a vector index, including:

- Vector retrieval patterns
- Content (vector fields and configuration)
- Physical data structure
- Basic operations

💡 Tip

Want to get started right away? See [Create a vector index](#).

Vector retrieval patterns

Azure AI Search supports two patterns for vector retrieval:

- **Classic search.** This pattern uses a search bar, query input, and rendered results. During query execution, the search engine or your application code vectorizes the user input. The search engine then performs vector search over the vector fields in your index and formulates a response that you render in a client app.

In Azure AI Search, results are returned as a flattened row set, and you can choose which fields to include in the response. Although the search engine matches on vectors, your index should have nonvector, human-readable content to populate the search results.

Classic search supports both [vector queries](#) and [hybrid queries](#).

- **Generative search.** Language models use data from Azure AI Search to respond to user queries. An orchestration layer typically coordinates prompts and maintains context, feeding search results into chat models like GPT. This pattern is based on the [retrieval-augmented generation \(RAG\)](#) architecture, where the search index provides grounding data.

Schema of a vector index

The schema of a vector index requires the following:

- Name
- Key field (string)
- One or more vector fields
- Vector configuration

Nonvector fields aren't required, but we recommend including them for hybrid queries or for returning verbatim content that doesn't go through a language model. For more information, see [Create a vector index](#).

Your index schema should reflect your [vector retrieval pattern](#). This section mostly covers field composition for classic search, but it also provides schema guidance for generative search.

Basic vector field configuration

Vector fields have unique data types and properties. Here's what a vector field looks like in a `fields` collection:

```
JSON

{
  "name": "content_vector",
  "type": "Collection(Edm.Single)",
  "searchable": true,
  "retrievable": true,
  "dimensions": 1536,
  "vectorSearchProfile": "my-vector-profile"
}
```

Only [certain data types](#) are supported for vector fields. The most common type is `Collection(Edm.Single)`, but using narrow types can save on storage.

Vector fields must be searchable and retrievable, but they can't be filterable, facetable, or sortable. They also can't have analyzers, normalizers, or synonym map assignments.

The `dimensions` property must be set to the number of embeddings generated by the embedding model. For example, text-embedding-ada-002 generates 1,536 embeddings for each chunk of text.

Vector fields are indexed using algorithms specified in a *vector search profile*, which is defined elsewhere in the index and not shown in this example. For more information, see [Add a vector search configuration](#).

Fields collection for basic vector workloads

Vector indexes require more than just vector fields. For example, all indexes must have a key field, which is `id` in the following example:

```
JSON

{
  "name": "example-basic-vector-idx",
  "fields": [
    { "name": "id", "type": "Edm.String", "searchable": false, "filterable": true,
      "retrievable": true, "key": true },
    { "name": "content_vector", "type": "Collection(Edm.Single)", "searchable": true,
      "retrievable": true, "dimensions": 1536, "vectorSearchProfile": null },
    { "name": "content", "type": "Edm.String", "searchable": true, "retrievable": true,
      "analyzer": null },
    { "name": "metadata", "type": "Edm.String", "searchable": true, "filterable": true,
      "retrievable": true, "sortable": true, "facetable": true }
  ]
}
```

Other fields, such as the `content` field, provide the human-readable equivalent of the `content_vector` field. If you're using language models exclusively for response formulation, you can omit nonvector content fields, but solutions that push search results directly to client apps should have nonvector content.

Metadata fields are useful for filters, especially if they include origin information about the source document. Although you can't filter directly on a vector field, you can set prefilter, postfilter, or strict postfilter (preview) modes to filter before or after vector query execution.

Schema generated by the import wizard

We recommend the [Import data \(new\) wizard](#) for evaluation and proof-of-concept testing. The wizard generates the example schema in this section.

The wizard chunks your content into smaller search documents, which benefits RAG apps that use language models to formulate responses. Chunking helps you stay within the input limits of language models and the token limits of semantic ranker. It also improves precision in

similarity search by matching queries against chunks pulled from multiple parent documents. For more information, see [Chunk large documents for vector search solutions](#).

For each search document in the following example, there's one chunk ID, parent ID, chunk, title, and vector field. The wizard:

- Populates the `chunk_id` and `parent_id` fields with base64-encoded blob metadata (path).
- Extracts the `chunk` and `title` fields from the blob content and blob name, respectively.
- Creates the `vector` field by calling an Azure OpenAI embedding model that you provide to vectorize the `chunk` field. Only the vector field is fully generated during this process.

JSON

```
"name": "example-index-from-import-wizard",
"fields": [
    { "name": "chunk_id", "type": "Edm.String", "key": true, "searchable": true,
    "filterable": true, "retrievable": true, "sortable": true, "facetable": true,
    "analyzer": "keyword"},

    { "name": "parent_id", "type": "Edm.String", "searchable": true, "filterable": true,
    "retrievable": true, "sortable": true},

    { "name": "chunk", "type": "Edm.String", "searchable": true, "filterable": false,
    "retrievable": true, "sortable": false},

    { "name": "title", "type": "Edm.String", "searchable": true, "filterable": true,
    "retrievable": true, "sortable": false},

    { "name": "vector", "type": "Collection(Edm.Single)", "searchable": true,
    "retrievable": true, "dimensions": 1536, "vectorSearchProfile": "vector-
    1707768500058-profile"}]
```

Schema for generative search

If you're designing vector storage for RAG and chat-style apps, you can create two indexes:

- One for static content that you indexed and vectorized.
- One for conversations that can be used in prompt flows.

For illustrative purposes, this section uses the [chat-with-your-data-solution-accelerator](#) to create the `chat-index` and `conversations` indexes.

Home > contosochat-search

contosochat-search | Indexes

Search service

Search management

Indexes

Add index Refresh Delete

Filter by name...

Name	Document Count	Storage Size
conversations	14	434.61 KB
chat-index	191	5.42 MB

The following fields from `chat-index` support generative search experiences:

JSON

```
"name": "example-index-from-accelerator",
"fields": [
    { "name": "id", "type": "Edm.String", "searchable": false, "filterable": true,
" retrievable": true },
    { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false,
" retrievable": true },
    { "name": "content_vector", "type": "Collection(Edm.Single)", "searchable": true,
" retrievable": true, "dimensions": 1536, "vectorSearchProfile": "my-vector-
profile" },
    { "name": "metadata", "type": "Edm.String", "searchable": true, "filterable": false,
" retrievable": true },
    { "name": "title", "type": "Edm.String", "searchable": true, "filterable": true,
" retrievable": true, "facetable": true },
    { "name": "source", "type": "Edm.String", "searchable": true, "filterable": true,
" retrievable": true },
    { "name": "chunk", "type": "Edm.Int32", "searchable": false, "filterable": true,
" retrievable": true },
    { "name": "offset", "type": "Edm.Int32", "searchable": false, "filterable": true,
" retrievable": true }
]
```

The following fields from `conversations` support orchestration and chat history:

JSON

```
"fields": [
    { "name": "id", "type": "Edm.String", "key": true, "searchable": false,
"filterable": true, "retrievable": true, "sortable": false, "facetable": false },
    { "name": "conversation_id", "type": "Edm.String", "searchable": false,
"filterable": true, "retrievable": true, "sortable": false, "facetable": true },
    { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false,
"retrievable": true },
    { "name": "content_vector", "type": "Collection(Edm.Single)", "searchable": true,
"retrievable": true, "dimensions": 1536, "vectorSearchProfile": "default-
profile" },
```

```

        {
            "name": "metadata", "type": "Edm.String", "searchable": true, "filterable": false,
            "retrievable": true },
        {
            "name": "type", "type": "Edm.String", "searchable": false, "filterable": true,
            "retrievable": true, "sortable": false, "facetable": true },
        {
            "name": "user_id", "type": "Edm.String", "searchable": false, "filterable": true,
            "retrievable": true, "sortable": false, "facetable": true },
        {
            "name": "sources", "type": "Collection(Edm.String)", "searchable": false,
            "filterable": true, "retrievable": true, "sortable": false, "facetable": true },
        {
            "name": "created_at", "type": "Edm.DateTimeOffset", "searchable": false,
            "filterable": true, "retrievable": true },
        {
            "name": "updated_at", "type": "Edm.DateTimeOffset", "searchable": false,
            "filterable": true, "retrievable": true }
    ]
]

```

The following screenshot shows search results for `conversations` in [Search explorer](#):

```

Results
18
19     {
20         "@search.score": 1,
21         "id": "ND1mODY4MjgtOWU2ZC00YTY3LTgwNTItNmI20WUyYzllZjRj",
22         "conversation_id": "01db26eb-f781-462b-8da3-0ec10e551a35",
23         "content": "The Gulf Stream carries a lot of heat from the Equator toward the far North Atlantic, m",
24         "metadata": "{\"conversation_id\": \"01db26eb-f781-462b-8da3-0ec10e551a35\", \"sources\": [\"doc_26...\"],
25         \"type\": \"assistant\",
26         \"user_id\": null,
27         \"sources\": [
28             \"doc_2005da260b463009d5e230b09a55acedf51fbcd7\",
29             \"doc_541c34b9a54b97ac888034a21c73fc6910243741\"
30         ],
31         \"created_at\": \"2024-01-15T05:19:52Z\",
32         \"updated_at\": \"2024-01-15T05:19:52Z\"
33     },
34     {
35         "@search.score": 1,
36         "id": "NDM1NWM0MzTzGzmZi00ZmQ4Ltk3YTgtY2MyMGU3YmrhNTVm",
37         "conversation_id": "01db26eb-f781-462b-8da3-0ec10e551a35",
38         "content": "what can you tell me about winds",
39         "metadata": "{\"type\": \"user\", \"conversation_id\": \"01db26eb-f781-462b-8da3-0ec10e551a35\", \"s...\"},
40         \"type\": \"user\",
41         \"user_id\": null,
42         \"sources\": [],
43         \"created_at\": \"2024-01-15T19:51:12Z\",
44         \"updated_at\": \"2024-01-15T19:51:12Z\"
45     }

```

In our example, the search score is 1.00 because the search is unqualified. Several fields support orchestration and prompt flows:

- `conversation_id` identifies each chat session.
- `type` indicates whether the content is from the user or the assistant.
- `created_at` and `updated_at` age out chats from the history.

Physical structure and size

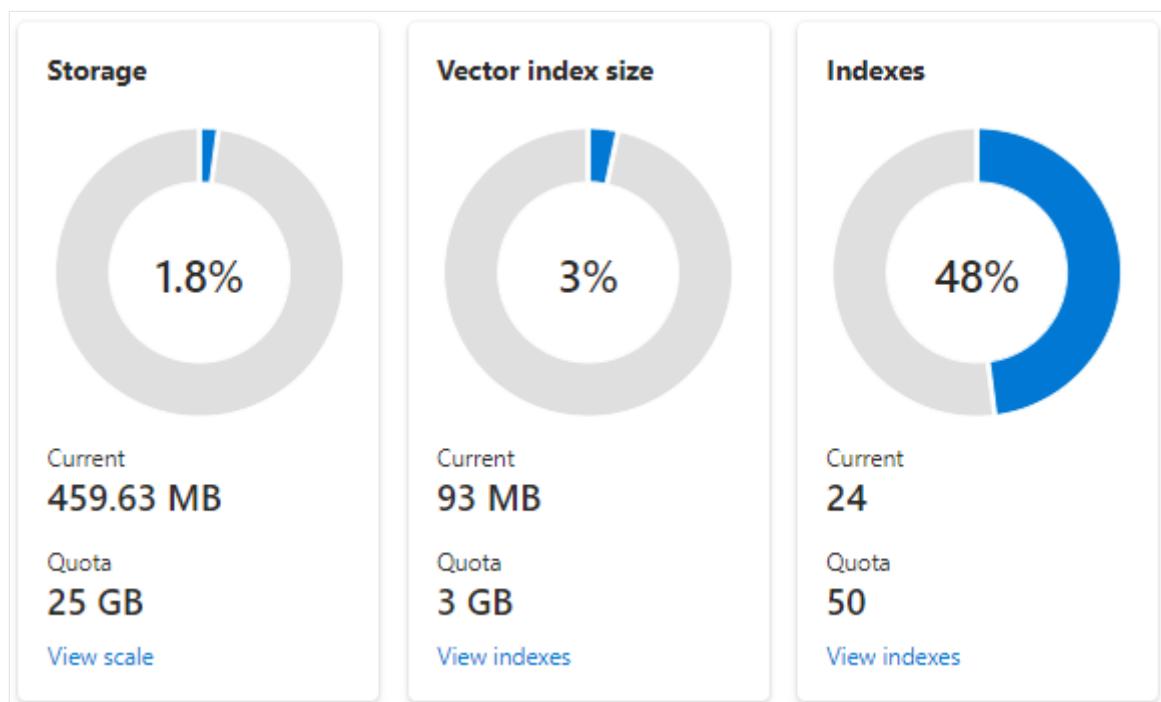

In Azure AI Search, the physical structure of an index is largely an internal implementation. You can access its schema, load and query its content, monitor its size, and manage its capacity. However, Microsoft manages the infrastructure and physical data structures stored with your search service.

The size and substance of an index are determined by the:

- Quantity and composition of your documents.
- Attributes on individual fields. For example, more storage is required for filterable fields.
- Index configuration, including the vector configuration that specifies how the internal navigation structures are created. You can choose HNSW or exhaustive KNN for similarity search.

Azure AI Search imposes limits on vector storage, which helps maintain a balanced and stable system for all workloads. To help you stay under the limits, vector usage is tracked and reported separately in the Azure portal and programmatically through service and index statistics.

The following screenshot shows an S1 service configured with one partition and one replica. This service has 24 small indexes, each with an average of one vector field consisting of 1,536 embeddings. The second tile shows the quota and usage for vector indexes. Because a vector index is an internal data structure created for each vector field, storage for vector indexes is always a fraction of the overall storage used by the index. Nonvector fields and other data structures consume the rest.

Vector index limits and estimations are covered in [another article](#), but two points to emphasize are that maximum storage depends on the creation date and pricing tier of your search service. Newer same-tier services have significantly more capacity for vector indexes. For these reasons, you should:

- [Check the creation date of your search service](#). If it was created before April 3, 2024, you might be able to [upgrade your service](#) for greater capacity.

- Choose a scalable tier if you anticipate fluctuations in vector storage requirements. For older search services, the Basic tier is fixed at one partition. Consider Standard 1 (S1) and higher for more flexibility and faster performance. You can also [switch between Basic and Standard \(S1, S2, and S3\) tiers](#).

Basic operations and interaction

This section introduces vector runtime operations, including connecting to and securing a single index.

ⓘ Note

There's no portal or API support for moving or copying an index. Typically, you either point your application deployment to a different search service (using the same index name) or revise the name to create a copy on your current search service and then build it.

Index isolation

In Azure AI Search, you work with one index at a time. All index-related operations target a single index. There's no concept of related indexes or the joining of independent indexes for either indexing or querying.

Continuously available

An index is immediately available for queries as soon as the first document is indexed, but it's not fully operational until all documents are indexed. Internally, an index is [distributed across partitions and executes on replicas](#). The physical index is managed internally. You manage the logical index.

An index is continuously available and can't be paused or taken offline. Because it's designed for continuous operation, updates to its content and additions to the index itself happen in real time. If a request coincides with a document update, queries might temporarily return incomplete results.

Query continuity exists for document operations, such as refreshing or deleting, and for modifications that don't affect the existing structure or integrity of an index, such as adding new fields. Structural updates, such as changing existing fields, are typically managed using a drop-and-rebuild workflow in a development environment or by creating a new version of the index on the production service.

To avoid an [index rebuild](#), some customers who are making small changes "version" a field by creating a new one that coexists with a previous version. Over time, this leads to orphaned content by way of obsolete fields and obsolete custom analyzer definitions, especially in a production index that's expensive to replicate. You can address these issues during planned updates to the index as part of index lifecycle management.

Endpoint connection

All vector indexing and query requests target an index. Endpoints are usually one of the following:

 [Expand table](#)

Endpoint	Connection and access control
<code><your-service>.search.windows.net/indexes</code>	Targets the indexes collection. Used when creating, listing, or deleting an index. Admin rights are required for these operations and available through admin API keys or a Search Contributor role .
<code><your-service>.search.windows.net/indexes/<your-index>/docs</code>	Targets the documents collection of a single index. Used when querying an index or data refresh. For queries, read rights are sufficient and available through query API keys or a data reader role. For data refresh, admin rights are required.

How to connect to Azure AI Search

1. [Make sure you have permissions](#) or an [API access key](#). Unless you're querying an existing index, you need admin rights or a Contributor role assignment to manage and view content on a search service.
2. [Start with the Azure portal](#). The person who created the search service can view and manage it, including granting access to others on the [Access control \(IAM\)](#) page.
3. Move on to other clients for programmatic access. For first steps, we recommend [Quickstart: Vector searching using REST](#) and the [azure-search-vector-samples](#) repo.

Manage vector stores

Azure provides a [monitoring platform](#) that includes diagnostic logging and alerting. We recommend that you:

- [Enable diagnostic logging](#).

- Set up alerts.
- Analyze query and index performance.

Secure access to vector data

Azure AI Search implements data encryption, private connections for no-internet scenarios, and role assignments for secure access through Microsoft Entra ID. For more information about enterprise security features, see [Security in Azure AI Search](#).

Knowledge store in Azure AI Search

! Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in agentic retrieval workflows.

Knowledge store is secondary storage for [AI-enriched content created by a skillset](#) in Azure AI Search. In Azure AI Search, an indexing job always sends output to a search index, but if you attach a skillset to an indexer, you can optionally also send AI-enriched output to a container or table in Azure Storage. A knowledge store can be used for independent analysis or downstream processing in non-search scenarios like knowledge mining.

The two outputs of indexing, a search index and knowledge store, are mutually exclusive products of the same pipeline. They're derived from the same inputs and contain the same data, but their content is structured, stored, and used in different applications.

Physically, a knowledge store is [Azure Storage](#), either Azure Table Storage, Azure Blob Storage, or both. Any tool or process that can connect to Azure Storage can consume the contents of a knowledge store. There's no query support in Azure AI Search for retrieving content from a knowledge store.

When viewed through Azure portal, a knowledge store looks like any other collection of tables, objects, or files. The following screenshot shows a knowledge store composed of three tables. You can adopt a naming convention, such as a `kstore` prefix, to keep your content together.

The screenshot shows the Azure Storage browser (preview) interface for a storage account named 'demoblobstorage'. The left sidebar includes links for Overview, Activity log, Tags, Diagnose and solve problems, Access Control (IAM), Data migration, Events, and Storage browser (preview). The 'Storage browser (preview)' link is highlighted with a red box. The main area displays a list of storage entities under 'Tables'. A red box highlights the 'Tables' link in the navigation bar and the list of tables. The tables listed are: kstoreProjectionDemoDocument, kstoreProjectionDemoEntities, kstoreProjectionDemoKeyPhrases, and MsAzSearchIndexerCacheIndex33b0d... .

Benefits of knowledge store

The primary benefits of a knowledge store are two-fold: flexible access to content, and the ability to shape data.

Unlike a search index that can only be accessed through queries in Azure AI Search, a knowledge store is accessible to any tool, app, or process that supports connections to Azure Storage. This flexibility opens up new scenarios for consuming the analyzed and enriched content produced by an enrichment pipeline.

The same skillset that enriches data can also be used to shape data. Some tools like Power BI work better with tables, whereas a data science workload might require a complex data structure in a blob format. Adding a **Shaper skill** to a skillset gives you control over the shape of your data. You can then pass these shapes to projections, either tables or blobs, to create physical data structures that align with the data's intended use.

The following video explains both of these benefits and more.

<https://www.youtube-nocookie.com/embed/XWzLBP8iWqg?version=3>

Knowledge store definition

A knowledge store is defined inside a skillset definition and it has two components:

- A connection string to Azure Storage

- **Projections** that determine whether the knowledge store consists of tables, objects or files. The projections element is an array. You can create multiple sets of table-object-file combinations within one knowledge store.

JSON

```
"knowledgeStore": {
  "storageConnectionString": "<YOUR-AZURE-STORAGE-ACCOUNT-CONNECTION-STRING>",
  "projections": [
    {
      "tables": [ ],
      "objects": [ ],
      "files": [ ]
    }
  ]
}
```

The type of projection you specify in this structure determines the type of storage used by knowledge store, but not its structure. Fields in tables, objects, and files are determined by Shaper skill output if you're creating the knowledge store programmatically, or by the Import data wizard if you're using the Azure portal.

- `tables` project enriched content into Table Storage. Define a table projection when you need tabular reporting structures for inputs to analytical tools or export as data frames to other data stores. You can specify multiple `tables` within the same projection group to get a subset or cross section of enriched documents. Within the same projection group, table relationships are preserved so that you can work with all of them.

Projected content isn't aggregated or normalized. The following screenshot shows a table, sorted by key phrase, with the parent document indicated in the adjacent column. In contrast with data ingestion during indexing, there's no linguistic analysis or aggregation of content. Plural forms and differences in casing are considered unique instances.

Content.metadata_storage_name	Content.KeyPhrases
Cognitive Services and Content Intelligence.pptx	Computer Vision
10-K-FY16.html	computing device
10-K-FY16.html	computing devices
MSFT_FY17_10K.docx	computing devices
10-K-FY16.html	Computing segment
Cognitive Services and Bots (spanish).pdf	confianza

- `objects` project JSON document into Blob storage. The physical representation of an `object` is a hierarchical JSON structure that represents an enriched document.
- `files` project image files into Blob storage. A `file` is an image extracted from a document, transferred intact to Blob storage. Although it's named "files", it shows up in Blob Storage, not file storage.

Create a knowledge store

To create knowledge store, use the Azure portal or an API.

You need [Azure Storage](#), a [skillset](#), and an [indexer](#). Because indexers require a search index, you also need to provide an [index definition](#).

Go with the Azure portal approach for the fastest route to a finished knowledge store. Or, choose the REST API for a deeper understanding of how objects are defined and related.

Azure portal

[Create your first knowledge store in four steps](#) using the [Import data wizard](#).

1. Define a data source that contains the data you want to enrich.
2. Define a skillset. The skillset specifies enrichment steps and the knowledge store.
3. Define an index schema. You might not need one, but indexers require it. The wizard can infer an index.
4. Complete the wizard. Data extraction, enrichment, and knowledge store creation occur in this last step.

The wizard automates several tasks. Specifically, both data shaping and projections (definitions of physical data structures in Azure Storage) are created for you.

Connect with apps

Once enriched content exists in storage, any tool or technology that connects to Azure Storage can be used to explore, analyze, or consume the contents. The following list is a start:

- [Storage Explorer](#) or Storage browser in the Azure portal to view enriched document structure and content. Consider this as your baseline tool for viewing knowledge store contents.

- [Power BI](#) for reporting and analysis.
- [Azure Data Factory](#) for further manipulation.

Content lifecycle

Each time you run the indexer and skillset, the knowledge store is updated if the skillset or underlying source data has changed. Any changes picked up by the indexer are propagated through the enrichment process to the projections in the knowledge store, ensuring that your projected data is a current representation of content in the originating data source.

Note

While you can edit the data in the projections, any edits will be overwritten on the next pipeline invocation, assuming the document in source data is updated.

Changes in source data

For data sources that support change tracking, an indexer will process new and changed documents, and bypass existing documents that have already been processed. Timestamp information varies by data source, but in a blob container, the indexer looks at the `lastmodified` date to determine which blobs need to be ingested.

Changes to a skillset

If you're making changes to a skillset, you should [enable caching of enriched documents](#) to reuse existing enrichments where possible.

Without incremental caching, the indexer will always process documents in order of the high water mark, without going backwards. For blobs, the indexer would process blobs sorted by `lastModified`, regardless of any changes to indexer settings or the skillset. If you change a skillset, previously processed documents aren't updated to reflect the new skillset. Documents processed after the skillset change will use the new skillset, resulting in index documents being a mix of old and new skillsets.

With incremental caching, and after a skillset update, the indexer will reuse any enrichments that are unaffected by the skillset change. Upstream enrichments are pulled from cache, as are any enrichments that are independent and isolated from the skill that was changed.

Deletions

Although an indexer creates and updates structures and content in Azure Storage, it doesn't delete them. Projections continue to exist even when the indexer or skillset is deleted. As the owner of the storage account, you should delete a projection if it's no longer needed.

Next steps

Knowledge store offers persistence of enriched documents, useful when designing a skillset, or the creation of new structures and content for consumption by any client applications capable of accessing an Azure Storage account.

The simplest approach for creating enriched documents is [through the Azure portal](#), but a REST client and REST APIs can provide more insight into how objects are created and referenced programmatically.

[Create a knowledge store using REST](#)

Indexers in Azure AI Search

06/23/2025

An *indexer* in Azure AI Search is a crawler that extracts textual data from cloud data sources and populates a search index using field-to-field mappings between source data and a search index. This approach is sometimes referred to as a 'pull model' because the search service pulls data in without you having to write any code that adds data to an index.

Indexers also drive [skillset execution and AI enrichment](#), where you can configure skills to integrate extra processing of content en route to an index. A few examples are OCR over image files, text split skill for data chunking, and calling embedding models to generate vectors for vector search.

Indexers target [supported data sources](#). An indexer configuration specifies a data source (origin) and a search index (destination). Several sources, such as Azure Blob Storage, have more indexer configuration properties specific to that content type.

You can run indexers on demand or on a recurring data refresh schedule that runs as often as every five minutes. More frequent updates preclude the use of indexers, requiring that you implement a '[push model](#)' that simultaneously pushes data to both Azure AI Search and your external data source for data synchronization.

A search service runs one indexer job per search unit. If you need concurrent processing, make sure you have [sufficient replicas](#). Indexers don't run in the background, so you might detect more query throttling than usual if the service is under pressure.

Indexer scenarios and use cases

You can use an indexer as the sole means for data ingestion, or in combination with other techniques. The following table summarizes the main scenarios.

[] [Expand table](#)

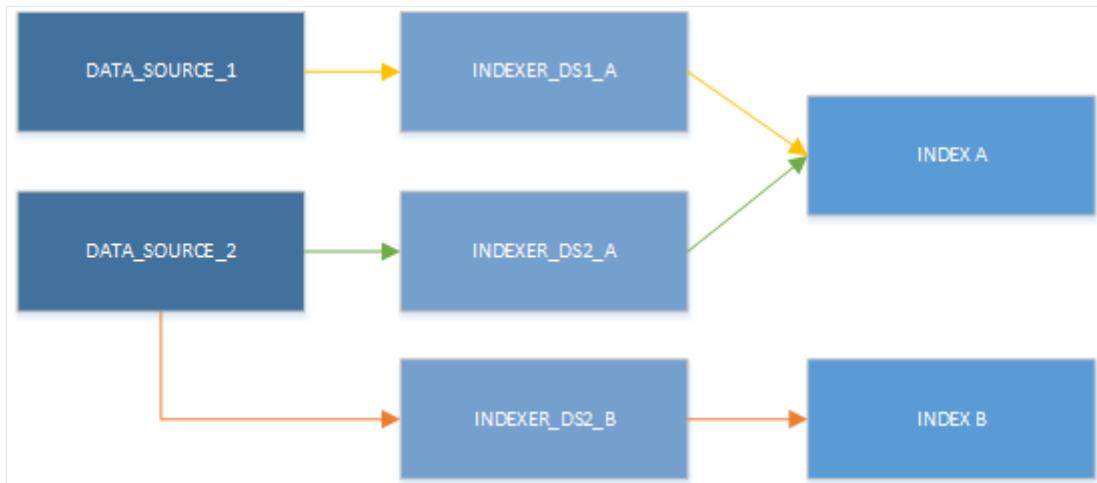

Scenario	Strategy
Single data source	This pattern is the simplest: one data source is the sole content provider for a search index. Most supported data sources provide some form of change detection so that subsequent indexer runs pick up the difference when content is added or updated in the source.
Multiple data sources	An indexer specification can have only one data source, but the search index itself can accept content from multiple sources, where each indexer job brings new content from a different data provider. Each source can contribute its share of full documents,

Scenario	Strategy
	<p>or populate selected fields in each document. For a closer look at this scenario, see Tutorial: Index from multiple data sources.</p>
Multiple indexers	<p>Multiple data sources are typically paired with multiple indexers if you need to vary run time parameters, the schedule, or field mappings.</p> <p>Cross-region scale out of Azure AI Search is a variation of this scenario. You might have copies of the same search index in different regions. To synchronize search index content, you could have multiple indexers pulling from the same data source, where each indexer targets a different search index in each region.</p> <p>Parallel indexing of very large data sets also requires a multi-indexer strategy, where each indexer targets a subset of the data.</p>
Content transformation	<p>Indexers drive skillset execution and AI enrichment. Content transforms are defined in a skillset that you attach to the indexer. You can use skills to incorporate data chunking and vectorization.</p>

You should plan on creating one indexer for every target index and data source combination. You can have multiple indexers writing into the same index, and you can reuse the same data source for multiple indexers. However, an indexer can only consume one data source at a time, and can only write to a single index. As the following graphic illustrates, one data source provides input to one indexer, which then populates a single index:

Although you can only use one indexer at a time, resources can be used in different combinations. The main takeaway of the next illustration is to notice is that a data source can be paired with more than one indexer, and multiple indexers can write to same index.

Supported data sources

Indexers crawl data stores on Azure and outside of Azure.

- [Azure Blob Storage](#)
- [Azure Cosmos DB](#)
- [Azure Data Lake Storage Gen2](#)
- [Azure SQL Database](#)
- [Azure Table Storage](#)
- [Azure SQL Managed Instance](#)
- [SQL Server on Azure Virtual Machines](#)
- [Azure Files \(in preview\)](#)
- [Azure MySQL \(in preview\)](#)
- [SharePoint in Microsoft 365 \(in preview\)](#)
- [Azure Cosmos DB for MongoDB \(in preview\)](#)
- [Azure Cosmos DB for Apache Gremlin \(in preview\)](#)
- [OneLake \(in preview\)](#)

Azure Cosmos DB for Cassandra is not supported.

Indexers accept flattened row sets, such as a table or view, or items in a container or folder. In most cases, it creates one search document per row, record, or item.

Indexer connections to remote data sources can be made using standard Internet connections (public) or encrypted private connections when you use a shared private link. You can also set up connections to authenticate using a managed identity. For more information about secure connections, see [Indexer access to content protected by Azure network security features](#) and [Connect to a data source using a managed identity](#).

Stages of indexing

On an initial run, when the index is empty, an indexer will read in all of the data provided in the table or container. On subsequent runs, the indexer can usually detect and retrieve just the data that has changed. For blob data, change detection is automatic. For other data sources like Azure SQL or Azure Cosmos DB, change detection must be enabled.

For each document it receives, an indexer implements or coordinates multiple steps, from document retrieval to a final search engine "handoff" for indexing. Optionally, an indexer also drives [skillset execution and outputs](#), assuming a skillset is defined.

Stage 1: Document cracking

Document cracking is the process of opening files and extracting content. Text-based content can be extracted from files on a service, rows in a table, or items in container or collection.

You can also enable image extraction during document cracking for an [extra fee ↗](#). This is disabled by default and can be enabled via the `imageAction` property in the [indexer parameters configuration](#). Review some [image scenarios](#) for indexer image handling.

Depending on the data source, the indexer will try different operations to extract potentially indexable content:

- When the document is a file with embedded images, such as a PDF, the indexer extracts text, images, and metadata. Indexers can open files from [Azure Blob Storage](#), [Azure Data Lake Storage Gen2](#), and [SharePoint](#).
- When the document is a record in [Azure SQL](#), the indexer will extract non-binary content from each field in each record.
- When the document is a record in [Azure Cosmos DB](#), the indexer will extract non-binary content from fields and subfields from the Azure Cosmos DB document.

Note that the document cracking process can also be triggered later during the optional [skillset execution](#) stage, using skillsets, for data transformation. Adding a skillset with [image skills](#) allows document cracking to extract images and queue them for processing.

Stage 2: Field mappings

An indexer extracts text from a source field and sends it to a destination field in an index or knowledge store. When field names and data types coincide, the path is clear. However, you might want different names or types in the output, in which case you need to tell the indexer how to map the field.

To [specify field mappings](#), enter the source and destination fields in the indexer definition.

Field mapping occurs after document cracking, but before transformations, when the indexer is reading from the source documents. When you define a field mapping, the value of the source field is sent as-is to the destination field with no modifications.

Stage 3: Skillset execution

Skillset execution is an optional step that invokes built-in or custom AI processing. Skillsets can add optical character recognition (OCR) or other forms of image analysis if the content is binary. Skillsets can also add natural language processing. For example, you can add text translation or key phrase extraction.

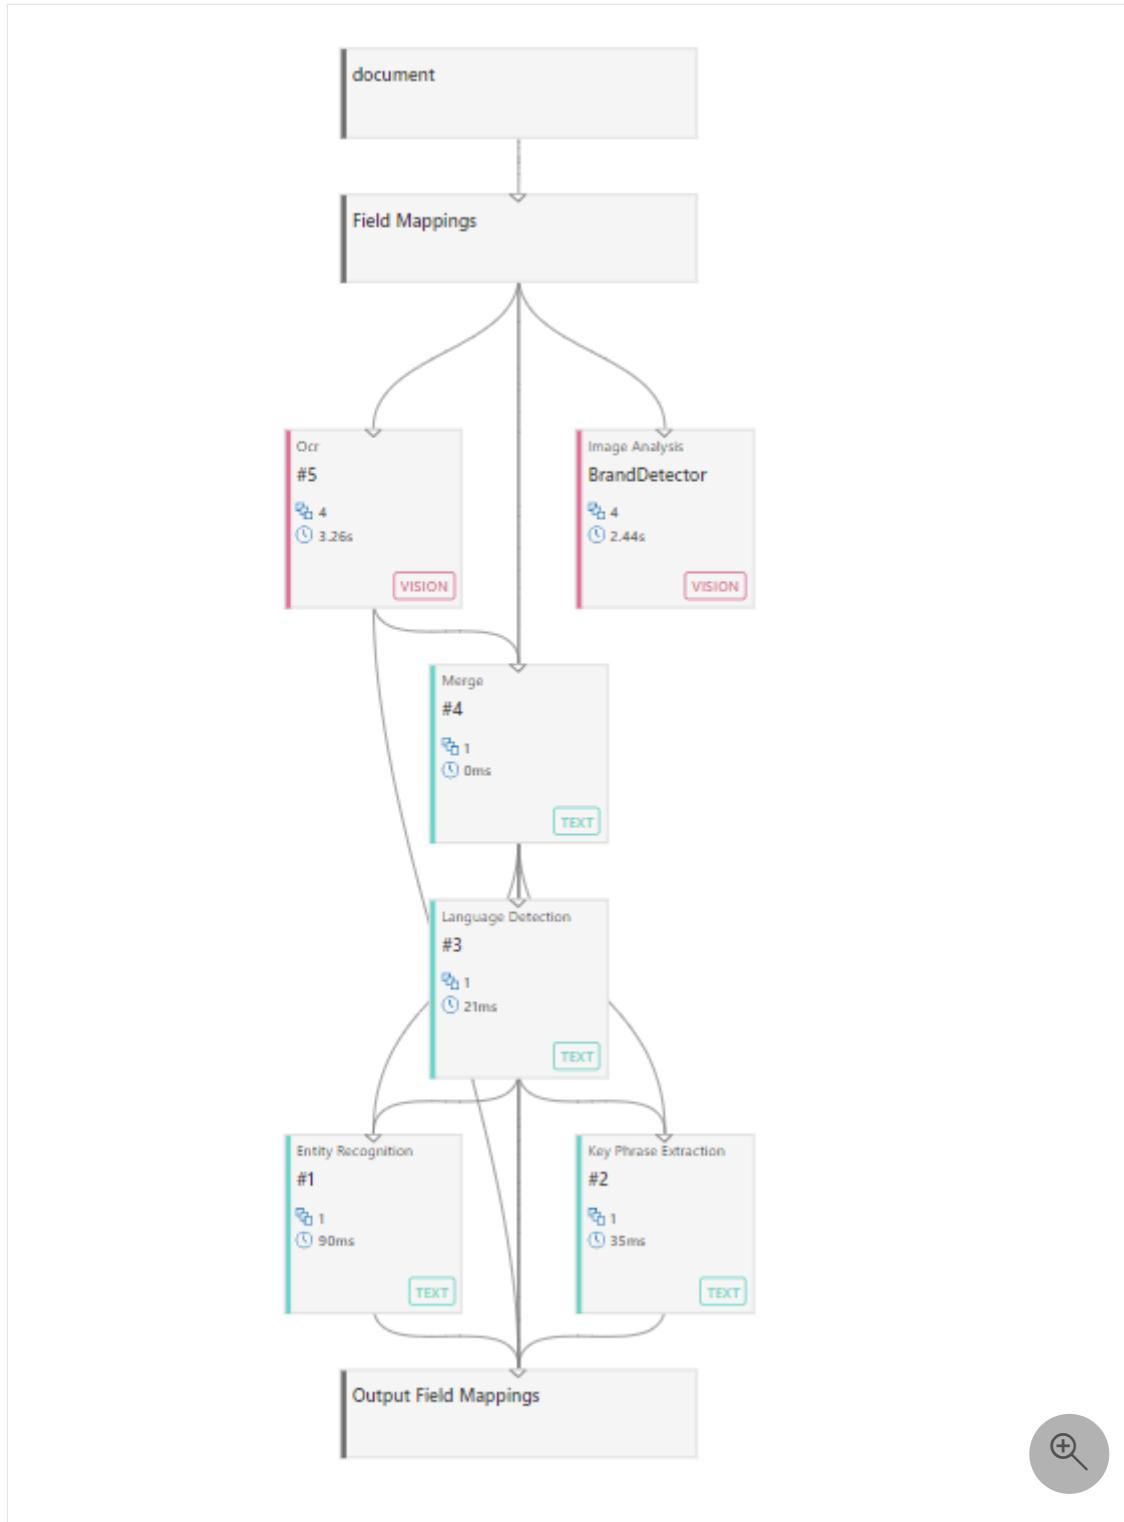

Whatever the transformation, skillset execution is where enrichment occurs. If an indexer is a pipeline, you can think of a [skillset](#) as a "pipeline within the pipeline".

Stage 4: Output field mappings

If you include a skillset, you'll need to [specify output field mappings](#) in the indexer definition. The output of a skillset is manifested internally as a tree structure referred to as an *enriched document*. Output field mappings allow you to select which parts of this tree to map into fields in your index.

Despite the similarity in names, output field mappings and field mappings build associations from different sources. Field mappings associate the content of source field to a destination field in a search index. Output field mappings associate the content of an internal enriched document (skill outputs) to destination fields in the index. Unlike field mappings, which are considered optional, an output field mapping is required for any transformed content that should be in the index.

The next image shows a sample indexer [debug session](#) representation of the indexer stages: document cracking, field mappings, skillset execution, and output field mappings.

Basic workflow

Indexers can offer features that are unique to the data source. In this respect, some aspects of indexer or data source configuration will vary by indexer type. However, all indexers share the same basic composition and requirements. Steps that are common to all indexers are covered below.

Step 1: Create a data source

Indexers require a *data source* object that provides a connection string and possibly credentials. Data sources are independent objects. Multiple indexers can use the same data source object to load more than one index at a time.

You can create a data source using any of these approaches:

- Using the Azure portal, on the **Data sources** tab of your search service pages, select **Add data source** to specify the data source definition.
- Using the Azure portal, the [Import data wizard](#) outputs a data source.
- Using the REST APIs, call [Create Data Source](#).
- Using the Azure SDK for .NET, call [SearchIndexerDataSourceConnection class](#)

Step 2: Create an index

An indexer will automate some tasks related to data ingestion, but creating an index is generally not one of them. As a prerequisite, you must have a predefined index that contains corresponding target fields for any source fields in your external data source. Fields need to match by name and data type. If not, you can [define field mappings](#) to establish the association.

For more information, see [Create an index](#).

Step 3: Create and run (or schedule) the indexer

An indexer definition consists of properties that uniquely identify the indexer, specify which data source and index to use, and provide other configuration options that influence run time behaviors, including whether the indexer runs on demand or on a schedule.

Any errors or warnings about data access or skillset validation will occur during indexer execution. Until indexer execution starts, dependent objects such as data sources, indexes, and skillsets are passive on the search service.

For more information, see [Create an indexer](#)

After the first indexer run, you can [rerun it on demand](#) or [set up a schedule](#).

You can monitor [indexer status in the Azure portal](#) or through [Get Indexer Status API](#). You should also [run queries on the index](#) to verify the result is what you expected.

Indexers don't have dedicated processing resources. Based on this, indexers' status may show as idle before running (depending on other jobs in the queue) and run times may not be predictable. Other factors define indexer performance as well, such as document size, document complexity, image analysis, among others.

Next steps

Now that you've been introduced to indexers, a next step is to review indexer properties and parameters, scheduling, and indexer monitoring. Alternatively, you could return to the list of [supported data sources](#) for more information about a specific source.

- [Create indexers](#)
- [Reset and run indexers](#)
- [Schedule indexers](#)
- [Define field mappings](#)
- [Monitor indexer status](#)

AI enrichment in Azure AI Search

In Azure AI Search, *AI enrichment* refers to integration with [Foundry Tools](#) to process content that isn't searchable in its raw form. Through enrichment, analysis and inference are used to create searchable content and structure where none previously existed.

Because Azure AI Search is used for text and vector queries, the purpose of AI enrichment is to improve the utility of your content in search-related scenarios. Raw content must be text or images (you can't enrich vectors), but the output of an enrichment pipeline can be vectorized and indexed in a search index using skills like [Text Split skill](#) for chunking and [Azure OpenAI Embedding skill](#) for vector encoding. For more information about using skills in vector scenarios, see [Integrated data chunking and embedding](#).

AI enrichment is based on [skills](#).

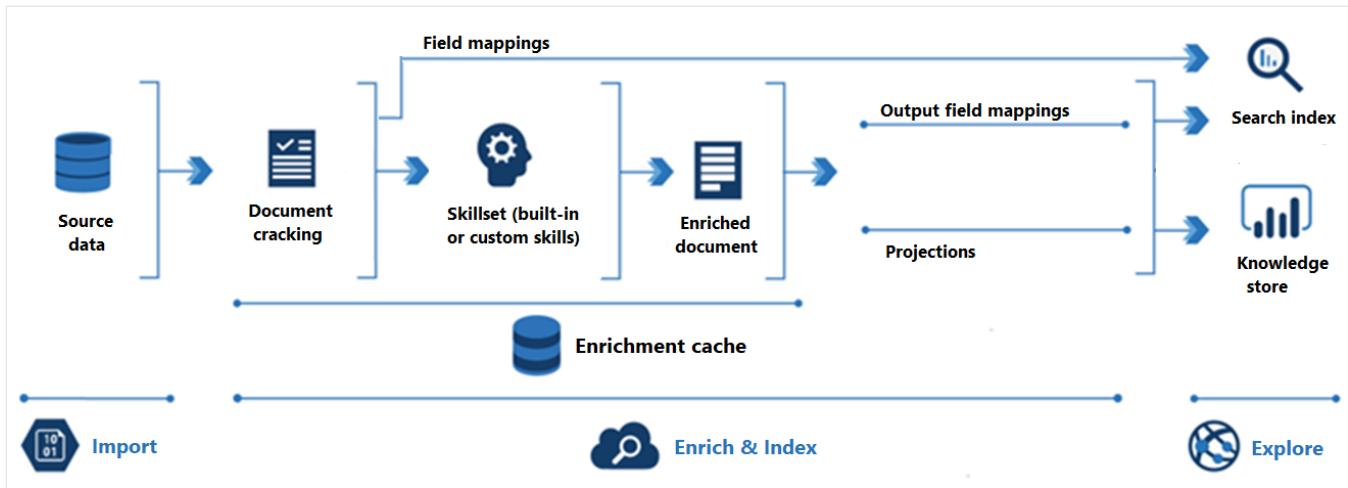

[Built-in skills](#) tap Foundry Tools. They apply the following transformations and processing to raw content:

- Translation and language detection for multilingual search.
- Entity recognition to extract people names, places, and other entities from large chunks of text.
- Key phrase extraction to identify and output important terms.
- Optical character recognition (OCR) to recognize printed and handwritten text in binary files.
- Image analysis to describe image content and output the descriptions as searchable text fields.
- Text embeddings via Azure OpenAI for integrated vectorization.
- Multimodal embeddings via Azure Vision in Foundry Tools for text and image vectorization.

Custom skills run your external code. You can use custom skills for any custom processing you want to include in the pipeline.

AI enrichment is an extension of an [indexer pipeline](#) that connects to Azure data sources. An enrichment pipeline has all of the components of an indexer pipeline (indexer, data source, index) and a [skillset](#) that specifies atomic enrichment steps.

The following diagram shows the progression of AI enrichment:

Import is the first step. Here, the indexer connects to a data source and pulls content (documents) into the search service. [Azure Blob Storage](#) is the most common resource used in AI enrichment scenarios, but any supported data source can provide content.

Enrich & Index covers most of the AI enrichment pipeline:

- Enrichment starts when the indexer [cracks documents](#) and extracts images and text. The type of processing that occurs next depends on your data and the skills you've added to a skillset. Images can be forwarded to [skills that perform image processing](#). Text content is queued for text and natural language processing. Internally, skills create an [enriched document](#) that collects transformations as they occur.
- Enriched content is generated during skillset execution and is temporary unless you save it. You can enable an [enrichment cache](#) to persist skill outputs for reuse in future skillset executions.
- To get content into a search index, the indexer must have mapping information for sending enriched content to target field. [Field mappings](#) (explicit or implicit) set the data path from source data to a search index. [Output field mappings](#) set the data path from enriched documents to an index.
- Indexing is the process wherein raw and enriched content is ingested into the physical data structures of a [search index](#) (its files and folders). Lexical analysis and tokenization occur in this step.

Exploration is the last step. Output is always a [search index](#) that you can query from a client app. Output can optionally be a [knowledge store](#) consisting of blobs and tables in Azure Storage that are accessed through data exploration tools or downstream processes. If you're creating a knowledge store, [projections](#) determine the data path for enriched content. The same enriched content can appear in both indexes and knowledge stores.

When to use AI enrichment

Enrichment is useful if raw content is unstructured text, image content, or content that needs language detection and translation. Applying AI through the [built-in skills](#) can unlock this content for full-text search and data science applications.

You can also create [custom skills](#) to provide external processing. Open-source, third-party, or first-party code can be integrated into the pipeline as a custom skill. Classification models that identify salient characteristics of various document types fall into this category, but any external package that adds value to your content could be used.

Use-cases for built-in skills

Built-in skills are based on the Foundry Tools APIs: [Azure Vision](#) and [Azure Language](#). Unless your content input is small, expect to [attach a billable Microsoft Foundry resource](#) to run larger workloads.

A [skillset](#) that's assembled using built-in skills is well suited for the following application scenarios:

- **Image processing** skills include [Optical Character Recognition \(OCR\)](#) and identification of [visual features](#), such as facial detection, image interpretation, image recognition (famous people and landmarks), or attributes like image orientation. These skills create text representations of image content for full-text search in Azure AI Search.
- **Machine translation** is provided by the [Text Translation](#) skill, often paired with [language detection](#) for multi-language solutions.
- **Natural language processing** analyzes chunks of text. Skills in this category include [Entity Recognition](#), [Sentiment Detection \(including opinion mining\)](#), and [Personal Identifiable Information Detection](#). With these skills, unstructured text is mapped as searchable and filterable fields in an index.

Use-cases for custom skills

[Custom skills](#) execute external code that you provide and wrap in the [custom skill web interface](#). Several examples of custom skills can be found in the [azure-search-power-skills](#) GitHub repository.

Custom skills aren't always complex. For example, if you have an existing package that provides pattern matching or a document classification model, you can wrap it in a custom skill.

Storing output

In Azure AI Search, an indexer saves the output it creates. A single indexer run can create up to three data structures that contain enriched and indexed output.

[+] [Expand table](#)

Data store	Required	Location	Description
searchable index	Required	Search service	Used for full-text search and other query forms. Specifying an index is an indexer requirement. Index content is populated from skill outputs, plus any source fields that are mapped directly to fields in the index.
knowledge store	Optional	Azure Storage	Used for downstream apps like knowledge mining, data science, and multimodal search. A knowledge store is defined within a skillset. Its definition determines whether your enriched documents are projected as tables or objects (files or blobs) in Azure Storage. For multimodal search scenarios , you can save extracted images to the knowledge store and reference them at query time, allowing the images to be returned directly to client apps.
enrichment cache	Optional	Azure Storage	Used for caching enrichments for reuse in subsequent skillset executions. The cache stores imported, unprocessed content (cracked documents). It also stores the enriched documents created during skillset execution. Caching is helpful if you're using image analysis or OCR, and you want to avoid the time and expense of reprocessing image files.

Indexes and knowledge stores are fully independent of each other. While you must attach an index to satisfy indexer requirements, if your sole objective is a knowledge store, you can ignore the index after it's populated.

Exploring content

After you define and load a [search index](#) or [knowledge store](#), you can explore its data.

Query a search index

[Run queries](#) to access the enriched content generated by the pipeline. The index is like any other you might create for Azure AI Search: you can supplement text analysis with custom analyzers, invoke fuzzy search queries, add filters, or experiment with scoring profiles to tune search relevance.

Use data exploration tools on a knowledge store

In Azure Storage, a [knowledge store](#) can assume the following forms: a blob container of JSON documents, a blob container of image objects, or tables in Table Storage. You can use [Storage Explorer](#), [Power BI](#), or any app that connects to Azure Storage to access your content.

- A blob container captures enriched documents in their entirety, which is useful if you're creating a feed into other processes.
- A table is useful if you need slices of enriched documents, or if you want to include or exclude specific parts of the output. For analysis in Power BI, tables are the recommended data source for data exploration and visualization in Power BI.

Availability and pricing

AI enrichment is available in regions that offer Foundry Tools. To check the availability of AI enrichment, see the [regions list](#).

Billing follows a Standard pricing model. Costs associated with built-in skills are incurred when you specify an Azure OpenAI in Foundry Models resource or Foundry resource key in the skillset. There are also costs associated with image extraction, as metered by Azure AI Search. However, text extraction and utility skills aren't billable. For more information, see [How you're charged for Azure AI Search](#).

Checklist: A typical workflow

An enrichment pipeline consists of [indexers](#) that have [skillsets](#). Post-indexing, you can query an index to validate your results.

Start with a subset of data in a [supported data source](#). Indexer and skillset design is an iterative process. The work goes faster with a small representative data set.

1. Create a [data source](#) that specifies a connection to your data.
2. [Create a skillset](#). Unless your project is small, you should [attach a Foundry resource](#). If you're [creating a knowledge store](#), define it within the skillset.
3. [Create an index schema](#) that defines a search index.
4. [Create and run the indexer](#) to bring all of the previous components together. This step retrieves the data, runs the skillset, and loads the index.

An indexer is also where you specify field mappings and output field mappings that set up the data path to a search index.

Optionally, [enable enrichment caching](#) in the indexer configuration. This step allows you to reuse existing enrichments later on.

5. [Run queries](#) to evaluate results or [start a debug session](#) to work through any skillset issues.

To repeat any of the previous steps, [reset the indexer](#) before you run it. Alternatively, you can delete and recreate the objects on each run (recommended if you're using the free tier). If you enabled caching, the indexer pulls from the cache if the source data is unchanged and if your edits to the pipeline don't invalidate the cache.

Integrated vector embedding in Azure AI Search

Integrated vectorization is an extension of the indexing and query pipelines in Azure AI Search. It adds the following capabilities:

- Vector encoding during indexing
- Vector encoding during queries

[Data chunking](#) isn't a hard requirement, but unless your raw documents are small, chunking is necessary for meeting the token input requirements of embedding models.

Vector conversions are one-way: nonvector-to-vector. For example, there's no vector-to-text conversion for queries or results, such as converting a vector result to a human-readable string, which is why indexes contain both vector and nonvector fields.

Integrated vectorization speeds up the development and minimizes maintenance tasks during data ingestion and query time because there are fewer operations that you have to implement manually. This capability is now generally available.

Using integrated vectorization during indexing

For integrated data chunking and vector conversions, you're taking a dependency on the following components:

- An [indexer](#), which retrieves raw data from a [supported data source](#) and drives the pipeline engine.
- A [search index](#) to receive the chunked and vectorized content.
- A [skillset](#) configured for:
 - [Text Split skill](#), used to chunk the data.
 - An embedding skill, used to generate vector arrays, which can be any of the following:
 - [AzureOpenAIEmbedding skill](#), attached to text-embedding-ada-002, text-embedding-3-small, text-embedding-3-large on Azure OpenAI.
 - [Custom skill](#) that points to another embedding model on Azure or on another site.
 - [Azure Vision multimodal embeddings skill \(preview\)](#) that points to the multimodal API for Azure Vision.

- [AML skill](#) that points to select models in the Microsoft Foundry model catalog.

Using integrated vectorization in queries

For text-to-vector conversion during queries, you take a dependency on these components:

- A query that specifies one or more vector fields.
- A text string that's converted to a vector at query time.
- [A vectorizer](#), defined in the index schema, assigned to a vector field, and used automatically at query time to convert a text query to a vector. The vectorizer you set up must match the embedding model used to encode your content.

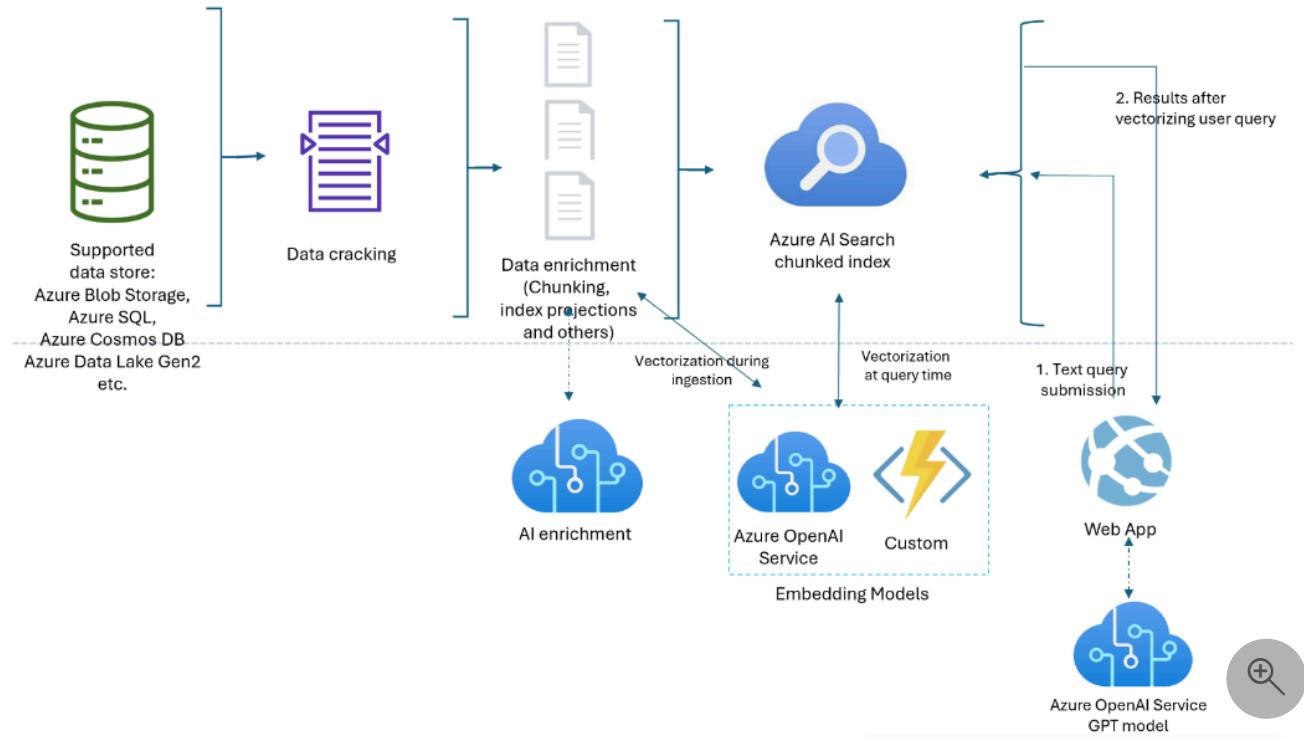

[] [Expand table](#)

Embedding skill	Vectorizer
AzureOpenAIEmbedding skill	Azure OpenAI vectorizer
Custom skill	Custom Web API vectorizer
Azure Vision multimodal embeddings skill (preview)	Azure Vision vectorizer
AML skill pointing to the model catalog in Foundry portal	Microsoft Foundry model catalog vectorizer

Component diagram

The following diagram shows the components of integrated vectorization.

Azure AI Search processing

The workflow is an indexer pipeline. Indexers retrieve data from supported data sources and initiate data enrichment (or applied AI) by calling Azure OpenAI or Foundry Tools or custom code for text-to-vector conversions or other processing.

The diagram focuses on integrated vectorization, but your solution isn't limited to this list. You can add more skills for AI enrichment, create a knowledge store, add semantic ranking, add relevance tuning, and other query features.

Availability and pricing

Integrated vectorization is available in all regions and tiers. However, if you're using skills and vectorizers for AI enrichment, regional requirements might apply. For more information, see [Attach a Foundry resource to a skillset](#).

If you're using a custom skill and an Azure hosting mechanism (such as an Azure function app, Azure Web App, and Azure Kubernetes), check the [Azure product by region page](#) for feature availability.

Data chunking (Text Split skill) is free and available on all Foundry Tools in all regions.

! Note

Some older search services created before January 1, 2019 are deployed on infrastructure that doesn't support vector workloads. If you try to add a vector field to a schema and get

an error, it's a result of outdated services. In this situation, you must create a new search service to try out the vector feature.

What scenarios can integrated vectorization support?

- Subdivide large documents into chunks, useful for vector and nonvector scenarios. For vectors, chunks help you meet the input constraints of embedding models. For nonvector scenarios, you might have a chat-style search app where GPT is assembling responses from indexed chunks. You can use vectorized or nonvectorized chunks for chat-style search.
- Build a vector store where all of the fields are vector fields, and the document ID (required for a search index) is the only string field. Query the vector store to retrieve document IDs, and then send the document's vector fields to another model.
- Combine vector and text fields for hybrid search, with or without semantic ranking. Integrated vectorization simplifies all of the [scenarios supported by vector search](#).

How to use integrated vectorization

For query-only vectorization:

1. [Add a vectorizer](#) to an index. It should be the same embedding model used to generate vectors in the index.
2. [Assign the vectorizer](#) to a vector profile, and then assign a vector profile to the vector field.
3. [Formulate a vector query](#) that specifies the text string to vectorize.

A more common scenario - data chunking and vectorization during indexing:

1. [Create a data source](#) connection to a supported data source for indexer-based indexing.
2. [Create a skillset](#) that calls [Text Split skill](#) for chunking and [Azure OpenAI Embedding](#) or another embedding skill to vectorize the chunks.
3. [Create an index](#) that specifies a [vectorizer](#) for query time, and assign it to vector fields.
4. [Create an indexer](#) to drive everything, from data retrieval, to skillset execution, through indexing. We recommend running the indexer [on a schedule](#) to pick up changed documents or any documents that were missed due to throttling.

Optionally, [create secondary indexes](#) for advanced scenarios where chunked content is in one index, and nonchunked in another index. Chunked indexes (or secondary indexes) are useful

for RAG apps.

💡 Tip

[Try the Import data \(new\) wizard](#) in the Azure portal to explore integrated vectorization before writing any code.

Secure connections to vectorizers and models

If your architecture requires private connections that bypass the internet, you can create a [shared private link connection](#) to the embedding models used by skills during indexing and vectorizers at query time.

Shared private links only work for Azure-to-Azure connections. If you're connecting to OpenAI or another external model, the connection must be over the public internet.

For vectorization scenarios, you would use:

- `openai_account` for embedding models hosted on an Azure OpenAI resource.
- `sites` for embedding models accessed as a [custom skill](#) or [custom vectorizer](#). The `sites` group ID is for App services and Azure functions, which you could use to host an embedding model that isn't one of the Azure OpenAI embedding models.

Benefits

Here are some of the key benefits of the integrated vectorization:

- No separate data chunking and vectorization pipeline. Code is simpler to write and maintain.
- Automate indexing end-to-end. When data changes in the source (such as in Azure Storage, Azure SQL, or Cosmos DB), the indexer can move those updates through the entire pipeline, from retrieval, to document cracking, through optional AI-enrichment, data chunking, vectorization, and indexing.
- Batching and retry logic is built in (non-configurable). Azure AI Search has internal retry policies for throttling errors that surface due to the Azure OpenAI endpoint maxing out on token quotas for the embedding model. We recommend putting the indexer on a schedule (for example, every 5 minutes) so the indexer can process any calls that are throttled by the Azure OpenAI endpoint despite of the retry policies.

- Projecting chunked content to secondary indexes. Secondary indexes are created as you would any search index (a schema with fields and other constructs), but they're populated in tandem with a primary index by an indexer. Content from each source document flows to fields in primary and secondary indexes during the same indexing run.

Secondary indexes are intended for question and answer or chat style apps. The secondary index contains granular information for more specific matches, but the parent index has more information and can often produce a more complete answer. When a match is found in the secondary index, the query returns the parent document from the primary index. For example, assuming a large PDF as a source document, the primary index might have basic information (title, date, author, description), while a secondary index has chunks of searchable content.

Limitations

Make sure you know the [Azure OpenAI quotas and limits for embedding models](#). Azure AI Search has retry policies, but if the quota is exhausted, retries fail.

Azure OpenAI token-per-minute limits are per model, per subscription. Keep this in mind if you're using an embedding model for both query and indexing workloads. If possible, [follow best practices](#). Have an embedding model for each workload, and try to deploy them in different subscriptions.

On Azure AI Search, remember there are [service limits](#) by tier and workloads.

Next steps

- [Set up integrated vectorization](#)
- [Configure a vectorizer in a search index](#)
- [Configure index projections in a skillset](#)

Last updated on 11/18/2025

Agentic retrieval in Azure AI Search

ⓘ Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

What is agentic retrieval? In Azure AI Search, *agentic retrieval* is a new multi-query pipeline designed for complex questions posed by users or agents in chat and copilot apps. It's intended for [Retrieval Augmented Generation \(RAG\)](#) patterns and agent-to-agent workflows.

Here's what it does:

- Uses a large language model (LLM) to break down a complex query into smaller, focused subqueries for better coverage over your indexed content. Subqueries can include chat history for extra context.
- Runs subqueries in parallel. Each subquery is semantically reranked to promote the most relevant matches.
- Combines the best results into a unified response that an LLM can use to generate answers with your proprietary content.
- The response is modular yet comprehensive in how it also includes a query plan and source documents. You can choose to use just the search results as grounding data, or invoke the LLM to formulate an answer.

This high-performance pipeline helps you generate high quality grounding data (or an answer) for your chat application, with the ability to answer complex questions quickly.

Programmatically, agentic retrieval is supported through a new [Knowledge Base object](#) in the 2025-11-01-preview and in Azure SDK preview packages that provide the feature. A knowledge base's retrieval response is designed for downstream consumption by other agents and chat apps.

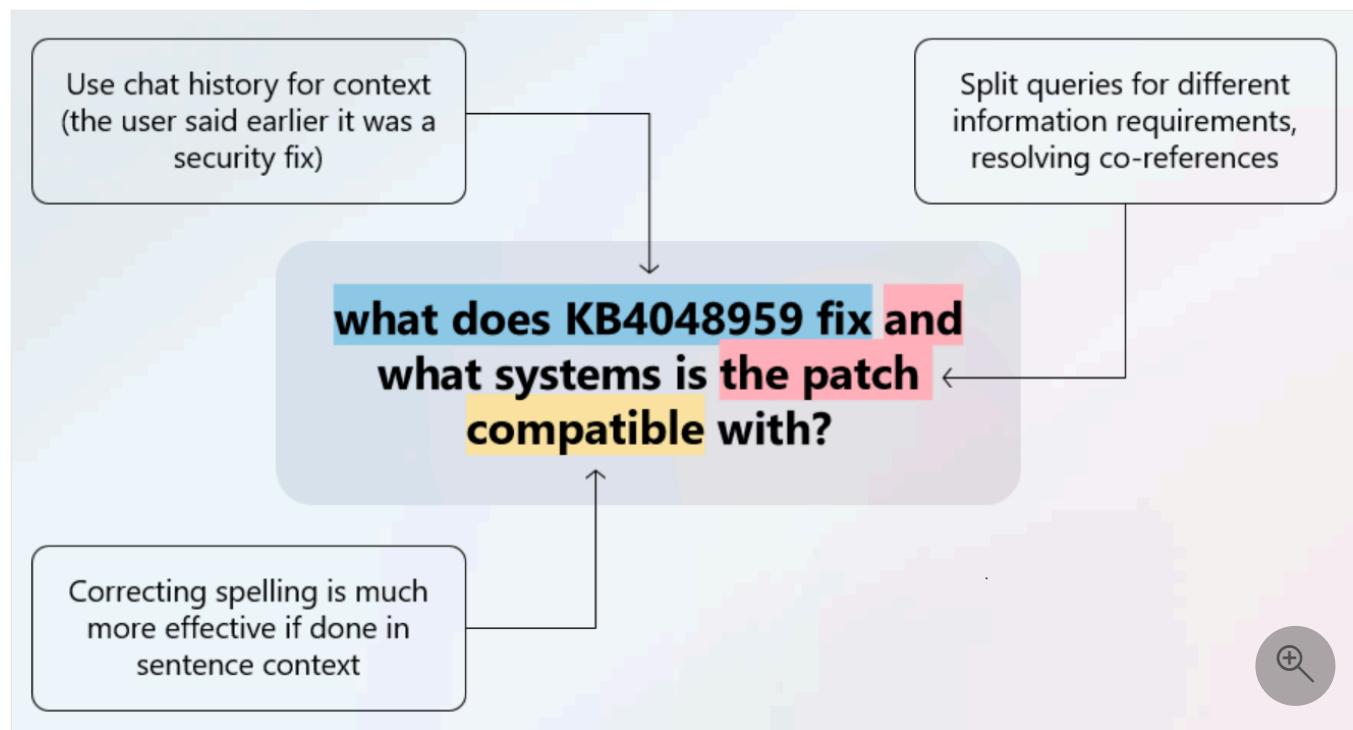

Why use agentic retrieval

You should use agentic retrieval when you want to provide agents and apps with the most relevant content for answering harder questions, leveraging chat context and your proprietary content.

The *agentic* aspect is a reasoning step in query planning processing that's performed by a supported large language model (LLM) that you provide. The LLM analyzes the entire chat thread to identify the underlying information need. Instead of a single, catch-all query, the LLM breaks down compound questions into focused subqueries based on: user questions, chat history, and parameters on the request. The subqueries target your indexed documents (plain text and vectors) in Azure AI Search. This hybrid approach ensures you surface both keyword matches and semantic similarities at once, dramatically improving recall.

The *retrieval* component is the ability to run subqueries simultaneously, merge results, semantically rank results, and return a three-part response that includes grounding data for the next conversation turn, reference data so that you can inspect the source content, and an activity plan that shows query execution steps.

Query expansion and parallel execution, plus the retrieval response, are the key capabilities of agentic retrieval that make it the best choice for generative AI (RAG) applications.

Agentic retrieval adds latency to query processing, but it makes up for it by adding these capabilities:

- Reads in chat history as an input to the retrieval pipeline.
- Deconstructs a complex query that contains multiple "asks" into component parts. For example: "find me a hotel near the beach, with airport transportation, and that's within walking distance of vegetarian restaurants."
- Rewrites an original query into multiple subqueries using synonym maps (optional) and LLM-generated paraphrasing.
- Corrects spelling mistakes.
- Executes all subqueries simultaneously.

- Outputs a unified result as a single string. Alternatively, you can extract parts of the response for your solution. Metadata about query execution and reference data is included in the response.

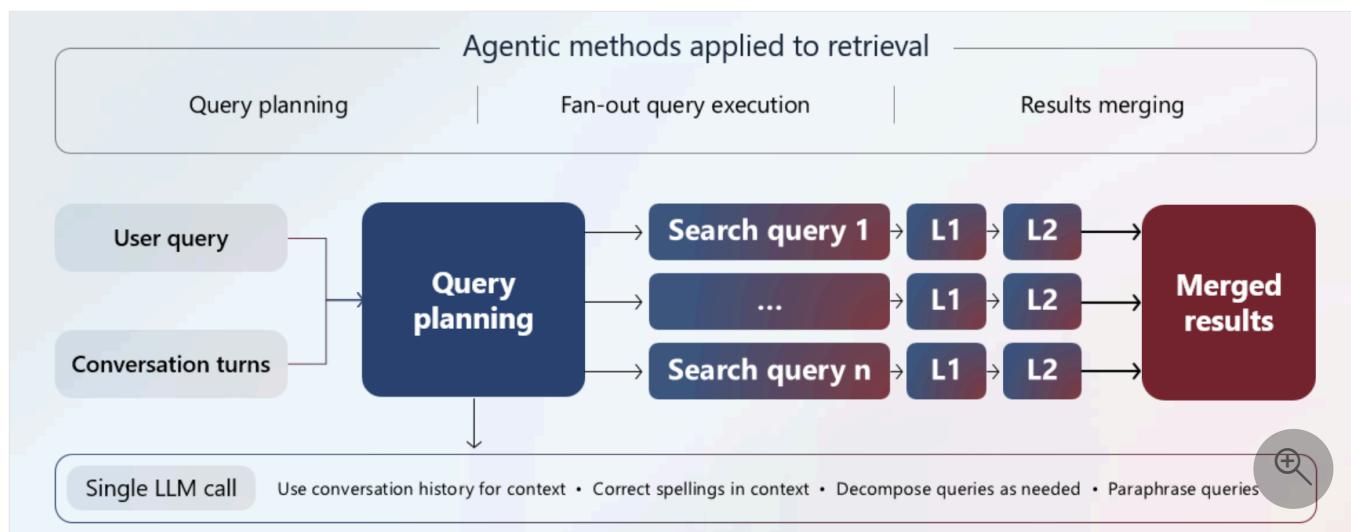

Agentic retrieval invokes the entire query processing pipeline multiple times for each subquery, but it does so in parallel, preserving the efficiency and performance necessary for a reasonable user experience.

(!) Note

Including an LLM in query planning adds latency to a query pipeline. You can mitigate the effects by using faster models, such as gpt-4o-mini, and summarizing the message threads. You can minimize latency and costs by setting properties that limit LLM processing. You can also exclude LLM processing altogether for just text and hybrid search and your own query planning logic.

Architecture and workflow

Agentic retrieval is designed for conversational search experiences that use an LLM to intelligently break down complex queries. The system coordinates multiple Azure services to deliver comprehensive search results.

How it works

The agentic retrieval process works as follows:

1. **Workflow initiation:** Your application calls a knowledge base with retrieve action that provides a query and conversation history.

2. **Query planning:** A knowledge base sends your query and conversation history to an LLM, which analyzes the context and breaks down complex questions into focused subqueries. This step is automated and not customizable.
3. **Query execution:** The knowledge base sends the subqueries to your knowledge sources. All subqueries run simultaneously and can be keyword, vector, and hybrid search. Each subquery undergoes semantic reranking to find the most relevant matches. References are extracted and retained for citation purposes.
4. **Result synthesis:** The system combines all results into a unified response with three parts: merged content, source references, and execution details.

Your search index determines query execution and any optimizations that occur during query execution. Specifically, if your index includes searchable text and vector fields, a hybrid query executes. If the only searchable field is a vector field, then only pure vector search is used. The index semantic configuration, plus optional scoring profiles, synonym maps, analyzers, and normalizers (if you add filters) are all used during query execution. You must have named defaults for a semantic configuration and a scoring profile.

Required components

[] [Expand table](#)

Component	Service	Role
LLM	Azure	Creates subqueries from conversation context and later uses
	OpenAI	grounding data for answer generation
Knowledge base	Azure AI Search	Orchestrates the pipeline, connecting to your LLM and managing query parameters
Knowledge source	Azure AI Search	Wraps the search index with properties pertaining to knowledge base usage
Search index	Azure AI Search	Stores your searchable content (text and vectors) with semantic configuration
Semantic ranker	Azure AI Search	Required component that reranks results for relevance (L2 reranking)

Integration requirements

Your application drives the pipeline by calling the knowledge base and handling the response. The pipeline returns grounding data that you pass to an LLM for answer generation in your

conversation interface. For implementation details, see [Tutorial: Build an end-to-end agentic retrieval solution](#).

! Note

Only gpt-4o, gpt-4.1, and gpt-5 series models are supported for query planning. You can use any model for final answer generation.

How to get started

To create an agentic retrieval solution, you must use a preview REST API version or a prerelease Azure SDK package that provides the functionality.

Currently, Azure portal support for agentic retrieval is limited to the 2025-08-01-preview. We recommend using a programmatic approach to access the latest features.

Quickstarts

- [Quickstart: Use agentic retrieval in Azure AI Search](#)
 - This quickstart supports C#, Java, JavaScript, Python, TypeScript, and REST.
- [Quickstart: Use agentic retrieval in the Azure portal](#)
 - The portal uses the 2025-08-01-preview, which uses the previous "knowledge agent" terminology and doesn't support all 2025-11-01-preview features. Breaking changes apply to objects created in this quickstart.

Availability and pricing

Agentic retrieval is available in [selected regions](#). Knowledge sources and knowledge bases also have [maximum limits](#) that vary by service tier.

It has a dependency on premium features. If you disable semantic ranker for your search service, you effectively disable agentic retrieval.

[] [Expand table](#)

Plan	Description
Free	A free tier search service provides 50 million free agentic reasoning tokens per month. On higher tiers, you can choose between the free plan (default) and the standard plan.

Plan	Description
Standard	The standard plan is pay-as-you-go pricing once the monthly free quota is consumed. After the free quota is used up, you are charged an additional fee for each additional one million agentic reasoning tokens. You aren't notified when the transition occurs. For more information about charges by currency, see the Azure AI Search pricing page .

Token-based billing for LLM-based query planning and [answer synthesis](#) (optional) is pay-as-you-go in Azure OpenAI. It's token based for both input and output tokens. The model you assign to the knowledge base is the one [charged for token usage](#). For example, if you use gpt-4o, the token charge appears in the bill for gpt-4o.

Token-based billing for agentic retrieval is the number of tokens returned by each subquery.

 [Expand table](#)

Aspect	Classic single-query pipeline	Agentic retrieval multi-query pipeline
Unit	Query based (1,000 queries) per unit of currency	Token based (1 million tokens per unit of currency)
Cost per unit	Uniform cost per query	Uniform cost per token
Cost estimation	Estimate query count	Estimate token usage
Free tier	1,000 free queries	50 million free tokens

Example: Estimate costs

Agentic retrieval has two billing models: billing from Azure OpenAI (query planning and, if enabled, answer synthesis) and billing from Azure AI Search for agentic retrieval.

This pricing example omits answer synthesis, but helps illustrate the estimation process. Your costs could be lower. For the actual price of transactions, see [Azure OpenAI pricing](#).

Estimated billing costs for query planning

To estimate the query plan costs as pay-as-you-go in Azure OpenAI, let's assume gpt-4o-mini:

- 15 cents for 1 million input tokens.
- 60 cents for 1 million output tokens.
- 2,000 input tokens for average chat conversation size.
- 350 tokens for average output plan size.

Estimated billing costs for query execution

To estimate agentic retrieval token counts, start with an idea of what an average document in your index looks like. For example, you might approximate:

- 10,000 chunks, where each chunk is one to two paragraphs of a PDF.
- 500 tokens per chunk.
- Each subquery reranks up to 50 chunks.
- On average, there are three subqueries per query plan.

Calculating price of execution

1. Assume we make 2,000 agentic retrievals with three subqueries per plan. This gives us about 6,000 total queries.
2. Rerank 50 chunks per subquery, which is 300,000 total chunks.
3. Average chunk is 500 tokens, so the total tokens for reranking is 150 million.
4. Given a hypothetical price of 0.022 per token, \$3.30 is the total cost for reranking in US dollars.
5. Moving on to query plan costs: 2,000 input tokens multiplied by 2,000 agentic retrievals equal 4 million input tokens for a total of 60 cents.
6. Estimate the output costs based on an average of 350 tokens. If we multiply 350 by 2,000 agentic retrievals, we get 700,000 output tokens total for a total of 42 cents.

Putting it all together, you'd pay about \$3.30 for agentic retrieval in Azure AI Search, 60 cents for input tokens in Azure OpenAI, and 42 cents for output tokens in Azure OpenAI, for \$1.02 for query planning total. The combined cost for the full execution is \$4.32.

Last updated on 11/18/2025

Full text search in Azure AI Search

Article • 03/07/2025

Full text search is an approach in information retrieval that matches on plain text stored in an index. For example, given a query string "hotels in San Diego on the beach", the search engine looks for tokenized strings based on those terms. To make scans more efficient, query strings undergo lexical analysis: lower-casing all terms, removing stop words like "the", and reducing terms to primitive root forms. When matching terms are found, the search engine retrieves documents, ranks them in order of relevance, and returns the top results.

Query execution can be complex. This article is for developers who need a deeper understanding of how full text search works in Azure AI Search. For text queries, Azure AI Search seamlessly delivers expected results in most scenarios, but occasionally, you might get a result that seems "off" somehow. In these situations, having a background in the four stages of Lucene query execution (query parsing, lexical analysis, document matching, and scoring) can help you identify specific changes to query parameters or index configuration that produce the desired outcome.

ⓘ Note

Azure AI Search uses [Apache Lucene](#) for full text search, but Lucene integration isn't exhaustive. We selectively expose and extend Lucene functionality to enable the scenarios important to Azure AI Search.

Architecture overview and diagram

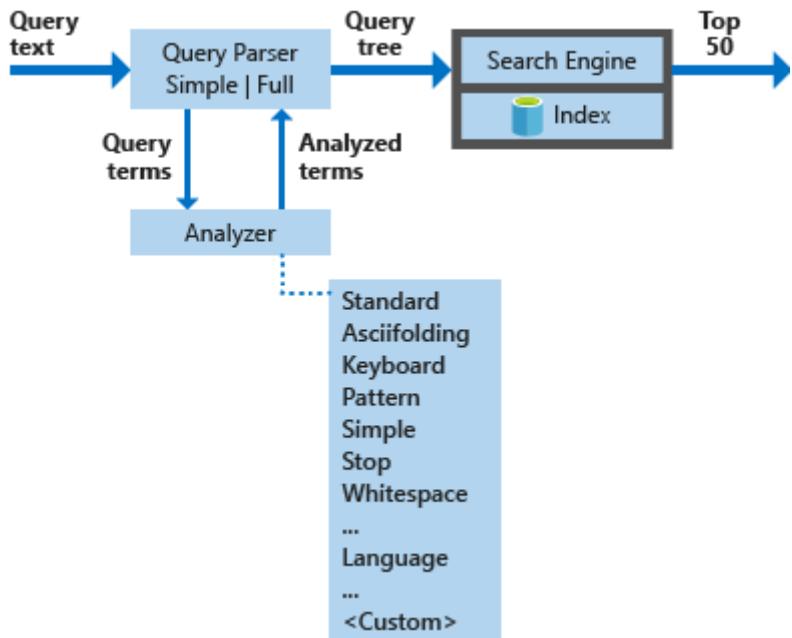

Query execution has four stages:

1. Query parsing
2. Lexical analysis
3. Document retrieval
4. Scoring

A full text search query starts with parsing the query text to extract search terms and operators. There are two parsers so that you can choose between speed and complexity. An analysis phase is next, where individual query terms are sometimes broken down and reconstituted into new forms. This step helps to cast a broader net over what could be considered as a potential match. The search engine then scans the index to find documents with matching terms and scores each match. A result set is then sorted by a

relevance score assigned to each individual matching document. Those at the top of the ranked list are returned to the calling application.

The following diagram illustrates the components used to process a search request:

[] Expand table

Key components	Functional description
Query parsers	Separate query terms from query operators and create the query structure (a query tree) to be sent to the search engine.
Analyzers	Perform lexical analysis on query terms. This process can involve transforming, removing, or expanding query terms.
Index	An efficient data structure used to store and organize searchable terms extracted from indexed documents.
Search engine	Retrieves and scores matching documents based on the contents of the inverted index.

Anatomy of a search request

A search request is a complete specification of what should be returned in a result set. In its simplest form, it's an empty query with no criteria of any kind. A more realistic example includes parameters, several query terms, perhaps scoped to certain fields, with possibly a filter expression and ordering rules.

The following example is a search request you might send to Azure AI Search using the [REST API](#):

```
POST /indexes/hotels/docs/search?api-version=2024-07-01
{
  "search": "Spacious, air-condition* +\"Ocean view\"",
  "searchFields": "description, title",
  "searchMode": "any",
  "filter": "price ge 60 and price lt 300",
  "orderby": "geo.distance(location, geography'POINT(-159.476235
22.227659)'),",
  "queryType": "full"
}
```

For this request, the search engine does the following operations:

1. Finds documents where the price is at least \$60 and less than \$300.
2. Executes the query. In this example, the search query consists of phrases and terms: "Spacious, air-condition* +\"Ocean view\"" (Users typically don't enter punctuation, but by including it in the example, we can explain how analyzers handle it.)

For this query, the search engine scans the description and title fields specified in "searchFields" for documents that contain "Ocean view", and additionally on the term "spacious", or on terms that start with the prefix "air-condition". The "searchMode" parameter is used to match on any term (default) or all of them, for cases where a term isn't explicitly required (+).

3. Orders the resulting set of hotels by proximity to a given geography location, and then returns the results to the calling application.

Most of this article is about processing of the *search query*: "Spacious, air-condition* +\"Ocean view\"". Filtering and ordering are out of scope. For more information, see the [Search API reference documentation](#).

Stage 1: Query parsing

As noted, the query string is the first line of the request:

```
"search": "Spacious, air-condition* +\"Ocean view\"",
```

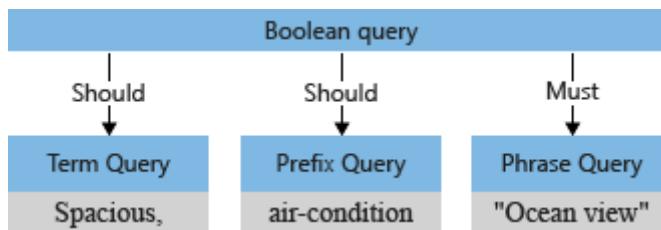

The query parser separates operators (such as `*` and `+` in the example) from search terms and deconstructs the search query into *subqueries* of a supported type:

- *term query* for standalone terms (like `spacious`)
- *phrase query* for quoted terms (like `ocean view`)
- *prefix query* for terms followed by a prefix operator `*` (like `air-condition`)

For a full list of supported query types, see [Lucene query syntax](#).

Operators associated with a subquery determine whether the query "must be" or "should be" satisfied in order for a document to be considered a match. For example, `+"Ocean view"` is "must" due to the `+` operator.

The query parser restructures the subqueries into a *query tree* (an internal structure representing the query), which it passes to the search engine. In the first stage of query parsing, the query tree looks like this:

Supported parsers: Simple and Full Lucene

Azure AI Search exposes two different query languages: `simple` (default) and `full`. By setting the `queryType` parameter with your search request, you tell the query parser which query language you choose so that it knows how to interpret the operators and syntax.

- The [Simple query language](#) is intuitive and robust, often suitable for interpreting user input as-is without client-side processing. It supports query operators familiar from web search engines.
- The [Full Lucene query language](#), which you get by setting `queryType=full`, extends the default Simple query language by adding support for more operators and query types like wildcard, fuzzy, regex, and field-scoped queries. For example, a regular expression sent in Simple query syntax would be interpreted as a query string and not an expression. The example request in this article uses the Full Lucene query language.

Impact of searchMode on the parser

Another search request parameter that affects parsing is the "searchMode" parameter. It controls the default operator for Boolean queries: any (default) or all.

When "searchMode=any", which is the default, the space delimiter between spacious and air-condition is OR (||), making the sample query text equivalent to:

```
Spacious, ||air-condition*+"Ocean view"
```

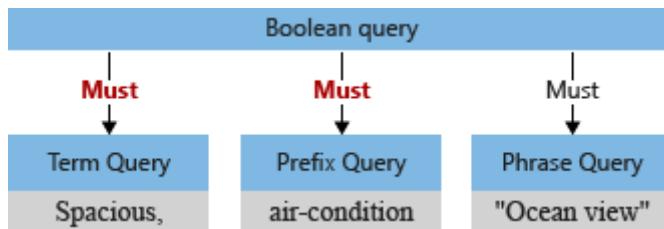

Explicit operators, such as + in +"Ocean view", are unambiguous in boolean query construction (the term *must* match). Less obvious is how to interpret the remaining terms: spacious and air-condition. Should the search engine find matches on ocean view *and* spacious *and* air-condition? Or should it find ocean view plus *either one* of the remaining terms?

By default ("searchMode=any"), the search engine assumes the broader interpretation. Either field *should* be matched, reflecting "or" semantics. The initial query tree illustrated previously, with the two "should" operations, shows the default.

Suppose that we now set "searchMode=all". In this case, the space is interpreted as an "and" operation. Both of the remaining terms must be present in the document to qualify as a match. The resulting sample query would be interpreted like this:

```
+Spacious,+air-condition*+"Ocean view"
```

A modified query tree for this query, where a matching document is the intersection of all three subqueries, would look like this:

① Note

Choosing "searchMode=any" over "searchMode=all" is a decision best made by running representative queries. Users who are likely to include operators (common when searching document stores) might find results more intuitive if

"searchMode=all" informs boolean query constructs. For more information about the interplay between "searchMode" and operators, see [Simple query syntax](#).

Stage 2: Lexical analysis

Lexical analyzers process *term queries* and *phrase queries* after the query tree is structured. An analyzer accepts the text inputs given to it by the parser, processes the text, and then sends back tokenized terms to be incorporated into the query tree.

The most common form of lexical analysis is *linguistic analysis*, which transforms query terms based on rules specific to a given language. This involves:

- Reducing a query term to the root form of a word.
- Removing non-essential words ([stopwords](#), such as "the" or "and" in English).
- Breaking a composite word into component parts.
- Lowercasing an uppercase word.

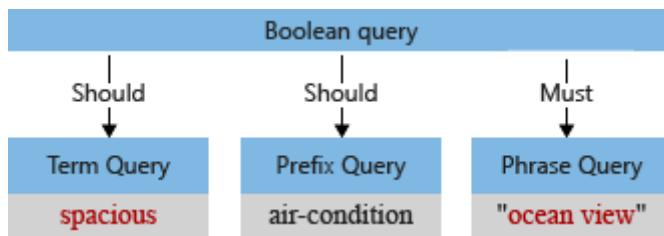

All of these operations tend to erase differences between the text input provided by the user and the terms stored in the index. Such operations go beyond text processing and require in-depth knowledge of the language itself. To add this layer of linguistic awareness, Azure AI Search supports a long list of [language analyzers](#) from both Lucene and Microsoft.

Note

Depending on your scenario, analysis requirements can range from minimal to elaborate. You can control the complexity of lexical analysis by selecting one of the predefined analyzers or by creating your own [custom analyzer](#). Analyzers are scoped to searchable fields and are specified as part of a field definition. This allows you to vary lexical analysis on a per-field basis. If unspecified, the *standard* Lucene analyzer is used.

In our example, prior to analysis, the initial query tree has the term "Spacious," with an uppercase "S" and a comma that the query parser interprets as a part of the query term (a comma isn't considered a query language operator).

When the default analyzer processes the term, it will lowercase "ocean view" and "spacious" and remove the comma character. The modified query tree looks like this:

Testing analyzer behaviors

The behavior of an analyzer can be tested using the [Analyze API](#). Provide the text you want to analyze to see what terms the given analyzer generates. For example, to see how the standard analyzer would process the text "air-condition", you can issue the following request:

JSON

```
{
  "text": "air-condition",
  "analyzer": "standard"
}
```

The standard analyzer breaks the input text into the following two tokens, annotating them with attributes like start and end offsets (used for hit highlighting) as well as their position (used for phrase matching):

JSON

```
{
  "tokens": [
    {
      "token": "air",
      "startOffset": 0,
      "endOffset": 3,
      "position": 0
    },
    {
      "token": "condition",
      "startOffset": 4,
      "endOffset": 13,
      "position": 1
    }
  ]
}
```

Exceptions to lexical analysis

Lexical analysis applies only to query types that require complete terms, either a term query or a phrase query. It doesn't apply to query types with incomplete terms—prefix query, wildcard query, and regex query—or to a fuzzy query. Those query types, including the prefix query with the term `air-condition*` in our example, are added directly to the query tree, bypassing the analysis stage. The only transformation performed on query terms of those types is lowercasing.

Stage 3: Document retrieval

Document retrieval refers to finding documents with matching terms in the index. This stage is best understood through an example. Let's start with a hotels index that has the following simple schema:

```
JSON

{
    "name": "hotels",
    "fields": [
        { "name": "id", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "title", "type": "Edm.String", "searchable": true },
        { "name": "description", "type": "Edm.String", "searchable": true }
    ]
}
```

Further assume that this index contains the following four documents:

```
JSON

{
    "value": [
        {
            "id": "1",
            "title": "Hotel Atman",
            "description": "Spacious rooms, ocean view, walking distance to
the beach."
        },
        {
            "id": "2",
            "title": "Beach Resort",
            "description": "Located on the north shore of the island of
Kaua'i. Ocean view."
        },
        {
            "id": "3",
            "title": "Playa Hotel",
            "description": "Comfortable, air-conditioned rooms with ocean
view."
        }
    ]
}
```

```
    },
    {
        "id": "4",
        "title": "Ocean Retreat",
        "description": "Quiet and secluded"
    }
]
```

How terms are indexed

To understand retrieval, it helps to know a few basics about indexing. The unit of storage is an inverted index, one for each searchable field. Within an inverted index is a sorted list of all terms from all documents. Each term maps to the list of documents in which it occurs, as evident in the example below.

To produce the terms in an inverted index, the search engine performs lexical analysis over the content of documents, similar to what happens during query processing:

1. *Text inputs* are passed to an analyzer, lowercased, stripped of punctuation, and so forth, depending on the analyzer configuration.
2. *Tokens* are the output of lexical analysis.
3. *Terms* are added to the index.

It's common, but not required, to use the same analyzers for search and indexing operations so that query terms look more like terms inside the index.

ⓘ Note

Azure AI Search lets you specify different analyzers for indexing and search via additional `indexAnalyzer` and `searchAnalyzer` field parameters. If unspecified, the analyzer set with the `analyzer` property is used for both indexing and searching.

Inverted index for example documents

Returning to our example, for the `title` field, the inverted index looks like this:

[+] [Expand table](#)

Term	Document list
atman	1

Term	Document list
beach	2
hotel	1, 3
ocean	4
playa	3
resort	3
retreat	4

In the title field, only *hotel* shows up in two documents: 1 and 3.

For the **description** field, the index looks like this:

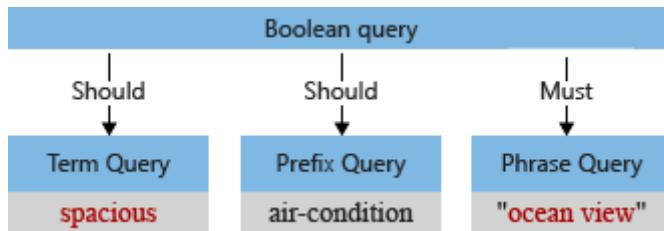

[\[\] Expand table](#)

Term	Document list
air	3
and	4
beach	1
conditioned	3
comfortable	3
distance	1
island	2
kaua'i	2
located	2
north	2
ocean	1, 2, 3
of	2
on	2
quiet	4
rooms	1, 3

Term	Document list
secluded	4
shore	2
spacious	1
the	1, 2
to	1
view	1, 2, 3
walking	1
with	3

Matching query terms against indexed terms

Given the inverted indexes above, let's return to the sample query and see how matching documents are found for our example query. Recall that the final query tree looks like this:

During query execution, individual queries are executed against the searchable fields independently.

- The TermQuery, "spacious", matches document 1 (Hotel Atman).
- The PrefixQuery, "air-condition*", doesn't match any documents.

This behavior sometimes confuses developers. Although the term air-conditioned exists in the document, it's split into two terms by the default analyzer. Recall that prefix queries, which contain partial terms, aren't analyzed. Therefore, terms with the prefix "air-condition" are looked up in the inverted index and not found.

- The PhraseQuery, "ocean view", looks up the terms "ocean" and "view" and checks the proximity of terms in the original document. Documents 1, 2, and 3 match this query in the description field. Notice document 4 has the term "ocean" in the title but isn't considered a match, as we're looking for the "ocean view" phrase rather than individual words.

Note

A search query is executed independently against all searchable fields in the Azure AI Search index unless you limit the fields set with the `searchFields` parameter, as illustrated in the example search request. Documents that match in any of the selected fields are returned.

On the whole, for the query in question, the documents that match are 1, 2, and 3.

Stage 4: Scoring

Every document in a search result set is assigned a relevance score. The function of the relevance score is to rank higher those documents that best answer a user question as expressed by the search query. The score is computed based on statistical properties of terms that matched. At the core of the scoring formula is [term frequency-inverse document frequency](#) (TF/IDF). In queries containing rare and common terms, TF/IDF promotes results containing the rare term. For example, in a hypothetical index with all Wikipedia articles, from documents that matched the query *the president*, documents matching on *president* are considered more relevant than documents matching on *the*.

Scoring example

Recall the three documents that matched our example query:

```
search=Spacious, air-condition* +"Ocean view"
```

JSON

```
{
  "value": [
    {
      "@search.score": 0.25610128,
      "id": "1",
      "title": "Hotel Atman",
      "description": "Spacious rooms, ocean view, walking distance to the beach."
    },
    {
      "@search.score": 0.08951007,
      "id": "3",
      "title": "Playa Hotel",
      "description": "Comfortable, air-conditioned rooms with ocean view."
```

```
        },
        {
            "@search.score": 0.05967338,
            "id": "2",
            "title": "Ocean Resort",
            "description": "Located on a cliff on the north shore of the island of Kauai. Ocean view."
        }
    ]
}
```

Document 1 matched the query best because both the term *spacious* and the required phrase *ocean view* occur in the description field. The next two documents match only the phrase *ocean view*. You might be surprised that the relevance scores for documents 2 and 3 are different, even though they matched the query in the same way. That's because the scoring formula has more components than just TF/IDF. In this case, document 3 was assigned a slightly higher score because its description is shorter. Learn about [Lucene's Practical Scoring Formula](#) ↗ to understand how field length and other factors can influence the relevance score.

Some query types (wildcard, prefix, and regex) always contribute a constant score to the overall document score. This allows matches found through query expansion to be included in the results without affecting the ranking.

An example illustrates why this matters. Wildcard searches, including prefix searches, are ambiguous by definition because the input is a partial string with potential matches on a very large number of disparate terms. Consider an input of "tour*", with matches found on "tours", "tourettes", and "tourmaline". Given the nature of these results, there's no way to reasonably infer which terms are more valuable than others. For this reason, we ignore term frequencies when scoring results in queries of types wildcard, prefix, and regex. In a multi-part search request that includes partial and complete terms, results from the partial input are incorporated with a constant score to avoid bias towards potentially unexpected matches.

Relevance tuning

There are two ways to tune relevance scores in Azure AI Search:

- **Scoring profiles** promote documents in the ranked list of results based on a set of rules. In our example, we could consider documents that matched in the title field more relevant than documents that matched in the description field. Additionally, if our index had a price field for each hotel, we could promote documents with lower prices. Learn more about [adding scoring profiles to a search index](#).

- **Term boosting** (available only in the Full Lucene query syntax) provides a boosting operator `^` that can be applied to any part of the query tree. In our example, instead of searching on the prefix `air-condition*`, one could search for either the exact term `air-condition` or the prefix, but documents that match on the exact term are ranked higher by applying boost to the term query: `air-condition^2||air-condition*`. Learn more about [term boosting in a query](#).

Scoring in a distributed index

All indexes in Azure AI Search are automatically split into multiple shards, allowing us to quickly distribute the index among multiple nodes during service scale up or scale down. When a search request is issued, it's issued against each shard independently. The results from each shard are then merged and ordered by score (if no other ordering is defined). It's important to know that the scoring function weights query term frequency against its inverse document frequency in all documents within the shard, not across all shards!

This means a relevance score *could* be different for identical documents if they reside on different shards. Fortunately, such differences tend to disappear as the number of documents in the index grows due to more even term distribution. It's not possible to assume on which shard any given document will be placed. However, assuming a document key doesn't change, it will always be assigned to the same shard.

In general, document score isn't the best attribute for ordering documents if order stability is important. For example, given two documents with an identical score, there's no guarantee that one appears first in subsequent runs of the same query. Document score should only give a general sense of document relevance relative to other documents in the results set.

Conclusion

The success of commercial search engines has raised expectations for full text search over private data. For almost any kind of search experience, we now expect the engine to understand our intent, even when terms are misspelled or incomplete. We might even expect matches based on near equivalent terms or synonyms that we never specified.

From a technical standpoint, full text search is highly complex, requiring sophisticated linguistic analysis and a systematic approach to processing in ways that distill, expand, and transform query terms to deliver a relevant result. Given the inherent complexities, there are many factors that can affect the outcome of a query. For this reason, investing

the time to understand the mechanics of full text search offers tangible benefits when trying to work through unexpected results.

This article explored full text search in the context of Azure AI Search. We hope it gives you sufficient background to recognize potential causes and resolutions for addressing common query problems.

Next steps

- Build the sample index, try out different queries, and review results. For instructions, see [Build and query an index in the Azure portal](#).
- Try other query syntax from the [Search Documents](#) example section or from [Simple query syntax](#) in Search explorer in the Azure portal.
- Review [scoring profiles](#) if you want to tune ranking in your search application.
- Apply [language-specific lexical analyzers](#).
- [Configure custom analyzers](#) for either minimal processing or specialized processing on specific fields.

Vector search in Azure AI Search

Vector search is an information retrieval approach that supports indexing and querying over numeric representations of content. Because the content is numeric rather than plain text, matching is based on vectors that are most similar to the query vector, which enables matching across:

- Semantic or conceptual likeness. For example, "dog" and "canine" are conceptually similar but linguistically distinct.
- Multilingual content, such as "dog" in English and "hund" in German.
- Multiple content types, such as "dog" in plain text and an image of a dog.

This article provides an overview of vector search in Azure AI Search, including supported scenarios, availability, and integration with other Azure services.

Tip

Want to get started right away? Follow these steps:

1. [Provide embeddings](#) for your index or [generate embeddings](#) in an indexer pipeline.
2. [Create a vector index](#).
3. [Run vector queries](#).

What scenarios can vector search support?

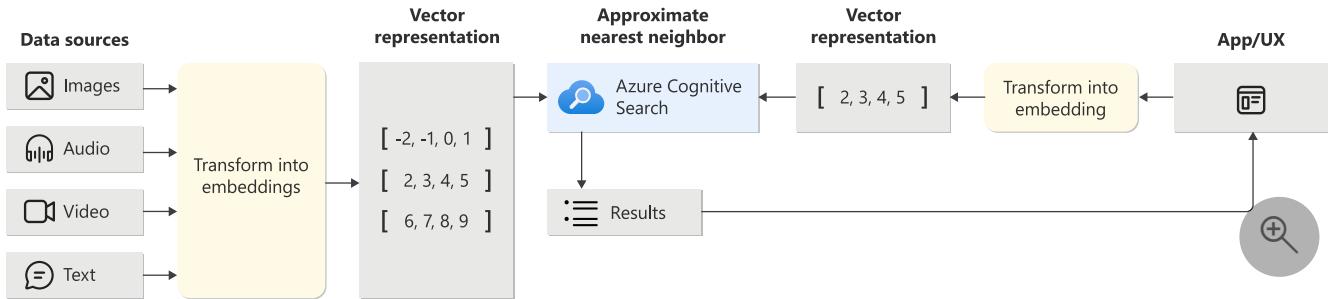

Vector search supports the following scenarios:

- **Similarity search.** Encode text using embedding models or open-source models, such as OpenAI embeddings or SBERT, respectively. You then retrieve documents using queries that are also encoded as vectors.
- **Hybrid search.** Azure AI Search defines hybrid search as the execution of vector search and [keyword search](#) in the same request. Vector support is implemented at the field level. If an index contains vector and nonvector fields, you can write a query that targets both. The queries execute in parallel, and the results are merged into a single response and ranked accordingly.
- **Multimodal search.** Encode text and images using multimodal embeddings, such as [OpenAI CLIP](#) or [GPT-4 Turbo with Vision](#) in Azure OpenAI, and then query an embedding space composed of vectors from both content types.

- **Multilingual search.** Azure AI Search is designed for extensibility. If you have embedding models and chat models trained in multiple languages, you can call them through custom or built-in skills on the indexing side or vectorizers on the query side. For more control over text translation, use the [multi-language capabilities](#) supported by Azure AI Search for nonvector content in hybrid search scenarios.
- **Filtered vector search.** A query request can include a vector query and a [filter expression](#). Filters apply to text and numeric fields. They're useful for metadata filters and for including or excluding search results based on filter criteria. Although a vector field isn't filterable, you can set up a filterable text or numeric field. The search engine can process the filter before or after executing the vector query.
- **Vector database.** Azure AI Search stores the data that you query over. Use it as a [pure vector index](#) when you need long-term memory or a knowledge base, grounding data for the [retrieval-augmented generation \(RAG\)](#) architecture, or an app that uses vectors.

How does vector search work?

Azure AI Search supports indexing, storing, and querying vector embeddings from a search index. The following diagram shows the indexing and query workflows for vector search.

On the indexing side, Azure AI Search uses a [nearest neighbors algorithm](#) to place similar vectors close together in an index. Internally, it creates [vector indexes](#) for each vector field.

How you get embeddings from your source content into Azure AI Search depends on your processing approach:

- For internal processing, Azure AI Search offers [integrated data chunking and vectorization](#) in an indexer pipeline. You provide the necessary resources, such as endpoints and connection information for Azure OpenAI. Azure AI Search then makes the calls and handles the transitions. This approach requires an indexer, a supported data source, and a skillset that drives chunking and embedding.
- For external processing, you can [generate embeddings](#) outside of Azure AI Search and push the prevectorized content directly into [vector fields](#) in your search index.

On the query side, your client app collects user input, typically through a prompt. You can add an encoding step to vectorize the input and then send the vector query to your Azure AI Search index for similarity search. As with indexing, you can use [integrated vectorization](#) to encode the query. For either approach, Azure AI Search returns documents with the requested k nearest neighbors (kNN) in the results.

Azure AI Search supports [hybrid scenarios](#) that run vector and keyword search in parallel and return a unified result set, which often provides better results than vector or keyword search alone. For hybrid search, both vector and nonvector content are ingested into the same index for queries that run simultaneously.

Availability and pricing

Vector search is available in [all regions](#) and on [all tiers](#) at no extra charge. However, generating embeddings or using AI enrichment for vectorization might incur charges from the model provider.

For portal and programmatic access to vector search, you can use:

- The [Import data \(new\) wizard](#) in the Azure portal.
- The [Search Service REST APIs](#).
- The Azure SDKs for [.NET](#), [Python](#), and [JavaScript](#).
- [Other Azure offerings](#), such as Microsoft Foundry.

! Note

- Some search services created before January 1, 2019 don't support vector workloads. If you try to add a vector field to a schema and get an error, it's a result of outdated services. In this situation, you must create a new search service to try out the vector feature.
- Search services created after April 3, 2024 offer [higher quotas for vector indexes](#). If you have an older service, you might be able to [upgrade your service](#) for higher vector quotas.

Azure integration and related services

Azure AI Search is deeply integrated across the Azure AI platform. The following table lists products that are useful in vector workloads.

Product	Integration
Azure OpenAI	Azure OpenAI provides embedding models and chat models. Demos and samples target the text-embedding-ada-002 model. We recommend Azure OpenAI for generating embeddings for text.
Foundry Tools	Image Retrieval Vectorize Image API supports vectorization of image content. We recommend this API for generating embeddings for images.
Foundry Agent Service	In Azure AI Search, you can create an <i>indexed knowledge source</i> that points to a search index containing vector fields and a vectorizer. You can then parent the knowledge source to a <i>knowledge base</i> and connect the knowledge base to Foundry Agent Service , providing your agents with vector search results for enhanced knowledge retrieval.
Azure data platforms: Azure Blob Storage, Azure Cosmos DB, Azure SQL, Microsoft OneLake	You can use indexers to automate data ingestion, and then use integrated vectorization to generate embeddings. Azure AI Search can automatically index vector data from Azure blob indexers , Azure Cosmos DB for NoSQL indexers , Azure Data Lake Storage Gen2 , Azure Table Storage , and Microsoft OneLake . For more information, see Add vector fields to a search index..

It's also commonly used in open-source frameworks like [LangChain](#).

Hybrid search using vectors and full text in Azure AI Search

A hybrid search is a single query request configured for both full-text and vector queries. It executes against a search index that contains searchable, plain-text content and generated embeddings. For query purposes, hybrid search:

- Is a single query request that includes both `search` and `vectors` query parameters.
- Executes full-text search and vector search in parallel.
- Merges results from each query using [Reciprocal Rank Fusion \(RRF\)](#).

This article explains the concepts, benefits, and limitations of hybrid search. Links at the end provide usage instructions and next steps. You can also watch the [embedded video](#) for an explanation of how hybrid retrieval contributes to high-quality generative search applications.

Why use hybrid search?

Hybrid search combines the strengths of vector search and keyword search. The advantage of vector search is finding information that's conceptually similar to your search query, even if there are no keyword matches in the inverted index. The advantage of keyword or full-text search is precision, with the ability to apply optional semantic ranking that improves the quality of the initial results. Some scenarios, such as querying over product codes, highly specialized jargon, dates, and people's names, can perform better with keyword search because it can identify exact matches.

Benchmark testing on real-world and benchmark datasets indicates that hybrid retrieval with semantic ranker offers significant benefits in search relevance.

The following video explains how hybrid retrieval gives you optimal grounding data for generating useful AI responses.

<https://www.youtube-nocookie.com/embed/Xwx1DJ0qCk> ↗

How does hybrid search work?

In a search index, vector fields containing embeddings coexist with textual and numerical fields, allowing you to formulate hybrid queries that execute simultaneously. Hybrid queries take advantage of existing text-based functionality like filtering, facetting, sorting, scoring profiles, and [semantic ranking](#) on your text fields, while executing a similarity search against vectors in a single search request.

Hybrid search combines results from both full-text and vector queries, which use different ranking functions such as BM25 for text, and Hierarchical Navigable Small World (HNSW) and exhaustive K Nearest Neighbors (eKNN) for vectors. An [RRF](#) algorithm merges the results. The query response provides just one result set, using RRF to rank the unified results.

Structure of a hybrid query

Hybrid search relies on a search index that contains fields of various [data types](#), including plain text and numbers, geo coordinates if you want geospatial search, and vectors to mathematically represent a chunk of text. You can use almost all query capabilities in Azure AI Search with a vector query, except for pure text client-side interactions, such as autocomplete and suggestions.

A representative hybrid query might look like the following. For brevity, the vector queries have placeholder values.

HTTP

```
POST https://{{searchServiceName}}.search.windows.net/indexes/hotels-vector-quickstart/docs/search?api-version=2025-09-01
content-type: application/JSON

{
    "count": true,
    "search": "historic hotel walk to restaurants and shopping",
    "select": "HotelId, HotelName, Category, Description, Address/City, Address/StateProvince",
    "filter": "geo.distance(Location, geography'POINT(-77.03241 38.90166)') le 300",
    "vectorFilterMode": "postFilter",
    "facets": [ "Address/StateProvince"],
    "vectorQueries": [
        {
            "kind": "vector",
            "vector": [ <array of embeddings> ]
            "k": 50,
            "fields": "DescriptionVector",
            "exhaustive": true,
            "oversampling": 20
        },
        {
            "kind": "vector",
            "vector": [ <array of embeddings> ]
            "k": 50,
            "fields": "Description_frVector",
            "exhaustive": false,
            "oversampling": 10
        }
    ],
    "skip": 0,
```

```
"top": 10,  
"queryType": "semantic",  
"queryLanguage": "en-us",  
"semanticConfiguration": "my-semantic-config"  
}
```

Key points:

- `search` specifies a single full-text search query.
- `vectorQueries` specifies vector queries, which can be multiple, targeting multiple vector fields. If the embedding space includes multi-lingual content, vector queries can find the match with no language analyzers or translation required. If you're using semantic ranker, set `k` to 50 to maximize its inputs.
- `select` specifies which fields to return in results, which should be human-readable text fields if you're showing them to users or sending them to a large language model (LLM).
- `filters` can specify geospatial search or other inclusion and exclusion criteria, such as whether parking is included. The geospatial query in this example finds hotels within a 300-kilometer radius of Washington D.C. You can apply the filter at the beginning or end of query processing. If you're using semantic ranker, you probably want post-filtering as the last step, but you should test to confirm which behavior is best for your queries.
- `facets` can be used to compute facet buckets over results that are returned from hybrid queries.
- `queryType=semantic` invokes [semantic ranker](#), applying machine reading comprehension to surface more relevant search results. Semantic ranking is optional. If you aren't using this feature, remove the last three lines of the hybrid query.

Filters and facets target data structures within the index that are distinct from the inverted indexes used for full-text search and the vector indexes used for vector search. As such, when filters and faceted operations execute, the search engine can apply the operational result to the hybrid search results in the response.

Notice how there's no `orderby` in the query. Explicit sort orders override relevanced-ranked results, so if you want similarity and BM25 relevance, omit sorting in your query.

A response from the query might look like the following JSON.

JSON

```
{  
  "@odata.count": 3,  
  "@search.facets": {  
    "Address/StateProvince": [  
      {  
        "count": 1,  
        "value": "NY"
```

```

        },
        {
            "count": 1,
            "value": "VA"
        }
    ]
},
"value": [
{
    "@search.score": 0.03333333507180214,
    "@search.rerankerScore": 2.5229012966156006,
    "HotelId": "49",
    "HotelName": "Swirling Currents Hotel",
    "Description": "Spacious rooms, glamorous suites and residences, rooftop pool, walking access to shopping, dining, entertainment and the city center.",
    "Category": "Luxury",
    "Address": {
        "City": "Arlington",
        "StateProvince": "VA"
    }
},
{
    "@search.score": 0.032522473484277725,
    "@search.rerankerScore": 2.111117362976074,
    "HotelId": "48",
    "HotelName": "Nordick's Valley Motel",
    "Description": "Only 90 miles (about 2 hours) from the nation's capital and nearby most everything the historic valley has to offer. Hiking? Wine Tasting? Exploring the caverns? It's all nearby and we have specially priced packages to help make our B&B your home base for fun while visiting the valley.",
    "Category": "Boutique",
    "Address": {
        "City": "Washington D.C.",
        "StateProvince": null
    }
}
]
}

```

Multimodal search in Azure AI Search

Multimodal search refers to the ability to ingest, understand, and retrieve information across multiple content types, including text, images, video, and audio. In Azure AI Search, multimodal search natively supports the ingestion of documents containing text and images and the retrieval of their content, enabling you to perform searches that combine both modalities.

Building a robust multimodal pipeline typically involves:

1. Extracting inline images and page text from documents.
2. Describing images in natural language.
3. Embedding both text and images into a shared vector space.
4. Storing the images for later use as annotations.

Multimodal search also requires preserving the order of information as it appears in the documents and executing [hybrid queries](#) that combine [full-text search](#) with [vector search](#) and [semantic ranking](#).

In practice, an application that uses multimodal search can answer questions like "What is the process to have an HR form approved?" even when the only authoritative description of the process lives inside an embedded diagram in a PDF file.

Why use multimodal search?

Traditionally, multimodal search requires separate systems for text and image processing, often requiring custom code and low-level configurations from developers. Maintaining these systems incurs higher costs, complexity, and effort.

Azure AI Search addresses these challenges by integrating images into the same retrieval pipeline as text. With a single multimodal pipeline, you can simplify setup and unlock information that resides in charts, screenshots, infographics, scanned forms, and other complex visuals.

Multimodal search is ideal for [retrieval-augmented generation \(RAG\)](#) scenarios. By interpreting the structural logic of images, multimodal search makes your RAG application or AI agent less likely to overlook important visual details. It also provides your users with detailed answers that can be traced back to their original sources, regardless of the source's modality.

How does multimodal search work?

To simplify the creation of a multimodal pipeline, Azure AI Search offers the [Import data \(new\)](#) wizard in the Azure portal. The wizard helps you configure a data source, define extraction and enrichment settings, and generate a multimodal index that contains text, embedded image references, and vector embeddings. For more information, see [Quickstart: Multimodal search in the Azure portal](#).

The wizard follows these steps to create a multimodal pipeline:

- 1. Extract content:** Choose from the [Document Extraction skill](#), [Document Layout skill](#), or [Azure Content Understanding skill](#) to obtain page text, inline images, and structural metadata. Each skill offers different capabilities for metadata extraction, table handling, and file format support. For detailed comparisons, see [Options for multimodal content extraction](#).
- 2. Chunk text:** The [Text Split skill](#) breaks the extracted text into manageable chunks for use in the remaining pipeline, such as the embedding skill.
- 3. Generate image descriptions:** The [GenAI Prompt skill](#) verbalizes images, producing concise natural-language descriptions for text search and embedding using a large language model (LLM).
- 4. Generate embeddings:** The embedding skill creates vector representations of text and images, enabling similarity and hybrid retrieval. You can call [Azure OpenAI](#), [Microsoft Foundry](#), or [Azure Vision](#) embedding models natively.
Alternatively, you can skip image verbalization and pass the extracted text and images directly to a multimodal embedding model through the [AML skill](#) or [Azure Vision multimodal embeddings skill](#). For more information, see [Options for multimodal content embedding](#).
- 5. Store extracted images:** The [knowledge store](#) contains extracted images that can be returned directly to client applications. When you use the wizard, an image's location is stored directly in the multimodal index, enabling convenient retrieval at query time.

Tip

To see multimodal search in action, plug your wizard-created index into the [multimodal RAG sample application](#) ↗. The sample demonstrates how a RAG application consumes a multimodal index and renders both textual citations and associated image snippets in the response. The sample also showcases the code-based process of data ingestion and indexing.

Options for multimodal content extraction

A multimodal pipeline begins by cracking each source document into chunks of text, inline images, and associated metadata. For this step, Azure AI Search provides three built-in skills:

- Document Extraction skill
- Document Layout skill
- Azure Content Understanding skill

 Expand table

Characteristic	Document Extraction skill	Document Layout skill	Azure Content Understanding skill
Text location metadata extraction (pages and bounding polygons)	No	Yes	Yes
Image location metadata extraction (pages and bounding polygons)	Yes	Yes	Yes
Table extraction and preservation	No	No	Yes (including cross-page tables)
Cross-page semantic units	Not applicable	Single page only	Yes (spans page boundaries)
Location metadata extraction based on file type	PDFs only.	Multiple supported file types according to the Azure Document Intelligence in Foundry Tools layout model .	Multiple supported file types , including PDF, DOCX, XLSX, and PPTX.
Billing for data extraction	Image extraction is billed according to Azure AI Search pricing .	Billed according to Document Layout pricing .	Billed according to Azure Content Understanding pricing .
Built-in chunking	No (use Text Split skill)	Yes (based on paragraph boundaries)	Yes (semantic chunking)
Recommended scenarios	Rapid prototyping or production pipelines where the exact position or detailed	RAG pipelines and agent workflows that need precise page numbers, on-page	Advanced document analysis requiring cross-page table extraction, semantic chunking, or consistent handling across

Characteristic	Document Extraction skill	Document Layout skill	Azure Content Understanding skill
	layout information isn't required.	highlights, or diagram overlays in client apps.	document formats (PDF, DOCX, XLSX, PPTX).

Options for multimodal content embedding

In Azure AI Search, retrieving knowledge from images can follow two complementary paths: image verbalization or direct embeddings. Understanding the distinctions helps you align cost, latency, and answer quality with the needs of your application.

Image verbalization followed by text embeddings

With this method, the [GenAI Prompt skill](#) invokes an LLM during ingestion to create a concise natural-language description of each extracted image, such as "Five-step HR access workflow that begins with manager approval." The description is stored as text and embedded alongside the surrounding document text, which you can then vectorize by calling the [Azure OpenAI](#), [Microsoft Foundry](#), or [Azure Vision](#) embedding models.

Because the image is now expressed in language, Azure AI Search can:

- Interpret the relationships and entities shown in a diagram.
- Supply ready-made captions that an LLM can cite verbatim in a response.
- Return relevant snippets for RAG applications or AI agent scenarios with grounded data.

The added semantic depth entails an LLM call for every image and a marginal increase in indexing time.

Direct multimodal embeddings

A second option is to pass the document-extracted images and text to a multimodal embedding model that produces vector representations in the same vector space. Configuration is straightforward, and no LLM is required at indexing time. Direct embeddings are well suited to visual similarity and "find-me-something-that-looks-like-this" scenarios.

Because the representation is purely mathematical, it doesn't convey why two images are related, and it doesn't offer the LLM ready context for citations or detailed explanations.

Combining both approaches

Many solutions need both encoding paths. Diagrams, flow charts, and other explanation-rich visuals are verbalized so that semantic information is available for RAG and AI agent grounding. Screenshots, product photos, or artwork are embedded directly for efficient similarity search. You can customize your Azure AI Search index and indexer skillset pipeline so it can store the two sets of vectors and retrieve them side by side.

Options for querying multimodal content

If your multimodal pipeline is powered by the GenAI Prompt skill, you can run [hybrid queries](#) over both plain text and verbalized images in your search index. You can also use filters to narrow the search results to specific content types, such as only text or only images.

Although the GenAI Prompt skill supports text-to-vector queries via hybrid search, it doesn't support [image-to-vector queries](#). Only the multimodal embedding models provide the vectorizers that convert images into vectors at query time.

To use images as query inputs for your multimodal index, you must use the [AML skill](#) or [Azure Vision multimodal embeddings skill](#) with an equivalent vectorizer. For more information, see [Configure a vectorizer in a search index](#).

Tutorials and samples

Retrieval Augmented Generation (RAG) in Azure AI Search

10/15/2025

Retrieval Augmented Generation (RAG) is a design pattern that augments the capabilities of a chat completion model like ChatGPT by adding an information retrieval step, incorporating your proprietary enterprise content for answer formulation. For an enterprise solution, it's possible to fully constrain generative AI to your enterprise content.

The decision about which information retrieval system to use is critical because it determines the inputs to the LLM. The information retrieval system should provide:

- Indexing strategies that load and refresh at scale, for all of your content, at the frequency you require.
- Query capabilities and relevance tuning. The system should return *relevant* results, in the short-form formats necessary for meeting the token length requirements of large language model (LLM) inputs. Query turnaround should be as fast as possible.
- Security, global reach, and reliability for both data and operations.
- Integration with embedding models for indexing, and chat models or language understanding models for retrieval.

Azure AI Search is a [proven solution for information retrieval](#) in a RAG architecture. It provides indexing and query capabilities, with the infrastructure and security of the Azure cloud. Through code and other components, you can design a comprehensive RAG solution that includes all of the elements for generative AI over your proprietary content.

You can choose between two approaches for RAG workloads: agentic retrieval, or the original query architecture for classic RAG.

(!) Note

New to copilot and RAG concepts? Watch [Vector search and state of the art retrieval for Generative AI apps](#).

Modern RAG with agentic retrieval

Azure AI Search now provides **agentic retrieval**, a specialized pipeline designed specifically for RAG patterns. This approach uses large language models to intelligently break down complex

user queries into focused subqueries, executes them in parallel, and returns structured responses optimized for chat completion models.

Agentic retrieval represents the evolution from traditional single-query RAG patterns to multi-query intelligent retrieval, providing:

- Context-aware query planning using conversation history
- Parallel execution of multiple focused subqueries
- Structured responses with grounding data, citations, and execution metadata
- Built-in semantic ranking for optimal relevance
- Optional answer synthesis that uses an LLM-formulated answer in the query response.

You need new objects for this pipeline: one or more knowledge sources, a knowledge agent, and the retrieve action that you call from application code, such as a tool that works with your agent.

For new RAG implementations, we recommend starting with [agentic retrieval](#). For existing solutions, consider migrating to take advantage of improved accuracy and context understanding.

Classic RAG pattern for Azure AI Search

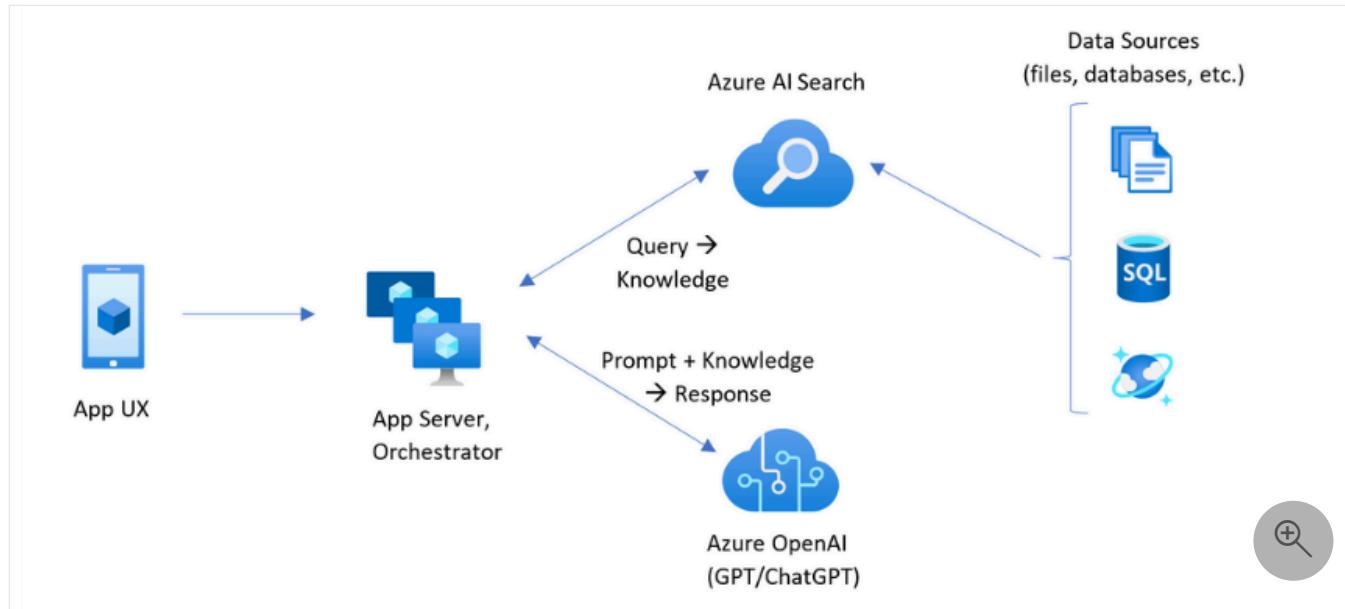

A RAG solution can be implemented on Azure AI Search using the original query execution architecture. With this approach, your application sends a single query request to Azure AI Search, the search engine processes the request, and returns search results to the caller. There's no side trip to an LLM for query planning or answer formulation. There's no query execution details in the response, and citations are built into the response only if you have fields in your index that provide a parent document name or page. This approach is faster and simpler with fewer components. Depending on your application requirements, it could be the best choice.

A high-level summary of classic RAG pattern built on Azure AI Search looks like this:

- Start with a user question or request (prompt).
- Send it as a query request to Azure AI Search to find relevant information.
- Return the top-ranked search results to an LLM.
- Use the natural language understanding and reasoning capabilities of the LLM to generate a response to the initial prompt.

Azure AI Search provides inputs to the LLM prompt, but doesn't train the model. In a traditional RAG pattern, there's no extra training. The LLM is pretrained using public data, but it generates responses that are augmented by information from the retriever, in this case, Azure AI Search.

RAG patterns that include Azure AI Search have the elements indicated in the following illustration.

- App UX (web app) for the user experience
- App server or orchestrator (integration and coordination layer)
- Azure AI Search (information retrieval system)
- Azure OpenAI (LLM for generative AI)

The web app provides the user experience, providing the presentation, context, and user interaction. Questions or prompts from a user start here. Inputs pass through the integration layer, going first to information retrieval to get the search results, but also go to the LLM to set the context and intent.

The app server or orchestrator is the integration code that coordinates the handoffs between information retrieval and the LLM. Common solutions include [Azure Semantic Kernel](#) or [LangChain](#) to coordinate the workflow. [LangChain integrates with Azure AI Search](#), making it easier to include Azure AI Search as a [retriever](#). [Llamaindex](#) and [Semantic Kernel](#) are other options.

The information retrieval system provides the searchable index, query logic, and the payload (query response). The search index can contain vectors or nonvector content. Although most samples and demos include vector fields, it's not a requirement. The query is executed using the existing search engine in Azure AI Search, which can handle keyword (or term) and vector queries. The index is created in advance, based on a schema you define, and loaded with your content that's sourced from files, databases, or storage.

The LLM receives the original prompt, plus the results from Azure AI Search. The LLM analyzes the results and formulates a response. If the LLM is ChatGPT, the user interaction might consist of multiple conversation turns. An Azure solution most likely uses Azure OpenAI, but there's no hard dependency on this specific service.

Searchable content in Azure AI Search

In Azure AI Search, all searchable content is stored in a search index that's hosted on your search service. A search index is designed for fast queries with millisecond response times, so its internal data structures exist to support that objective. To that end, a search index stores *indexed content*, and not whole content files like entire PDFs or images. Internally, the data structures include inverted indexes of [tokenized text](#), vector indexes for embeddings, and unaltered plain text for cases where verbatim matching is required (for example, in filters, fuzzy search, regular expression queries).

When you set up the data for your RAG solution, you use the features that create and load an index in Azure AI Search. An index includes fields that duplicate or represent your source content. An index field might be simple transference (a title or description in a source document becomes a title or description in a search index), or a field might contain the output of an external process, such as vectorization or skill processing that generates a representation or text description of an image.

Since you probably know what kind of content you want to search over, consider the indexing features that are applicable to each content type:

 Expand table

Content type	Indexed as	Features
text	tokens, unaltered text	Indexers can pull plain text from other Azure resources like Azure Storage and Cosmos DB. You can also push any JSON content to an index. To modify text in flight, use analyzers and normalizers to add lexical processing during indexing. Synonym maps are useful if source documents are missing terminology that might be used in a query.
text	vectors ¹	Text can be chunked and vectorized in an indexer pipeline, or handled externally and then indexed as vector fields in your index.
image	tokens, unaltered text ²	Skills for OCR and Image Analysis can process images for text recognition or image characteristics. Skills have an indexer requirement.
image	vectors ¹	Images can be vectorized in an indexer pipeline, or handled externally for a mathematical representation of image content and then indexed as vector fields in your index. You can use Azure AI Vision multimodal or an open source model like OpenAI CLIP to vectorize text and images in the same embedding space.

¹ Azure AI Search provides [integrated data chunking and vectorization](#), but you must take a dependency on indexers and skillsets. If you can't use an indexer, Microsoft's [Semantic Kernel](#)

or other community offerings can help you with a full stack solution. For code samples showing both approaches, see [azure-search-vectors-sample repo ↗](#).

² Image descriptions are converted to searchable text and added to the index. The images themselves are not stored in the index. **Skills** are built-in support for [applied AI](#). For image descriptions and verbalizations, the indexing pipeline makes an internal call to the Azure OpenAI or Azure AI Vision. These skills pass an extracted image for processing, and receive the output as text that's indexed by Azure AI Search. Skills are also used for integrated data chunking and embedding.

Vectors provide the best accommodation for dissimilar content (multiple file formats and languages) because content is expressed universally in mathematic representations. Vectors also support similarity search: matching on the coordinates that are most similar to the vector query. Compared to keyword search (or term search) that matches on tokenized terms, similarity search is more nuanced. It's a better choice if there's ambiguity or interpretation requirements in the content or in queries.

Content retrieval in Azure AI Search

Once your data is in a search index, you use the query capabilities of Azure AI Search to retrieve content.

In a non-RAG pattern, queries make a round trip from a search client. The query is submitted, it executes on a search engine, and the response returned to the client application. The response, or search results, consist exclusively of the verbatim content found in your index.

In a classic RAG pattern, queries and responses are coordinated between the search engine and the LLM. A user's question or query is forwarded to both the search engine and to the LLM as a prompt. The search results come back from the search engine and are redirected to an LLM. The response that makes it back to the user is generative AI, either a summation or answer from the LLM.

In a modern agentic retrieval RAG pattern, queries and responses integrate with LLMs for help with query planning and optional answer formulation. Query inputs can be richer, with chat history as well as the user's question. The LLM determines how to set up subqueries for the best coverage over your indexed content. The response includes not just search results, but the query execution details and source documents. You can optionally include answer formulation, which in other patterns occurs outside of the query pipeline.

Here are the capabilities in Azure AI Search that are used to formulate queries:

Query feature	Purpose	Why use it
Agentic search (preview)	Parallel query execution pipeline of multiple subqueries, returning a response designed for RAG workloads and agent consumer. Queries can be vector or keyword search. Semantic ranking ensures the best results of subquery are included in the final response structure. This is the recommended approach for RAG patterns based on Azure AI Search.	
Keyword search	Query execution over text and nonvector numeric content	Full text search is best for exact matches, rather than similar matches. Full text search queries are ranked using the BM25 algorithm and support relevance tuning through scoring profiles. It also supports filters and facets.
Vector search	Query execution over vector fields for similarity search, where the query string is one or more vectors.	Vectors can represent all types of content, in any language.
Hybrid search	Combines any or all of the above query techniques. Vector and nonvector queries execute in parallel and are returned in a unified result set.	The most significant gains in precision and recall are through hybrid queries.
Filters and facets	Applies to text or numeric (nonvector) fields only. Reduces the search surface area based on inclusion or exclusion criteria.	Adds precision to your queries.

Structure the query response

A query's response provides the input to the LLM, so the quality of your search results is critical to success. Results are a tabular row set. The composition or structure of the results depends on:

- Fields that determine which parts of the index are included in the response.
- Rows that represent a match from index.

Fields appear in search results when the attribute is " retrievable". A field definition in the index schema has attributes, and those determine whether a field is used in a response. Only " retrievable" fields are returned in full text or vector query results. By default all " retrievable" fields are returned, but you can use " select" to specify a subset. Besides " retrievable", there are no restrictions on the field. Fields can be of any length or type. Regarding length, there's no maximum field length limit in Azure AI Search, but there are limits on the [size of an API request](#).

Rows are matches to the query, ranked by relevance, similarity, or both. By default, results are capped at the top 50 matches for full text search or k-nearest-neighbor matches for vector search. You can change the defaults to increase or decrease the limit up to the maximum of 1,000 documents. You can also use top and skip paging parameters to retrieve results as a series of paged results.

Maximize relevance and recall

When you're working with complex processes, a large amount of data, and expectations for millisecond responses, it's critical that each step adds value and improves the quality of the end result. On the information retrieval side, *relevance tuning* is an activity that improves the quality of the results sent to the LLM. Only the most relevant or the most similar matching documents should be included in results.

Here are some tips for maximizing relevance and recall:

- [Hybrid queries](#) that combine keyword (nonvector) search and vector search give you maximum recall when the inputs are the same. In a hybrid query, if you double down on the same input, a text string and its vector equivalent generate parallel queries for keywords and similarity search, returning the most relevant matches from each query type in a unified result set.
- Hybrid queries can also be expansive. You can run similarity search over verbose chunked content, and keyword search over names, all in the same request.
- Relevance tuning is supported through:
 - [Scoring profiles](#) that boost the search score if matches are found in a specific search field or on other criteria.
 - [Semantic ranker](#) that re-ranks an initial results set, using semantic models from Bing to reorder results for a better semantic fit to the original query.
 - Query parameters for fine-tuning. You can [boost the importance of vector queries](#) or [adjust the amount of BM25-ranked results](#) in a hybrid query response. You can also [set minimum thresholds to exclude low scoring results](#) from a vector query.

In comparison and benchmark testing, hybrid queries with text and vector fields, supplemented with semantic ranking, produce the most relevant results.

Integration code and LLMs

A RAG solution that includes Azure AI Search can leverage [built-in data chunking and vectorization capabilities](#), or you can build your own using platforms like Semantic Kernel, LangChain, or LlamaIndex.

We recommend the [Azure OpenAI demo ↗](#) for an example of a full stack RAG chat app with Azure OpenAI and Azure AI Search.

How to get started

There are many ways to get started, including code-first solutions and demos.

For help with choosing between agentic retrieval and classic RAG, try a few quickstarts using your own data to understand the development effort and compare outcomes.

Docs

- [Try this agentic retrieval quickstart](#) to walk through the new and recommended approach for RAG.
- [Try this classic RAG quickstart](#) for a demonstration of query integration with chat models over a search index.
- [Review indexing concepts and strategies](#) to determine how you want to ingest and refresh data. Decide whether to use vector search, keyword search, or hybrid search. The kind of content you need to search over, and the type of queries you want to run, determines index design.
- [Review creating queries](#) to learn more about search request syntax and requirements.

ⓘ Note

Some Azure AI Search features are intended for human interaction and aren't useful in a RAG pattern. Specifically, you can skip features like autocomplete and suggestions. Other features like facets and orderby might be useful, but would be uncommon in a RAG scenario.

Querying in Azure AI Search

05/29/2025

Azure AI Search supports query constructs for a broad range of scenarios, from free-form text search, to highly specified query patterns, to vector search. All queries execute over a search index that stores searchable content.

Types of queries

 Expand table

Query form	Searchable content	Description
Full text search	Inverted indexes of tokenized terms.	Full text queries iterate over inverted indexes that are structured for fast scans, where a match can be found in potentially any field, within any number of search documents. Text is analyzed and tokenized for full text search.
Vector search	Vector indexes of generated embeddings.	Vector queries iterate over vector fields in a search index.
Hybrid search	All of the above, in a single search index.	Combines text search and vector search in a single query request. Text search works on plain text content in "searchable" and "filterable" fields. Vector search works on content in vector fields.
Agentic retrieval (preview)	All of the above, in a single search index.	This is an alternative retrieval path on Azure AI Search that leverages large language models for query planning. The response is designed for agent consumption, where the agent rather than search app client code coordinates the response delivered to the user.
Others	Plain text and human-readable content.	Raw content, extracted verbatim from source documents, supporting filters and pattern matching queries like geo-spatial search, fuzzy search, and fielded search.

The remainder of this article brings focus to the last category: classic queries that work on plain text and human-readable content, extracted intact from original source, used for filters and other specialized query forms. If you're creating a traditional search application that isn't using AI, this section explains the query methods that you can implement in your client code.

Autocomplete and suggested queries

Autocomplete or suggested results are alternatives to `search` that fire successive query requests based on partial string inputs (after each character) in a search-as-you-type experience. You can use `autocomplete` and `suggestions` parameter together or separately, as described in [this walkthrough](#), but you can't use them with `search`. Both completed terms and suggested queries are derived from index contents. The engine never returns a string or suggestion that is nonexistent in your index. For more information, see [Autocomplete \(REST API\)](#) and [Suggestions \(REST API\)](#).

Filter search

Filters are widely used in apps that are based on Azure AI Search. On application pages, filters are often visualized as facets in link navigation structures for user-directed filtering. Filters are also used internally to expose slices of indexed content. For example, you might initialize a search page using a filter on a product category, or a language if an index contains fields in both English and French.

You might also need filters to invoke a specialized query form, as described in the following table. You can use a filter with an unspecified search (`search=*`) or with a query string that includes terms, phrases, operators, and patterns.

[] [Expand table](#)

Filter scenario	Description
Range filters	In Azure AI Search, range queries are built using the <code>filter</code> parameter. For more information and examples, see Range filter example .
Faceted navigation	In faceted navigation tree, users can select facets. When backed by filters, search results narrow on each click. Each facet is backed by a filter that excludes documents that no longer match the criteria provided by the facet.

! Note

Text that's used in a filter expression is not analyzed during query processing. The text input is presumed to be a verbatim case-sensitive character pattern that either succeeds or fails on the match. Filter expressions are constructed using [OData syntax](#) and passed in a `filter` parameter in all *filterable* fields in your index. For more information, see [Filters in Azure AI Search](#).

Geospatial search

Geospatial search matches on a location's latitude and longitude coordinates for "find near me" or map-based search experience. In Azure AI Search, you can implement geospatial search by following these steps:

- Define a filterable field of one of these types: [Edm.GeographyPoint](#), [Collection\(Edm.GeographyPoint\)](#), [Edm.GeographyPolygon](#).
- Verify the incoming documents include the appropriate coordinates.
- After indexing is complete, build a query that uses a filter and a [geo-spatial function](#).

Geospatial search uses kilometers for distance. Coordinates are specified in this format:

(longitude, latitude).

Here's an example of a filter for geospatial search. This filter finds other `Location` fields in the search index that have coordinates within a 300-kilometer radius of the geography point (in this example, Washington D.C.). It returns address information in the result, and includes an optional `facets` clause for self-navigation based on location.

HTTP

```
POST https://{{searchServiceName}}.search.windows.net/indexes/hotels-vector-quickstart/docs/search?api-version=2024-07-01
{
    "count": true,
    "search": "*",
    "filter": "geo.distance(Location, geography'POINT(-77.03241 38.90166)') le 300",
    "facets": [ "Address/StateProvince"],
    "select": "HotelId, HotelName, Address/StreetAddress, Address/City, Address/StateProvince",
    "top": 7
}
```

For more information and examples, see [Geospatial search example](#).

Document look-up

In contrast with the previously described query forms, this one retrieves a single [search document by ID](#), with no corresponding index search or scan. Only the one document is requested and returned. When a user selects an item in search results, retrieving the document and populating a details page with fields is a typical response, and a document look-up is the operation that supports it.

Advanced search: fuzzy, wildcard, proximity, regex

An advanced query form depends on the Full Lucene parser and operators that trigger a specific query behavior.

[] [Expand table](#)

Query type	Usage	Examples and more information
Fielded search	<code>search</code> parameter, <code>queryType=full</code>	Build a composite query expression targeting a single field. Fielded search example
fuzzy search	<code>search</code> parameter, <code>queryType=full</code>	Matches on terms having a similar construction or spelling. Fuzzy search example
proximity search	<code>search</code> parameter, <code>queryType=full</code>	Finds terms that are near each other in a document. Proximity search example
term boosting	<code>search</code> parameter, <code>queryType=full</code>	Ranks a document higher if it contains the boosted term, relative to others that don't. Term boosting example
regular expression search	<code>search</code> parameter, <code>queryType=full</code>	Matches based on the contents of a regular expression. Regular expression example
wildcard or prefix search	<code>search</code> parameter with <code>*~</code> or <code>?</code> , <code>queryType=full</code>	Matches based on a prefix and tilde (~) or single character (?). Wildcard search example

Next steps

For a closer look at query implementation, review the examples for each syntax. If you're new to full text search, a closer look at what the query engine does might be an equally good choice.

Relevance in Azure AI Search

The true measure of relevance is *how well* a retrieved set of results meets your customer and user information needs. In this article, learn about:

- The main strategies for producing relevant results in Azure AI Search
- The mechanics of how relevance is measured
- The actions you can take to improve relevance

Strategies for highly relevant results

In Azure AI Search, two main strategies have emerged as the best approaches for producing highly relevant results.

- Hybrid search with semantic reranker
- Agentic retrieval (preview) with LLM-assisted query planning and answer formulation

[Hybrid search](#) delivers on relevance by combining the precision of keyword queries and the semantic similarity of vector queries in a search request targeting a single index. Keyword search operates over a verbatim query. Vector search runs an identical query using a vectorized version of the same string. The queries execute in parallel, looking for precise and semantically similar matches. Results are merged, ranked, and then rescored using a semantic ranker that promotes the most relevant matches. Using keyword and vector search *together* offsets the weaknesses of each approach as a standalone solution. Semantic reranker is an extra component that contributes to a better outcome.

[Agentic retrieval \(preview\)](#) delivers on relevance through smart integration with LLMs and a knowledge base that defines an entire search domain. The LLM can analyze and transform queries for more effective retrieval. It can decompose complex questions into targeted subqueries, refine vague requests, or generalize narrow ones for broader scope. In a typical agentic retrieval workload, the LLM answers the question using its reasoning power, context from chat history, and retrieval instructions to extract the very best content and use it to best advantage. This combination of LLM-assisted query planning, multi-source knowledge base search, and LLM reasoning is how agentic retrieval returns highly relevant results.

Relevance also depends on having grounding data of sufficient quantity and quality. In agentic retrieval, you can list multiple knowledge sources to expand the scope of what's searchable and provide logic for selecting specific ones.

How relevance is measured

Regardless of how content is retrieved, the relevance of any given result is determined by a ranking algorithm that evaluates the strength of a match based on how closely the query corresponds to content in the search corpus. When a match is found, an algorithm assigns a score, and results are ranked by that score and the topmost results are returned in the response.

Ranking occurs whenever the query request is for agentic retrieval and classic search for keyword, vector, and hybrid queries. It doesn't occur if the query invokes strict pattern matching, such as a filter-only query or a specialized query form like autocomplete, suggestions, geospatial search, fuzzy search, or regular expression search. A uniform search score of 1.0 indicates the absence of a ranking algorithm.

Levels of ranking

The query engine in Azure AI Search supports a multi-level approach to ranking search results, where there's a built-in ranking modality for each query type, plus extra ranking capabilities for extended relevance tuning.

This section describes the levels of scoring operations. For an illustration of how they work together, see the [diagram](#) in this article. A [comparison of all search score types and ranges](#) is also provided in this article.

[] Expand table

Level	Description
Level 1 (L1)	<p>Initial search score (<code>@search.score</code>).</p> <p>For text queries matching on tokenized strings, results are always initially ranked using the BM25 ranking algorithm.</p> <p>For vector queries, results are ranked using either Hierarchical Navigable Small World (HNSW) or exhaustive K-nearest neighbor (KNN). Image search or multimodal searches are based on vector queries and scored using the L1 vector ranking algorithms.</p>
Fused L1	<p>Scoring from multiple queries using the Reciprocal Ranking Fusion (RRF) algorithm. RRF is used for hybrid queries that include text and vector components. RRF is also used when multiple vector queries execute in parallel. A search score from RRF is reflected in <code>@search.score</code> over a different range.</p>
Level 2 (L2)	<p>Semantic ranking score (@search.reRankerScore) applies machine reading comprehension to the textual content retrieved by L1 ranking, rescoring the L1 results to better match the semantic intent of the query. L2 reranks L1 results because doing so saves time and money; it would be prohibitive to use semantic ranking as an L1 ranking system. Semantic ranking is a premium feature that bills for usage of the semantic ranking models. It's optional for text queries and vector queries that contain text, but required for agentic retrieval (preview).</p>

Level	Description
	Although agentic retrieval sends multiple queries to the query engine, the ranking algorithm for agentic retrieval is the semantic ranker.
Level 3 (L3)	Applies to agentic retrieval (preview) and a medium retrieval reasoning effort. L3 ranking refers to <i>iterative search</i> and it's invoked when the agentic retrieval engine and LLM agree that a second query pass is needed to return a more relevant result. For more information, see Medium retrieval and iterative search .

Relevance tuning

Relevance tuning is a technique for boosting search scores based on extra criteria such as weighted fields, freshness, or proximity. In Azure AI Search, relevance tuning options vary based on query type:

- For textual and numeric (nonvector) content in keyword or hybrid search, you can tune relevance through [scoring profiles](#) or invoking the [semantic ranker](#).
- For vector content in a hybrid query, you can [weight a vector field](#) to boost the importance of the vector component relative to the text component of the hybrid query.
- For pure vector queries, you can experiment between Hierarchical Navigable Small World (HNSW) and exhaustive K-nearest neighbors (KNN) to see if one algorithm outperforms the other for your scenario. HNSW graphing with an exhaustive KNN override at query time is the most flexible approach for comparison testing. You can also experiment with various embedding models to see which ones produce higher quality results. Finally, remember that a hybrid query or a vector query on documents that include nonvector fields are in-scope for relevance tuning, so it's just the vector fields themselves that can't participate in a relevance tuning effort.

Custom boosting logic using scoring profiles

[Scoring profiles](#) are an optional feature for boosting scores based on extra user-defined criteria. Criteria can include weighted fields where a match found in a specific field is given more weight than the same match found in a different field. Criteria can also be defined through functions that boost by freshness, proximity, magnitude, or range. There's no extra costs associated with scoring profiles. To use a scoring profile, you define it in an index and then specify it on a query.

Scoring logic applies to text and numeric nonvector content. You can use scoring profiles with:

- [Text \(keyword\) search](#)

- Pure vector queries
- Hybrid queries, where text and vector subqueries execute in parallel
- Semantically ranked queries

For standalone text queries, scoring profiles identify the top 1,000 matches in a [BM25-ranked search](#), with the top 50 matches returned in the response.

For pure vectors, the query is vector-only, but if the [k-matching documents](#) include nonvector fields with human-readable content, a scoring profile is applied to nonvector fields in `k` documents.

For the text component of a hybrid query, scoring profiles identify the top 1,000 matches in a BM25-ranked search. However, once those 1,000 results are identified, they're restored to their original BM25 order so that they can be rescored alongside vectors results in the final [Reciprocal Ranking Function \(RRF\)](#) ordering, where the scoring profile (identified as "final document boosting adjustment" in the illustration) is applied to the merged results, along with [vector weighting](#), and [semantic ranking](#) as the last step.

For semantically ranked queries (not shown in the diagram), assuming you use the latest preview REST API or a preview Azure SDK package, scoring profiles can be applied over an L2 ranked result set, generating a new `@search.rerankerBoostedScore` that determines the final ranking.

Types of search scores

Scored results are indicated for each match in the query response. This table lists all of the search scores with an associated range. Range varies by algorithm.

 [Expand table](#)

Score	Range	Algorithm
<code>@search.score</code>	0 through unlimited	BM25 ranking algorithm for text search
<code>@search.score</code>	0.333 - 1.00	HNSW or exhaustive KNN algorithm for vector search
<code>@search.score</code>	0 through an upper limit determined by the number of queries	RRF algorithm
<code>@search.rerankerScore</code>	0.00 - 4.00	Semantic ranking algorithm for L2 ranking

Score	Range	Algorithm
<code>@search.rerankerBoostedScore</code>	0 through unlimited	Semantic ranking with scoring profile boosting (scores can be significantly higher than 4)

Diagram of ranking algorithms

The following diagram illustrates how the ranking algorithms work together.

! Note

If you use semantic ranking, the `rankingOrder` property determines whether results are the semantically scored results (`@search.rerankerScore`) or the boosted scores (`@search.rerankerBoostedScore`) that are created after the scoring profile is applied.

Example query inclusive of all ranking algorithms

A query that generates the previous workflow might look like the following example. This hybrid semantic query is scored using RRF (based on L1 scores for text and vectors), and semantic ranking.

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/search?api-version=2025-11-01-preview

{
  "search": "cloud formation over water",

Reliability in Azure AI Search

Azure AI Search is a scalable search infrastructure that indexes heterogeneous content and enables retrieval through APIs, applications, and AI agents. It's suitable for enterprise search scenarios and AI-powered customer experiences that require dynamic content generation through chat completion models. As an Azure service, AI Search provides a range of capabilities to support your reliability requirements.

When you use Azure, [reliability is a shared responsibility](#). Microsoft provides a range of capabilities to support resiliency and recovery. You're responsible for understanding how those capabilities work within all of the services you use, and selecting the capabilities you need to meet your business objectives and uptime goals.

This article describes how to make Azure AI Search resilient to a variety of potential outages and problems, including transient faults, availability zone outages, region outages, and service maintenance. It also describes how you can use backups to recover from other types of problems, and highlights some key information about the Azure AI Search service level agreement (SLA).

Production deployment recommendations for reliability

For production workloads, we recommend that you:

- ✓ Use a [billable tier](#) that has at least [two replicas](#). This configuration makes your search service more resilient to transient faults and maintenance operations. It also meets the [service-level agreement \(SLA\)](#) for AI Search. The SLA requires two replicas for read-only workloads and three or more replicas for read-write workloads.
- ✓ Don't use the Free tier for production use. AI Search doesn't provide an SLA for the Free tier, which is limited to one replica.

Reliability architecture overview

When you use AI Search, you create a *search service*. Each search service supports many *search indexes* that store your searchable content.

AI Search isn't designed as a primary data store. Instead, you use *indexers* to connect your search service to external data sources. An indexer crawls the source data, invokes *skills* that perform processing and enrichment, and populates your index with the skill outputs.

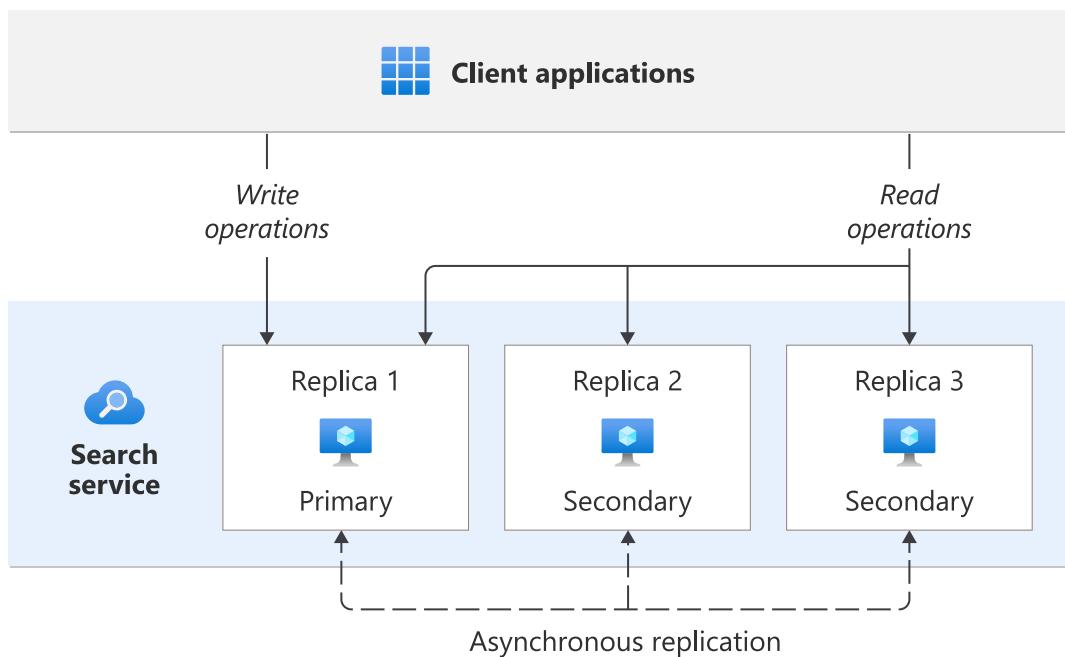

You also configure the number of *replicas* for your service. In AI Search, a replica is a copy of your service's search engine. You can think of a replica as representing a single virtual machine (VM). Each search service can have between 1 and 12 replicas.

The addition of multiple replicas allows AI Search to:

- Increase the availability of your search service.
- Perform maintenance on one replica while queries continue to run on other replicas.
- Handle higher indexing and query workloads.
- Improve resiliency by attempting to provision replicas in different availability zones, if your region supports them.

AI Search automatically assigns one replica to be the *primary replica*. All write operations are performed against that replica. The other replicas are used for read operations.

The following diagram illustrates how a search service with three replicas might be spread across three availability zones:

You can also configure the number of *partitions*, which represent the storage that the search indexes use.

It's important to understand the impact of adding replicas and partitions because they each affect read and write performance in different ways. For more information about replicas and partitions, see [Estimate and manage capacity of a search service](#).

Resilience to transient faults

Transient faults are short, intermittent failures in components. They occur frequently in a distributed environment like the cloud, and they're a normal part of operations. Transient faults correct themselves after a short period of time. It's important that your applications can handle transient faults, usually by retrying affected requests.

All cloud-hosted applications should follow the Azure transient fault handling guidance when they communicate with any cloud-hosted APIs, databases, and other components. For more information, see [Recommendations for handling transient faults](#).

AI Search indexers have built-in transient fault handling. If a data source is briefly unavailable, the indexer is designed to recover and retry. It uses change tracking to resume indexing from the last successfully indexed document.

Search services might experience transient faults during standard, unscheduled maintenance operations. Azure AI Search doesn't provide advance notification or allow scheduling of maintenance at specific times. Although every effort is made to minimize downtime, even for single-replica services, brief interruptions can still occur. To improve resiliency against these transient faults, we recommend that you use two or more replicas.

If you build any applications that interact with AI Search, they should handle transient faults. Use a retry strategy with exponential backoffs for both read and write operations.

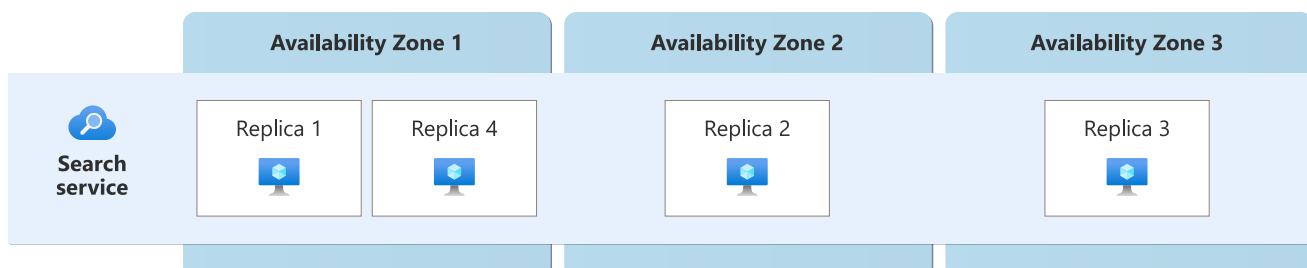

Resilience to availability zone failures

[Availability zones](#) are physically separate groups of datacenters within each Azure region. When one zone fails, services can fail over to one of the remaining zones.

AI Search is zone redundant, which means that your replicas are distributed across multiple availability zones within the search service region.

When you add two or more replicas to your service, AI Search attempts to place each replica in a different availability zone. For services that have more replicas than available zones, replicas are distributed across zones as evenly as possible.

The following diagram illustrates how an example search service with four replicas might be deployed across three availability zones:

Important

AI Search doesn't guarantee the exact placement of replicas. Placement is subject to capacity constraints, scaling operations, and other factors.

Requirements

Zone redundancy is automatically enabled when your search service meets all of the following criteria:

- **Region support:** Support for availability zones depends on infrastructure and storage. For a list of supported regions, see [Choose a region for AI Search](#).
- **Tier:** Your service must be on the [Basic tier or higher](#)
- **Number of replicas:** Your service must have [at least two replicas](#)

Note

AI Search attempts to distribute replicas across multiple zones when you have two or more replicas. However, for read-write workloads, you should use three or more replicas so that you receive the highest possible availability SLA.

Instance distribution across zones

AI Search attempts to place replicas across different availability zones. However, there are occasionally situations where all of the replicas of a search service might be placed into the same availability zone. This situation can happen when replicas are removed from your service, such as when you *scale in* by configuring your service to use fewer replicas. Replica removal doesn't trigger the remaining replicas to rebalance across the availability zones.

To reduce the likelihood of all of your replicas being placed into a single availability zone, you can manually trigger a scale-out operation immediately after a scale-in operation. For example, suppose that your search service has 10 replicas and you want to scale in to 7 replicas. Instead of performing a single scale operation, you can temporarily scale to 6 instances and then immediately scale to 7 instances to trigger zone rebalancing.

Cost

Each search service starts with one replica. Zone redundancy requires two or more replicas, which increases the cost to run the service. To understand the billing implications of replicas, use the [pricing calculator](#).

Configure availability zone support

If your search service meets the [requirements for zone redundancy](#), no extra configuration is necessary. Whenever possible, AI Search attempts to place your replicas in different availability zones.

Capacity planning and management

To prepare for availability zone failure, consider *overprovisioning* the number of replicas. Overprovisioning allows the search service to tolerate some capacity loss and continue to function without degraded performance. Adding replicas during an outage is challenging, so overprovisioning helps ensure that your search service can handle normal request volumes, even with reduced capacity. For more information, see [Manage capacity by overprovisioning](#).

Behavior when all zones are healthy

This section describes what to expect when search services are configured for zone redundancy and all availability zones are operational.

- **Traffic routing between zones:** AI Search performs automatic load balancing of all queries and writes across all of the available replicas. AI Search can send read operations to any replica in any availability zone. It sends write operations to a single primary replica that the AI Search service selects.
- **Data replication between zones:** Changes in data are automatically replicated between replicas across availability zones. Replication occurs asynchronously, which means that writes are committed to one primary replica before they're replicated to other replicas.

Behavior during a zone failure

This section describes what to expect when search services are configured for zone redundancy and an availability zone outage occurs.

- **Detection and response:** AI Search is responsible for detecting a failure in an availability zone. You don't need to do anything to initiate a zone failover.
- **Notification:** Microsoft doesn't automatically notify you when a zone is down. However:

- You can use [Azure Resource Health](#) to monitor for the health of an individual resource, and you can set up [Resource Health alerts](#) to notify you of problems.
- You can use [Azure Service Health](#) to understand the overall health of the service, including any zone failures, and you can set up [Service Health alerts](#) to notify you of problems.
- **Active requests:** Requests that replicas process in the failed zone are terminated. Clients should retry the requests by following the guidance for [handling transient faults](#).
- **Expected data loss:** If the affected availability zone only contains read replicas, no data loss is expected.

If the primary replica is lost because it was in the affected zone, then any write operations that haven't yet been replicated might be lost.

- **Expected downtime:** In most situations, a zone failure isn't expected to cause downtime to your search service for read operations because read replicas in other availability zones continue to serve requests.

If the primary replica is lost because it was in the affected zone, AI Search automatically promotes another replica to become the new primary so that write operations can resume. It typically takes a few seconds for the replica promotion to occur. During this time, write operations might not succeed. Ensure that your applications are prepared by following [transient fault handling guidance](#).

However, there are some unlikely situations where all of your search service's replicas might be in a single availability zone. In this scenario, you might experience downtime until the zone recovers. For more information, and to understand a workaround, see [Instance distribution](#).

- **Traffic rerouting:** When a zone fails, AI Search detects the failure and routes requests to active replicas in the surviving zones. If the primary replica is lost, another replica is promoted to be the new primary.

Zone recovery

When the availability zone recovers, AI Search automatically restores normal operations and begins routing traffic to available replicas across all zones, including the recovered zone.

Test for zone failures

AI Search manages traffic routing for zone-redundant services. You don't need to initiate or validate any zone failure processes.

Resilience to region-wide failures

AI Search is a single-region service. If the region becomes unavailable, your search service also becomes unavailable.

Custom multi-region solutions for resiliency

You can optionally deploy multiple AI Search services in different regions. You're responsible for deploying and configuring separate services in each region. If you create an identical deployment in a secondary Azure region that uses a multi-region architecture, your application becomes less susceptible to a single-region disaster.

When you follow this approach, you must synchronize indexes across regions to recover the last application state. You must also configure load balancing and failover policies.

To optimize the performance of your overall solution, look for opportunities to perform indexing on read-only replicas of your data sources. For example, some indexers support reading from a geo-distributed data source's read replicas.

For more information, see [Multi-region deployments in Azure AI Search](#).

Backup and restore

Because AI Search isn't a primary data storage solution, it doesn't provide self-service backup and restore options. However, you can use the `index-backup-restore` sample for [.NET](#) or [Python](#) to back up your index definition and its documents to a series of JSON files, which are then used to restore the index.

However, if you accidentally delete the index and don't have a backup, you can [rebuild the index](#). Rebuilding involves recreating the index on your search service and then reloading it by retrieving data from your primary data store.

Service-level agreement

The service-level agreement (SLA) for Azure services describes the expected availability of each service and the conditions that your solution must meet to achieve that availability expectation. For more information, see [SLAs for online services](#).

In AI Search, the availability SLA applies to search services that:

- Are configured to use a [billable tier](#).
- Have at least two [replicas](#) for read-only workloads (queries).
- Have at least three replicas for read-write workloads (queries and indexing).

Multi-region deployments in Azure AI Search

08/11/2025

Although Azure AI Search is a single-region service, you can achieve higher availability and resiliency by deploying multiple search services with identical configurations and content across multiple regions.

This article describes the components of a multi-region solution, which relies on your custom script or code to handle failover if a service becomes unavailable.

For more information about the reliability features of Azure AI Search, including intra-regional resiliency via availability zones, see [Reliability in Azure AI Search](#).

Why use multiple regions?

If you need two or more search services, creating them in different regions can meet the following operational requirements:

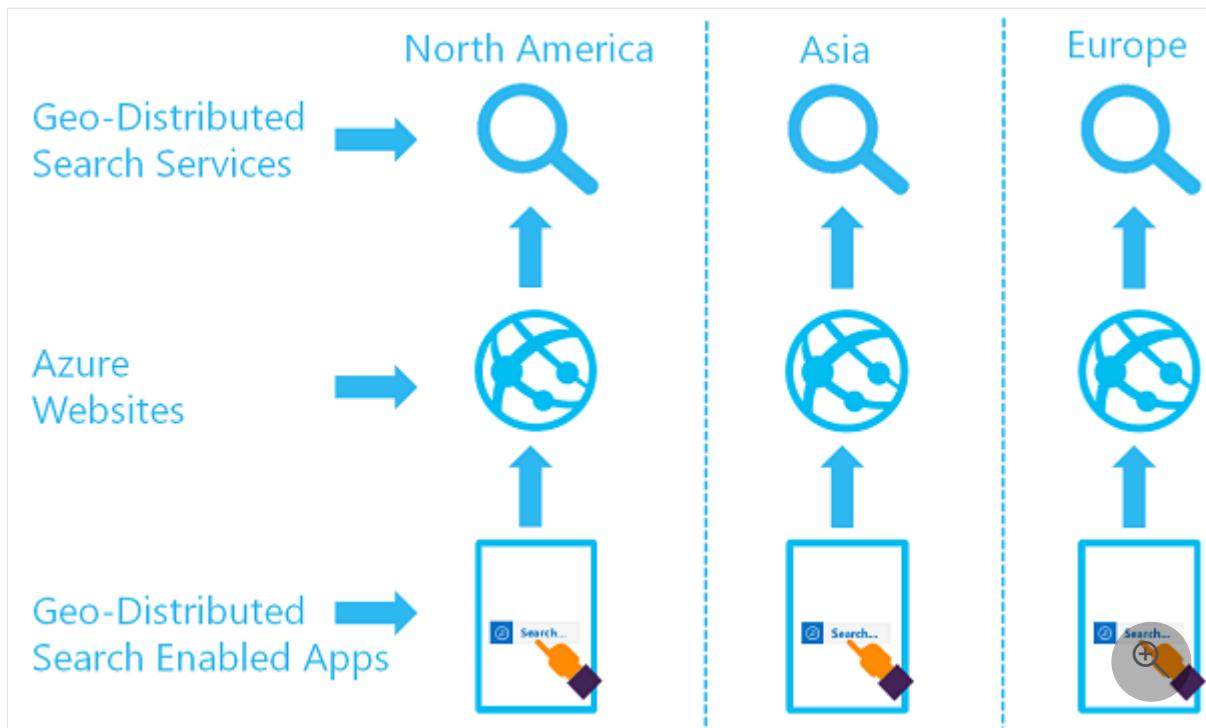

- **Resiliency to region outages.** If there's an outage, Azure AI Search doesn't provide instant failover to another region.
- **Fast performance for a globally distributed application.** If indexing and query requests come from around the world, users who are closest to the host data center experience faster performance. Creating more services in regions with close proximity to these users can equalize performance for everyone.

Multi-region architecture

In a multi-region setup, two or more search services are located in different regions and have synchronized indexes. Users are automatically routed to the service with the lowest latency.

Azure AI Search doesn't provide an automated method of index replication across regions. However, you can synchronize data using [push or pull model indexing](#), both of which are described in the following section. You can also add Azure Traffic Manager or another load balancer for [request redirection](#).

The following diagram illustrates a geo-distributed set of search services:

Tip

For a complete implementation, see the [Bicep sample](#) on GitHub. The sample deploys a fully configured, multi-region search solution that can be modified to your regions and indexing strategies.

Data synchronization

To synchronize two or more distinct search services, you can either:

- Push content into an index using [Documents - Index \(REST API\)](#) or an equivalent API in the Azure SDKs.
- Pull content into an index using an [indexer](#).

Push APIs

If you use the REST APIs to [push content into your index](#), you can synchronize multiple search services by sending updates to each service whenever changes occur. Ensure that your code handles cases in which an update fails for one service but succeeds for other services.

Data residency

When you create multiple search services in different regions, your content is stored in the region you chose for each service.

Azure AI Search doesn't store data outside of your specified region without your authorization. Authorization is implicit when you use features that write to Azure Storage, for which you provide a storage account in your preferred region. These features include:

- [Enrichment cache](#)
- [Debug sessions](#)
- [Knowledge store](#)

If your search service and storage account are in the same region, network traffic uses private IP addresses over the Microsoft backbone network, so you can't configure IP firewalls or private endpoints for network security. As an alternative, use the [trusted service exception](#).

Request failover and redirection

For redundancy at the request level, Azure provides several [load-balancing options](#):

Azure Application Gateway

Use [Azure Application Gateway](#) to load balance between servers in a region at the application layer.

By default, service endpoints are accessed through a public internet connection. Use Application Gateway if you set up a private endpoint for client connections that originate from within a virtual network.

As you evaluate these load-balancing options, consider the following points:

- Azure AI Search is a backend service that accepts indexing and query requests from a client.
- By default, service endpoints are accessed through a public internet connection. We recommend [Azure Application Gateway](#) for private endpoints that originate from within a virtual network.
- Azure AI Search accepts requests addressed to the `<your-search-service-name>.search.windows.net` endpoint. If you reach the same endpoint using a different DNS name in the host header, such as a CNAME, the request is rejected.
- Requests from the client to a search service must be authenticated. To access search operations, the caller must have [role-based permissions](#) or provide an [API key](#) with the

request.

Security in Azure AI Search

09/25/2025

Azure AI Search provides comprehensive security controls across network access, data access, and data protection to meet enterprise requirements. As a solution architect, you should understand three key security domains:

- **Network traffic patterns and network security:** Inbound, outbound, and internal traffic.
- **Access control mechanisms:** API keys or Microsoft Entra ID with roles.
- **Data residency and protection:** Encryption in transit, in use with optional confidential computing, and at rest with optional double encryption.

A search service supports multiple network security topologies, from IP firewall restrictions for basic protection to private endpoints for complete network isolation. Optionally, use a network security perimeter to create a logical boundary around your Azure PaaS resources. For enterprise scenarios requiring granular permissions, you can implement document-level access controls. All security features integrate with Azure's compliance framework and support common enterprise patterns like multitenancy and cross-service authentication using managed identities.

This article details the implementation options for each security layer to help you design appropriate security architectures for development and production environments.

Network traffic patterns

An Azure AI Search service can be hosted in the Azure public cloud, an Azure private cloud, or a sovereign cloud (such as Azure Government). By default, for all cloud hosts, the search service is typically accessed by client applications over public network connections. While that pattern is predominant, it's not the only traffic pattern that you need to care about. Understanding all points of entry as well as outbound traffic is necessary background for securing your development and production environments.

Azure AI Search has three basic network traffic patterns:

- Inbound requests made by a user or client to the search service (the predominant pattern)
- Outbound requests issued by the search service to other services on Azure and elsewhere
- Internal service-to-service requests over the secure Microsoft backbone network

Inbound traffic

Inbound requests that target a search service endpoint include:

- Create, read, update, or delete indexes and other objects on the search service
- Load an index with search documents
- Query an index
- Run indexer or skillset jobs

The [REST APIs](#) describe the full range of inbound requests that are handled by a search service.

At a minimum, all inbound requests must be authenticated using either of these options:

- Key-based authentication (default). Inbound requests provide a valid API key.
- Role-based access control. Authorization is through Microsoft Entra identities and role assignments on your search service.

Additionally, you can add [network security features](#) to further restrict access to the endpoint. You can create either inbound rules in an IP firewall, or create private endpoints that fully shield your search service from the public internet.

Outbound traffic

Outbound requests can be secured and managed by you. Outbound requests originate from a search service to other applications. These requests are typically made by indexers for text-based and multimodal indexing, custom skills-based AI enrichment, and vectorizations at query time. Outbound requests include both read and write operations.

The following list is a full enumeration of the outbound requests for which you can configure secure connections. A search service makes requests on its own behalf, and on the behalf of an indexer or custom skill.

 [Expand table](#)

Operation	Scenario
Indexers	Connect to external data sources to retrieve data (read access). For more information, see Indexer access to content protected by Azure network security .
Indexers	Connect to Azure Storage for write operations to knowledge stores , cached enrichments , debug sessions .
Custom skills	Connect to Azure functions, Azure web apps, or other apps running external code that's hosted off-service. The request for external processing is sent during skillset execution.
Indexers and integrated	Connect to Azure OpenAI and a deployed embedding model, or it goes through a custom skill to connect to an embedding model that you provide. The search service

Operation	Scenario
vectorization	sends text to embedding models for vectorization during indexing.
Vectorizers	Connect to Azure OpenAI or other embedding models at query time to convert user text strings to vectors for vector search.
Knowledge agents	Connect to chat completion models for agentic retrieval query planning, and also for formulating answers grounded in search results. If you're implementing a basic RAG pattern , your query logic calls an external chat completion model for formulating an answer grounded in search results. For this pattern, the connection to the model uses the identity of your client or user. The search service identity isn't used for the connection. In contrast, if you use knowledge agents in a RAG retrieval pattern, the outbound request is made by the search service managed identity.
Search service	Connect to Azure Key Vault for customer-managed encryption keys used to encrypt and decrypt sensitive data.

Outbound connections can generally be made using a resource's full access connection string that includes a key or a database login, or a [managed identity](#) if you're using Microsoft Entra ID and role-based access.

To reach Azure resources behind a firewall, [create inbound rules on other Azure resources that admit search service requests](#).

To reach Azure resources protected by Azure Private Link, [create a shared private link](#) that an indexer uses to make its connection.

Exception for same-region search and storage services

If Azure Storage and Azure AI Search are in the same region, network traffic is routed through a private IP address and occurs over the Microsoft backbone network. Because private IP addresses are used, you can't configure IP firewalls or a private endpoint for network security.

Configure same-region connections using either of the following approaches:

- [Trusted service exception](#)
- [Resource instance rules](#)

Internal traffic

Internal requests are secured and managed by Microsoft. You can't configure or control these connections. If you're locking down network access, no action on your part is required because internal traffic isn't customer-configurable.

Internal traffic consists of:

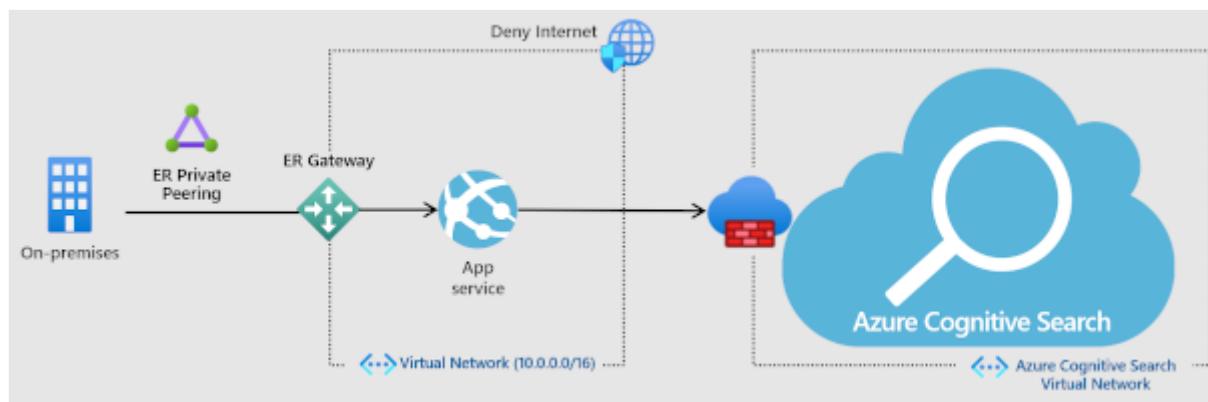

- Service-to-service calls for tasks like authentication and authorization through Microsoft Entra ID, resource logging sent to Azure Monitor, and [private endpoint connections](#) that utilize Azure Private Link.
- Requests for [built-in skills processing](#), with same-region requests directed to an internally hosted Azure AI multi-service resource used exclusively for built-in skills processing by Azure AI Search.
- Requests made to the various models that support [semantic ranking](#).

Network security

[Network security](#) protects resources from unauthorized access or attack by applying controls to network traffic. Azure AI Search supports networking features that can be your frontline of defense against unauthorized access.

Inbound connection through IP firewalls

A search service is provisioned with a public endpoint that allows access using a public IP address. To restrict which traffic comes through the public endpoint, create an inbound firewall rule that admits requests from a specific IP address or a range of IP addresses. All client connections must be made through an allowed IP address, or the connection is denied.

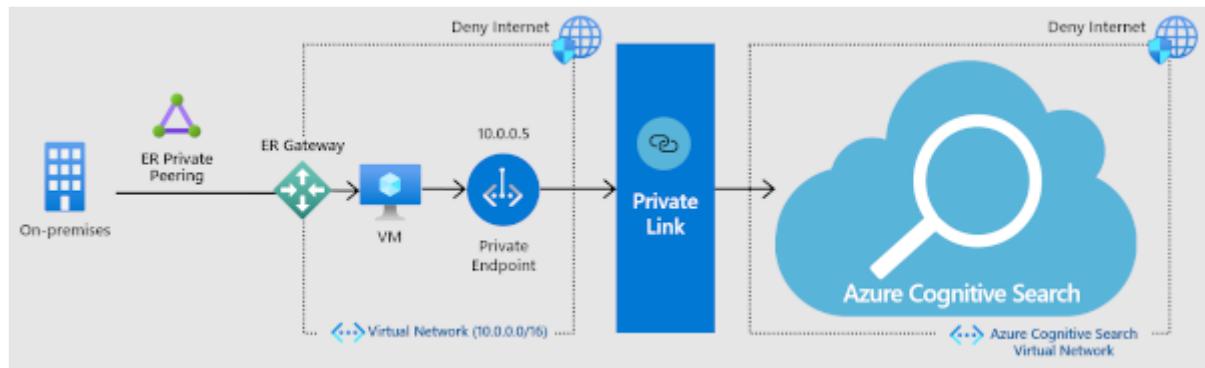

You can use the Azure portal to [configure firewall access](#).

Alternatively, you can use the management REST APIs. Starting with API version 2020-03-13, with the [IpRule](#) parameter, you can restrict access to your service by identifying IP addresses, individually or in a range, that you want to grant access to your search service.

Inbound connection to a private endpoint (network isolation, no Internet traffic)

For more stringent security, you can establish a [private endpoint](#) for Azure AI Search allows a client on a [virtual network](#) to securely access data in a search index over a [Private Link](#).

The private endpoint uses an IP address from the virtual network address space for connections to your search service. Network traffic between the client and the search service traverses over the virtual network and a private link on the Microsoft backbone network, eliminating exposure from the public internet. A virtual network allows for secure communication among resources, with your on-premises network as well as the Internet.

While this solution is the most secure, using more services is an added cost so be sure you have a clear understanding of the benefits before diving in. For more information about costs, see the [pricing page](#). For more information about how these components work together, [watch this video](#). Coverage of the private endpoint option starts at 5:48 into the video. For instructions on how to set up the endpoint, see [Create a Private Endpoint for Azure AI Search](#).

Network security perimeter

A network security perimeter is a logical network boundary around your platform-as-a-service (PaaS) resources that are deployed outside of a virtual network. It establishes a perimeter for controlling public network access to resources like Azure AI Search, Azure Storage, and Azure OpenAI. You can grant exceptions through explicit access rules for inbound and outbound traffic. This approach helps prevent data exfiltration while maintaining necessary connectivity for your applications.

Inbound client connections and service-to-service connections occur within the boundary, which simplifies and strengthens your defenses against unauthorized access. It's common in Azure AI Search solutions to use multiple Azure resources. The following resources can all be joined to an [existing network security perimeter](#):

- [Azure AI Search](#)
- [Azure OpenAI](#)
- [Azure Storage](#)
- [Azure Monitor](#)

For a complete list of eligible services, see [Onboarded private link resources](#).

Authentication

Once a request is admitted to the search service, it must still undergo authentication and authorization that determines whether the request is permitted. Azure AI Search supports two approaches:

- [Microsoft Entra authentication](#) establishes the caller (and not the request) as the authenticated identity. An Azure role assignment determines authorization.
- [Key-based authentication](#) is performed on the request (not the calling app or user) through an API key, where the key is a string composed of randomly generated numbers and letters that prove the request is from a trustworthy source. Keys are required on every request. Submission of a valid key is considered proof the request originates from a trusted entity.

Reliance on API key-based authentication means that you should have a plan for regenerating the admin key at regular intervals, per Azure security best practices. There are a maximum of two admin keys per search service. For more information about securing and managing API keys, see [Create and manage api-keys](#).

Key-based authentication is the default for data plane operations (creating and using objects on the search service). You can use both authentication methods, or [disable an approach](#) that you don't want available on your search service.

Authorization

Azure AI Search provides authorization models for service management and content management.

Privileged access

On a new search service, existing role assignments at the subscription level are inherited by the search service, and only Owners and User Access Administrators can grant access.

Control plane operations (service or resource creation and management) tasks are exclusively authorized through [role assignments](#), with no ability to use key-based authentication for service administration.

Control plane operations include create, configure, or delete the service, and manage security. As such, Azure role assignments will determine who can perform those tasks, regardless of

whether they're using the [portal](#), [PowerShell](#), or the [Management REST APIs](#).

Three basic roles (Owner, Contributor, Reader) apply to search service administration.

 Note

Using Azure-wide mechanisms, you can lock a subscription or resource to prevent accidental or unauthorized deletion of your search service by users with admin rights. For more information, see [Lock resources to prevent unexpected deletion](#).

Authorize access to content

Data plane operations refers to the objects created and used on a search service.

- For role-based authorization, [use Azure role assignments](#) to establish read-write access to operations.
- For key-based authorization, [an API key](#) and a qualified endpoint determine access. An endpoint might be the service itself, the indexes collection, a specific index, a documents collection, or a specific document. When chained together, the endpoint, the operation (for example, a create request) and the type of key (admin or query) authorize access to content and operations.

Restricting access to indexes

Using Azure roles, you can [set permissions on individual indexes](#) as long as it's done programmatically.

Using keys, anyone with an [admin key](#) to your service can read, modify, or delete any index in the same service. For protection against accidental or malicious deletion of indexes, your in-house source control for code assets is the solution for reversing an unwanted index deletion or modification. Azure AI Search has failover within the cluster to ensure availability, but it doesn't store or execute your proprietary code used to create or load indexes.

For multitenancy solutions requiring security boundaries at the index level, it's common to handle index isolation in the middle tier in your application code. For more information about the multitenant use case, see [Design patterns for multitenant SaaS applications and Azure AI Search](#).

Restricting access to documents

User permissions at the document level, also known as *row-level security*, is available as a preview feature and depends on the data source. If content originates from [Azure Data Lake Storage \(ADLS\) Gen2](#) or [Azure blobs](#), user permission metadata that originates in Azure Storage is preserved in indexer-generated indexes and enforced at query time so that only authorized content is included in search results.

For other data sources, you can [push a document payload that includes user or group permission metadata](#), and those permissions are retained in indexed content and also enforced at query time. This capability is also in preview.

If you can't use preview features and you require permissioned access over content in search results, there's a technique for applying filters that include or exclude documents based on user identity. This workaround adds a string field in the data source that represents a group or user identity, which you can make filterable in your index. For more information about this pattern, see [Security trimming based on identity filters](#). For more information about document access, see [Document-level access control](#).

Data residency

When you set up a search service, you choose a region that determines where customer data is stored and processed. Each region exists within a [geography \(Geo\)](#) ↗ that often includes multiple regions (for example, Switzerland is a Geo that contains Switzerland North and Switzerland West). Azure AI Search might replicate your data to another region within the same Geo for durability and high availability. The service won't store or process customer data outside of your specified Geo unless you configure a feature that has a dependency on another Azure resource, and that resource is provisioned in a different region.

Currently, the only external resource that a search service writes to is Azure Storage. The storage account is one that you provide, and it could be in any region. A search service writes to Azure Storage if you use any of the following features:

- [enrichment cache](#)
- [debug session](#)
- [knowledge store](#)

For more information about data residency, see [data residency in Azure](#) ↗ .

Exceptions to data residency commitments

Object names appear in the telemetry logs used by Microsoft to provide support for the service. Object names are stored and processed outside of your selected region or location. Object names include the names of indexes and index fields, aliases, indexers, data sources,

skillsets, synonym maps, resources, containers, and key vault store. Customers shouldn't place any sensitive data in name fields or create applications designed to store sensitive data in these fields.

Telemetry logs are retained for one and a half years. During that period, Microsoft might access and reference object names under the following conditions:

- Diagnose an issue, improve a feature, or fix a bug. In this scenario, data access is internal only, with no third-party access.
- During support, this information might be used to provide quick resolution to issues and escalate product team if needed

Data protection

At the storage layer, data encryption is built in for all service-managed content saved to disk, including indexes, synonym maps, and the definitions of indexers, data sources, and skillsets. Service-managed encryption applies to both long-term data storage and temporary data storage.

Optionally, you can add customer-managed keys (CMK) for supplemental encryption of indexed content for double encryption of data at rest. For services created after August 1 2020, CMK encryption extends to short-term data on temporary disks.

Data in transit

For search service connections over the public internet, Azure AI Search listens on HTTPS port 443.

Azure AI Search supports TLS 1.2 and 1.3 for client-to-service channel encryption:

- TLS 1.3 is the default on newer client operating systems and versions of .NET.
- TLS 1.2 is the default on older systems, but you can [explicitly set TLS 1.3 on a client request](#).

Earlier versions of TLS (1.0 or 1.1) aren't supported.

For more information, see [TLS support in .NET Framework](#).

Data in use

By default, Azure AI Search deploys your search service on standard Azure infrastructure. This infrastructure encrypts data at rest and in transit, but it doesn't protect data while it's being

actively processed in memory.

Optionally, you can use the [Azure portal](#) or [Services - Create or Update \(REST API\)](#) to configure confidential computing during service creation. Confidential computing protects data in use from unauthorized access, including from Microsoft, through hardware attestation and encryption. For more information, see [Confidential computing use cases](#).

The following table compares both compute types.

[] [Expand table](#)

Compute type	Description	Limitations	Cost	Availability
Default	Processes data on standard VMs with built-in encryption for data at rest and in transit. No hardware-based isolation for data in use.	No limitations.	No change to the base cost of free or billable tiers.	Available in all regions.
Confidential	Processes data on confidential VMs (DCasv5 or DCesv5) in a hardware-based trusted execution environment. Isolates computations and memory from the host operating system and other VMs.	Disables or restricts agentic retrieval , semantic ranker , query rewrite , skillset execution , and indexers that run in the multitenant environment ¹ .	Adds a 10% surcharge to the base cost of billable tiers. For more information, see the pricing page ↗.	Available in some regions. For more information, see the list of supported regions .

¹ When you enable this compute type, indexers can only run in the private execution environment, meaning they run from the search clusters hosted on confidential computing.

(i) Important

We only recommend confidential computing for organizations whose compliance or regulatory requirements necessitate data-in-use protection. For daily usage, the default compute type suffices.

Data at rest

For data handled internally by the search service, the following table describes the [data encryption models](#). Some features, such as knowledge store, incremental enrichment, and

indexer-based indexing, read from or write to data structures in other Azure Services. Services that have a dependency on Azure Storage can use the [encryption features](#) of that technology.

[+] [Expand table](#)

Model	Keys	Requirements	Restrictions	Applies to
server-side encryption	Microsoft-managed keys	None (built-in)	None, available on all tiers, in all regions, for content created after January 24, 2018.	Content (indexes and synonym maps) and definitions (indexers, data sources, skillsets) on data disks and temporary disks
server-side encryption	customer-managed keys	Azure Key Vault	Available on billable tiers, in specific regions, for content created after August 1, 2020.	Content (indexes and synonym maps) and definitions (indexers, data sources, skillsets) on data disks
server-side full encryption	customer-managed keys	Azure Key Vault	Available on billable tiers, in all regions, on search services after May 13, 2021.	Content (indexes and synonym maps) and definitions (indexers, data sources, skillsets) on data disks and temporary disks

When you introduce CMK encryption, you're encrypting content twice. For the objects and fields noted in the previous section, content is first encrypted with your CMK, and secondly with the Microsoft-managed key. Content is doubly encrypted on data disks for long-term storage, and on temporary disks used for short-term storage.

Service-managed keys

Service-managed encryption is a Microsoft-internal operation that uses 256-bit [AES encryption](#). It occurs automatically on all indexing, including on incremental updates to indexes that aren't fully encrypted (created before January 2018).

Service-managed encryption applies to all content on long-term and short-term storage.

Customer-managed keys (CMK)

Customers use CMK for two reasons: extra protection, and the ability to revoke keys, preventing access to content.

Customer-managed keys require another billable service, Azure Key Vault, which can be in a different region, but under the same Azure tenant, as Azure AI Search.

CMK support was rolled out in two phases. If you created your search service during the first phase, CMK encryption was restricted to long-term storage and specific regions. Services created in the second phase can use CMK encryption in any region. As part of the second wave rollout, content is CMK-encrypted on both long-term and short-term storage.

- The first rollout was on August 1, 2020 and included the following five regions. Search services created in the following regions supported CMK for data disks, but not temporary disks:
 - West US 2
 - East US
 - South Central US
 - US Gov Virginia
 - US Gov Arizona
- The second rollout on May 13, 2021 added encryption for temporary disks and extended CMK encryption to [all supported regions](#).

If you're using CMK from a service created during the first rollout and you also want CMK encryption over temporary disks, you need to create a new search service in your region of choice and redeploy your content. To determine your service creation date, see [Check your service creation or upgrade date](#).

Enabling CMK encryption will increase index size and degrade query performance. Based on observations to date, you can expect to see an increase of 30-60 percent in query times, although actual performance will vary depending on the index definition and types of queries. Because of the negative performance impact, we recommend that you only enable this feature on indexes that really require it. For more information, see [Configure customer-managed encryption keys in Azure AI Search](#).

Logging and monitoring

Azure AI Search doesn't log user identities so you can't refer to logs for information about a specific user. However, the service does log create-read-update-delete operations, which you might be able to correlate with other logs to understand the agency of specific actions.

Using alerts and the logging infrastructure in Azure, you can pick up on query volume spikes or other actions that deviate from expected workloads. For more information about setting up logs, see [Collect and analyze log data](#) and [Monitor query requests](#).

Compliance and governance

Azure AI Search participates in regular audits, and has been certified against many global, regional, and industry-specific standards for both the public cloud and Azure Government. For the complete list, download the [Microsoft Azure Compliance Offerings whitepaper](#) from the official Audit reports page.

We recommend that you regularly review [Azure AI Search compliance certifications and documentation](#) to ensure alignment with your regulatory requirements.

Use Azure Policy

For compliance, you can use [Azure Policy](#) to implement the high-security best practices of [Microsoft cloud security benchmark](#). The Microsoft cloud security benchmark is a collection of security recommendations, codified into security controls that map to key actions you should take to mitigate threats to services and data. There are currently 12 security controls, including [Network Security](#), Logging and Monitoring, and [Data Protection](#).

Azure Policy is a capability built into Azure that helps you manage compliance for multiple standards, including those of Microsoft cloud security benchmark. For well-known benchmarks, Azure Policy provides built-in definitions that provide both criteria and an actionable response that addresses noncompliance.

For Azure AI Search, there's currently one built-in definition. It's for resource logging. You can assign a policy that identifies search services that are missing resource logging, and then turn it on. For more information, see [Azure Policy Regulatory Compliance controls for Azure AI Search](#).

Use tags

Apply metadata tags to categorize search services based on data sensitivity and compliance requirements. This facilitates proper governance and security controls. For more information, see [Use tags to organize your Azure resources](#) and [General guidance – Organize Azure resources using tags](#).

Learn more

- [Azure security fundamentals](#)
- [Azure Security](#)
- [Microsoft Defender for Cloud](#)

We also recommend the following [video on security features](#). It's several years old and doesn't cover newer features, but it covers these features: CMK, IP firewalls, and private link. If you use those features, you might find this video helpful.

Quickstart: Connect to a search service

In this quickstart, you use role-based access control (RBAC) and Microsoft Entra ID to establish a keyless connection to your Azure AI Search service. You then use Python in Visual Studio Code to interact with your service.

Keyless connections provide enhanced security through granular permissions and identity-based authentication. We don't recommend hard-coded API keys, but if you prefer them, see [Connect to Azure AI Search using keys](#).

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#) in any region or tier.
- The [Azure CLI](#) for keyless authentication with Microsoft Entra ID.
- [Visual Studio Code](#) with the [Python extension](#) and [Jupyter package](#).

Configure role-based access

In this section, you enable RBAC on your Azure AI Search service and assign the necessary roles for creating, loading, and querying search objects. For more information about these steps, see [Connect to Azure AI Search using roles](#).

To configure access:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Settings > Keys**.
3. Select **Role-based access control** or **Both** if you need time to transition clients to RBAC.

Check access

6. Assign the **Search Service Contributor** role to your user account or managed identity.

7. Repeat the role assignment for **Search Index Data Contributor**.

Get service information

In this section, you retrieve the subscription ID and endpoint of your Azure AI Search service. If you only have one subscription, skip the subscription ID and only retrieve the endpoint. You use these values in the remaining sections of this quickstart.

To get your service information:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview**.
3. Make a note of the subscription ID and endpoint.

The screenshot shows the Azure portal interface for a search service named 'my-search-service'. The left sidebar has options like Activity log, Access control (IAM), Tags, Diagnose and solve problems, Resource visualizer, Search management, Indexes, Indexers, Data sources, and Aliases. The 'Overview' tab is selected. In the main content area, under the 'Essentials' section, there are several details: Resource group (move) : my-resource-group, Location (move) : East US, Subscription (move) : my-subscription, Subscription ID : aaaa0a0a-bb1b-cc2c-dd3d-eeeeee4e4e4e (highlighted with a red box), Status : Running, Date created : May 1, 2025, 12:18:59 PM, and Tags (edit) : Add tags. To the right, there are more details: Url : https://my-search-service.search.windows.net, Pricing tier : Basic, Replicas : 1 (No SLA), Partitions : 1, and Search units : 1. At the bottom, there are links for Get started, Properties, Usage, and Monitoring, and a magnifying glass icon.

Sign in to Azure

Before you connect to your Azure AI Search service, use the Azure CLI to sign in to the subscription that contains your service. This step establishes your Microsoft Entra identity, which `DefaultAzureCredential` uses to authenticate requests in the next section.

To sign in:

1. On your local system, open a command-line tool.
2. Check the active subscription and tenant in your local environment.

The screenshot shows a terminal window with the title 'Azure CLI'. Inside the terminal, the command `az account show` is typed and highlighted in blue, indicating it is being run or has been run.

3. If the active subscription and tenant aren't valid for your search service, run the following commands to update their values. You can find the subscription ID on the search service **Overview** page in the Azure portal. To find the tenant ID, select the name of your subscription on the **Overview** page, and then locate the **Parent management group** value.

Azure CLI

```
az account set --subscription <your-subscription-id>  
az login --tenant <your-tenant-id>
```

Connect to Azure AI Search

! Note

This section illustrates the basic Python pattern for keyless connections. For comprehensive guidance, see a specific quickstart or tutorial, such as [Quickstart: Use agentic retrieval in Azure AI Search](#).

You can use Python notebooks in Visual Studio Code to send requests to your Azure AI Search service. For request authentication, use the `DefaultAzureCredential` class from the Azure Identity library.

To connect using Python:

1. On your local system, open Visual Studio Code.
2. Create a `.ipynb` file.
3. Create a code cell to install the `azure-identity` and `azure-search-documents` libraries.

Python

```
pip install azure-identity azure-search-documents
```

4. Create another code cell to authenticate and connect to your search service.

Python

```
from azure.identity import DefaultAzureCredential  
from azure.search.documents.indexes import SearchIndexClient  
  
service_endpoint = "PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE"  
credential = DefaultAzureCredential()  
client = SearchIndexClient(endpoint = service_endpoint, credential =  
    credential)  
  
# List existing indexes  
indexes = client.list_indexes()  
  
for index in indexes:
```

```
index_dict = index.as_dict()
print(json.dumps(index_dict, indent = 2))
```

5. Set `service_endpoint` to the value you obtained in [Get service information](#).

6. Select **Run All** to run both code cells.

The output should list the existing indexes (if any) on your search service, indicating a successful connection.

Troubleshoot 401 errors

If you encounter a 401 error, follow these troubleshooting steps:

- Revisit [Configure role-based access](#). Your search service must have **Role-based access control** or **Both** enabled. Policies at the subscription or resource group level might override your role assignments.
- Revisit [Sign in to Azure](#). You must sign in to the subscription that contains your search service.
- Make sure your endpoint variable has surrounding quotes.
- If all else fails, restart your device to remove cached tokens and then repeat the steps in this quickstart, starting with [Sign in to Azure](#).

Quickstart: Use agentic retrieval in Azure AI Search

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In this quickstart, you use [agentic retrieval](#) to create a conversational search experience powered by documents indexed in Azure AI Search and a large language model (LLM) from Azure OpenAI in Foundry Models.

A *knowledge base* orchestrates agentic retrieval by decomposing complex queries into subqueries, running the subqueries against one or more *knowledge sources*, and returning results with metadata. By default, the knowledge base outputs raw content from your sources, but this quickstart uses the answer synthesis output mode for natural-language answer generation.

Although you can provide your own data, this quickstart uses [sample JSON documents](#) from NASA's Earth at Night e-book. The documents describe general science topics and images of Earth at night as observed from space.

! Tip

Want to get started right away? See the [azure-search-dotnet-samples](#) GitHub repository.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#) in any region that provides agentic retrieval.
- A [Microsoft Foundry project](#) and resource. When you create a project, the resource is automatically created.
- The [Azure CLI](#) for keyless authentication with Microsoft Entra ID.
- [Visual Studio Code](#).

Configure access

Before you begin, make sure you have permissions to access content and operations. We recommend Microsoft Entra ID for authentication and role-based access for authorization. You must be an **Owner** or **User Access Administrator** to assign roles. If roles aren't feasible, use [key-based authentication](#) instead.

To configure access for this quickstart, select both of the following tabs.

Azure AI Search

Azure AI Search provides the agentic retrieval pipeline. Configure access for yourself and your search service to read and write data, interact with Foundry, and run the pipeline.

On your Azure AI Search service:

1. [Enable role-based access.](#)
2. [Create a system-assigned managed identity.](#)
3. [Assign the following roles](#) to yourself.
 - **Search Service Contributor**
 - **Search Index Data Contributor**
 - **Search Index Data Reader**

ⓘ Important

Agentic retrieval has two token-based billing models:

- Billing from Azure AI Search for agentic retrieval.
- Billing from Azure OpenAI for query planning and answer synthesis.

For more information, see [Availability and pricing of agentic retrieval](#).

Get endpoints

Each Azure AI Search service and Foundry resource has an *endpoint*, which is a unique URL that identifies and provides network access to the resource. In a later section, you specify these endpoints to connect to your resources programmatically.

To get the endpoints for this quickstart, select both of the following tabs.

Azure AI Search

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview**.
3. Make a note of the endpoint, which should look like `https://my-service.search.windows.net`.

Deploy models

To use agentic retrieval, you must deploy two Azure OpenAI models to your Foundry project:

- An embedding model for text-to-vector conversion. This quickstart uses `text-embedding-3-large`, but you can use any `text-embedding` model.
- An LLM for query planning and answer generation. This quickstart uses `gpt-5-mini`, but you can use any [supported LLM for agentic retrieval](#).

For deployment instructions, see [Deploy Azure OpenAI models with Foundry](#).

Set up the environment

To set up the console application for this quickstart:

1. Create a folder named `quickstart-agentic-retrieval` to contain the application.
2. Open the folder in Visual Studio Code.
3. Select **Terminal > New Terminal**, and then run the following command to create a console application.

Console

```
dotnet new console
```

4. Install the [Azure AI Search client library](#) for .NET.

Console

```
dotnet add package Azure.Search.Documents --version 11.8.0-beta.1
```

5. Install the `dotenv.net` package to load environment variables from a `.env` file.

Console

```
dotnet add package dotenv.net
```

6. For keyless authentication with Microsoft Entra ID, install the [Azure.Identity](#) package.

Console

```
dotnet add package Azure.Identity
```

7. For keyless authentication with Microsoft Entra ID, sign in to your Azure account. If you have multiple subscriptions, select the one that contains your Azure AI Search service and Foundry project.

Console

```
az login
```

Run the code

To create and run the agentic retrieval pipeline:

1. Create a file named `.env` in the `quickstart-agentic-retrieval` folder.
2. Paste the following environment variables into the `.env` file.

```
SEARCH_ENDPOINT = PUT-YOUR-SEARCH-SERVICE-URL-HERE
AOAI_ENDPOINT = PUT-YOUR-AOAI-FOUNDRY-URL-HERE
```

3. Set `SEARCH_ENDPOINT` and `AOAI_ENDPOINT` to the values you obtained in [Get endpoints](#).
4. Paste the following code into the `Program.cs` file.

C#

```
using dotenv.net;
using System.Text.Json;
using Azure.Identity;
using Azure.Search.Documents;
```

```
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;
using Azure.Search.Documents.KnowledgeBases;
using Azure.Search.Documents.KnowledgeBases.Models;

namespace AzureSearch.Quickstart
{
    class Program
    {
        static async Task Main(string[] args)
        {
            // Load environment variables from the .env file
            // Ensure your .env file is in the same directory with the required
variables
            DotEnv.Load();

            string searchEndpoint =
Environment.GetEnvironmentVariable("SEARCH_ENDPOINT")
                ?? throw new InvalidOperationException("SEARCH_ENDPOINT isn't

    );
}

```

```

        Console.WriteLine(referenceJson);
    }

    // Clean up resources
    await indexClient.DeleteKnowledgeBaseAsync(knowledgeBaseName);
    Console.WriteLine($"Knowledge base '{knowledgeBaseName}' deleted
successfully.");

    await indexClient.DeleteKnowledgeSourceAsync(knowledgeSourceName);
    Console.WriteLine($"Knowledge source '{knowledgeSourceName}' 
deleted successfully.");

    await indexClient.DeleteIndexAsync(indexName);
    Console.WriteLine($"Index '{indexName}' deleted successfully.");
}
}
}

```

5. Build and run the application.

Console

dotnet run

Output

The output of the application should be similar to the following:

```

Index 'earth-at-night' created or updated successfully.
Documents uploaded to index 'earth-at-night' successfully.
Knowledge source 'earth-knowledge-source' created or updated successfully.
Knowledge base 'earth-knowledge-base' created or updated successfully.
Response:
Suburban belts show larger December brightening because holiday displays concentrate
in suburbs and outskirts where there is more yard space and many single-family homes
[ref_id:5], while urban cores—already having higher absolute light levels—tend to
show smaller relative increases (central areas typically brighten ~20–30%)
[ref_id:8][ref_id:5]. Phoenix's nighttime street grid is sharply visible because the
metropolitan area is laid out on a regular, continuously lit grid with bright
commercial and industrial nodes along major corridors like Grand Avenue [ref_id:0]
[ref_id:3], whereas long interstate stretches between Midwestern cities cross
sparsely populated or rural regions with far fewer continuous roadside lights and so
appear comparatively dim [ref_id:8].

```

Understand the code

Now that you've run the code, let's break down the key steps:

1. [Create a search index](#)
2. [Upload documents to the index](#)
3. [Create a knowledge source](#)
4. [Create a knowledge base](#)
5. [Set up messages](#)
6. [Run the retrieval pipeline](#)
7. [Continue the conversation](#)

Create a search index

In Azure AI Search, an index is a structured collection of data. The following code defines an index named `earth-at-night`, which you previously specified using the `indexName` variable.

The index schema contains fields for document identification and page content, embeddings, and numbers. The schema also includes configurations for semantic ranking and vector search, which uses your `text-embedding-3-large` deployment to vectorize text and match documents based on semantic or conceptual similarity.

C#

```
// Define fields for the index
var fields = new List<SearchField>
{
    new SimpleField("id", SearchFieldDataType.String) { IsKey = true, IsFilterable = true, IsSortable = true, IsFacetable = true },
    new SearchField("page_chunk", SearchFieldDataType.String) { IsFilterable = false, IsSortable = false, IsFacetable = false },
    new SearchField("page_embedding_text_3_large",
        SearchFieldDataType.Collection(SearchFieldDataType.Single)) { VectorSearchDimensions = 3072, VectorSearchProfileName = "hnsw_text_3_large" },
    new SimpleField("page_number", SearchFieldDataType.Int32) { IsFilterable = true, IsSortable = true, IsFacetable = true }
};

// Define a vectorizer
var vectorizer = new AzureOpenAIVectorizer(vectorizerName:
"azure_openai_text_3_large")
{
    Parameters = new AzureOpenAIVectorizerParameters
    {
        ResourceUri = new Uri(aoaiEndpoint),
        DeploymentName = aoaiEmbeddingDeployment,
        ModelName = aoaiEmbeddingModel
    }
};

// Define a vector search profile and algorithm
var vectorSearch = new VectorSearch()
{
```

```

Profiles =
{
    new VectorSearchProfile(
        name: "hnsw_text_3_large",
        algorithmConfigurationName: "alg"
    )
    {
        VectorizerName = "azure_openai_text_3_large"
    }
},
Algorithms =
{
    new HnswAlgorithmConfiguration(name: "alg")
},
Vectorizers =
{
    vectorizer
}
};

// Define a semantic configuration
var semanticConfig = new SemanticConfiguration(
    name: "semantic_config",
    prioritizedFields: new SemanticPrioritizedFields
    {
        ContentFields = { new SemanticField("page_chunk") }
    }
);

var semanticSearch = new SemanticSearch()
{
    DefaultConfigurationName = "semantic_config",
    Configurations = { semanticConfig }
};

// Create the index
var index = new SearchIndex(indexName)
{
    Fields = fields,
    VectorSearch = vectorSearch,
    SemanticSearch = semanticSearch
};

// Create the index client, deleting and recreating the index if it exists
var indexClient = new SearchIndexClient(new Uri(searchEndpoint), credential);
await indexClient.CreateOrUpdateIndexAsync(index);
Console.WriteLine($"Index '{indexName}' created or updated successfully.");

```

Upload documents to the index

Currently, the `earth-at-night` index is empty. The following code populates the index with JSON documents from [NASA's Earth at Night e-book](#). As required by Azure AI Search, each

document conforms to the fields and data types defined in the index schema.

C#

```
// Upload sample documents from the GitHub URL
string url = "https://raw.githubusercontent.com/Azure-Samples/azure-search-sample-data/refs/heads/main/nasa-e-book/earth-at-night-json/documents.json";
var httpClient = new HttpClient();
var response = await httpClient.GetAsync(url);
response.EnsureSuccessStatusCode();
var json = await response.Content.ReadAsStringAsync();
var documents = JsonSerializer.Deserialize<List<Dictionary<string, object>>>(json);
var searchClient = new SearchClient(new Uri(searchEndpoint), indexName, credential);
var searchIndexingBufferedSender = new
SearchIndexingBufferedSender<Dictionary<string, object>>(
    searchClient,
    new SearchIndexingBufferedSenderOptions<Dictionary<string, object>>
    {
        KeyFieldAccessor = doc => doc["id"].ToString(),
    }
);
await searchIndexingBufferedSender.UploadDocumentsAsync(documents);
await searchIndexingBufferedSender.FlushAsync();
Console.WriteLine($"Documents uploaded to index '{indexName}' successfully.");
```

Create a knowledge source

A knowledge source is a reusable reference to source data. The following code defines a knowledge source named `earth-knowledge-source` that targets the `earth-at-night` index.

`SourceDataFields` specifies which index fields are accessible for retrieval and citations. Our example includes only human-readable fields to avoid lengthy, uninterpretable embeddings in responses.

C#

```
// Create a knowledge source
var indexKnowledgeSource = new SearchIndexKnowledgeSource(
    name: knowledgeSourceName,
    searchIndexParameters: new SearchIndexKnowledgeSourceParameters(searchIndexName:
indexName)
{
    SourceDataFields = { new SearchIndexFieldReference(name: "id"), new
SearchIndexFieldReference(name: "page_chunk"), new SearchIndexFieldReference(name:
"page_number") }
}
);

await indexClient.CreateOrUpdateKnowledgeSourceAsync(indexKnowledgeSource);
```

```
Console.WriteLine($"Knowledge source '{knowledgeSourceName}' created or updated successfully.");
```

Create a knowledge base

To target `earth-knowledge-source` and your `gpt-5-mini` deployment at query time, you need a knowledge base. The following code defines a knowledge base named `earth-knowledge-base`, which you previously specified using the `knowledgeBaseName` variable.

`OutputMode` is set to `AnswerSynthesis`, enabling natural-language answers that cite the retrieved documents and follow the provided `AnswerInstructions`.

C#

```
// Create a knowledge base
var openAiParameters = new AzureOpenAIVectorizerParameters
{
    ResourceUri = new Uri(aaaiEndpoint),
    DeploymentName = aaaiGptDeployment,
    ModelName = aaaiGptModel
};

var model = new KnowledgeBaseAzureOpenAIModel(azureOpenAIParameters:
openAiParameters);

var knowledgeBase = new KnowledgeBase(
    name: knowledgeBaseName,
    knowledgeSources: new KnowledgeSourceReference[] { new
KnowledgeSourceReference(knowledgeSourceName) }
)
{
    RetrievalReasoningEffort = new KnowledgeRetrievalLowReasoningEffort(),
    OutputMode = KnowledgeRetrievalOutputMode.AnswerSynthesis,
    AnswerInstructions = "Provide a two sentence concise and informative answer
based on the retrieved documents.",
    Models = { model }
};

await indexClient.CreateOrUpdateKnowledgeBaseAsync(knowledgeBase);
Console.WriteLine($"Knowledge base '{knowledgeBaseName}' created or updated
successfully.");
```

Set up messages

Messages are the input for the retrieval route and contain the conversation history. Each message includes a role that indicates its origin, such as `system` or `user`, and content in natural language. The LLM you use determines which roles are valid.

The following code creates a system message, which instructs `earth-knowledge-base` to answer questions about the Earth at night and respond with "I don't know" when answers are unavailable.

C#

```
// Set up messages
string instructions = @"A Q&A agent that can answer questions about the Earth at
night.
If you don't have the answer, respond with ""I don't know"".";

var messages = new List<Dictionary<string, string>>
{
    new Dictionary<string, string>
    {
        { "role", "system" },
        { "content", instructions }
    }
};
```

Run the retrieval pipeline

You're ready to run agentic retrieval. The following code sends a two-part user query to `earth-knowledge-base`, which:

1. Analyzes the entire conversation to infer the user's information need.
2. Decomposes the compound query into focused subqueries.
3. Runs the subqueries concurrently against your knowledge source.
4. Uses semantic ranker to rerank and filter the results.
5. Synthesizes the top results into a natural-language answer.

C#

```
// Run agentic retrieval
var baseClient = new KnowledgeBaseRetrievalClient(
    endpoint: new Uri(searchEndpoint),
    knowledgeBaseName: knowledgeBaseName,
    tokenCredential: new DefaultAzureCredential()
);

messages.Add(new Dictionary<string, string>
{
    { "role", "user" },
    { "content", @"Why do suburban belts display larger December brightening than
urban cores even though absolute light levels are higher downtown? Why is the
Phoenix nighttime street grid is so sharply visible from space, whereas large
stretches of the interstate between midwestern cities remain comparatively dim?" }
});
```

```

var retrievalRequest = new KnowledgeBaseRetrievalRequest();
foreach (Dictionary<string, string> message in messages) {
    if (message["role"] != "system") {
        retrievalRequest.Messages.Add(new KnowledgeBaseMessage(content: new[] { new KnowledgeBaseMessageTextContent(message["content"]) }) { Role = message["role"] });
    }
}
retrievalRequest.RetrievalReasoningEffort = new KnowledgeRetrievalLowReasoningEffort();
var retrievalResult = await baseClient.RetrieveAsync(retrievalRequest);

messages.Add(new Dictionary<string, string>
{
    { "role", "assistant" },
    { "content", (retrievalResult.Value.Response[0].Content[0] as KnowledgeBaseMessageTextContent).Text }
});

```

Review the response, activity, and references

The following code displays the response, activity, and references from the retrieval pipeline, where:

- `Response` provides a synthesized, LLM-generated answer to the query that cites the retrieved documents. When answer synthesis isn't enabled, this section contains content extracted directly from the documents.
- `Activity` tracks the steps that were taken during the retrieval process, including the subqueries generated by your `gpt-5-mini` deployment and the tokens used for semantic ranking, query planning, and answer synthesis.
- `References` lists the documents that contributed to the response, each one identified by their `DocKey`.

C#

```

// Print the response, activity, and references
Console.WriteLine("Response:");
Console.WriteLine((retrievalResult.Value.Response[0].Content[0] as KnowledgeBaseMessageTextContent).Text);

Console.WriteLine("Activity:");
foreach (var activity in retrievalResult.Value.Activity)
{
    Console.WriteLine($"Activity Type: {activity.GetType().Name}");
    string activityJson = JsonSerializer.Serialize(
        activity,
        activity.GetType(),
        new JsonSerializerOptions { WriteIndented = true })

```

```

    );
    Console.WriteLine(activityJson);
}

Console.WriteLine("References:");
foreach (var reference in retrievalResult.Value.References)
{
    Console.WriteLine($"Reference Type: {reference.GetType().Name}");
    string referenceJson = JsonSerializer.Serialize(
        reference,
        reference.GetType(),
        new JsonSerializerOptions { WriteIndented = true }
    );
    Console.WriteLine(referenceJson);
}

```

Continue the conversation

The following code continues the conversation with `earth-knowledge-base`. After you send this user query, the knowledge base fetches relevant content from `earth-knowledge-source` and appends the response to the messages list.

C#

```

// Continue the conversation
messages.Add(new Dictionary<string, string>
{
    { "role", "user" },
    { "content", "How do I find lava at night?" }
});

retrievalRequest = new KnowledgeBaseRetrievalRequest();
foreach (Dictionary<string, string> message in messages) {
    if (message["role"] != "system") {
        retrievalRequest.Messages.Add(new KnowledgeBaseMessage(content: new[] { new
KnowledgeBaseMessageTextContent(message["content"]) }) { Role = message["role"] });
    }
}
retrievalRequest.RetrievalReasoningEffort = new
KnowledgeRetrievalLowReasoningEffort();
retrievalResult = await baseClient.RetrieveAsync(retrievalRequest);

messages.Add(new Dictionary<string, string>
{
    { "role", "assistant" },
    { "content", (retrievalResult.Value.Response[0].Content[0] as
KnowledgeBaseMessageTextContent).Text }
});

```

Review the new response, activity, and references

The following code displays the new response, activity, and references from the retrieval pipeline.

C#

```
// Print the new response, activity, and references
Console.WriteLine("Response:");
Console.WriteLine((retrievalResult.Value.Response[0].Content[0] as
KnowledgeBaseMessageTextContent).Text);

Console.WriteLine("Activity:");
foreach (var activity in retrievalResult.Value.Activity)
{
    Console.WriteLine($"Activity Type: {activity.GetType().Name}");
    string activityJson = JsonSerializer.Serialize(
        activity,
        activity.GetType(),
        new JsonSerializerOptions { WriteIndented = true }
    );
    Console.WriteLine(activityJson);
}

Console.WriteLine("References:");
foreach (var reference in retrievalResult.Value.References)
{
    Console.WriteLine($"Reference Type: {reference.GetType().Name}");
    string referenceJson = JsonSerializer.Serialize(
        reference,
        reference.GetType(),
        new JsonSerializerOptions { WriteIndented = true }
    );
    Console.WriteLine(referenceJson);
}
```

Clean up resources

When you work in your own subscription, it's a good idea to finish a project by determining whether you still need the resources you created. Resources that are left running can cost you money.

In the Azure portal, you can manage your Azure AI Search and Foundry resources by selecting **All resources** or **Resource groups** from the left pane.

Otherwise, the following code from `Program.cs` deleted the objects you created in this quickstart.

Delete the knowledge base

C#

```
await indexClient.DeleteKnowledgeBaseAsync(knowledgeBaseName);
Console.WriteLine($"Knowledge base '{knowledgeBaseName}' deleted successfully.");
```

Delete the knowledge source

C#

```
await indexClient.DeleteKnowledgeSourceAsync(knowledgeSourceName);
Console.WriteLine($"Knowledge source '{knowledgeSourceName}' deleted
successfully.");
```

Delete the search index

C#

```
await indexClient.DeleteIndexAsync(indexName);
Console.WriteLine($"Index '{indexName}' deleted successfully.");
```

Last updated on 11/18/2025

Quickstart: Vector search

In this quickstart, you work with a .NET app to create, populate, and query vectors. The code examples perform these operations by using the [Azure AI Search client library](#). The library provides an abstraction over the REST API for access to index operations such as data ingestion, search operations, and index management operations.

In Azure AI Search, a [vector store](#) has an index schema that defines vector and nonvector fields, a vector search configuration for algorithms that create the embedding space, and settings on vector field definitions that are evaluated at query time. The [Create Index](#) REST API creates the vector store.

(!) Note

This quickstart omits the vectorization step and provides inline embeddings. If you want to add [built-in data chunking and vectorization](#) over your own content, try the [Import data \(new\) wizard](#) for an end-to-end walkthrough.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription.
 - You can use a free search service for most of this quickstart, but we recommend the Basic tier or higher for larger data files.
 - To run the query example that invokes [semantic reranking](#), your search service must have [semantic ranker enabled](#).
- [Visual Studio Code](#) or [Visual Studio](#).
- [Git](#) to clone the sample repo.

Get service information

Requests to the search endpoint must be authenticated and authorized. While it's possible to use API keys or roles for this task, we recommend [using a keyless connection via Microsoft Entra ID](#).

This quickstart uses `DefaultAzureCredential`, which simplifies authentication in both development and production scenarios. However, for production scenarios, you might have

more advanced requirements that require a different approach. See [Authenticate .NET apps to Azure services by using the Azure SDK for .NET](#) to understand all of your options.

Clone the code and setup environment

1. Clone the repo containing the code for this quickstart.

```
Bash
```

```
git clone https://github.com/Azure-Samples/azure-search-dotnet-samples
```

This repo has .NET code examples for several articles each in a separate subfolder.

2. Open the subfolder `quickstart-Vector-Search` in Visual Studio Code, or double click the `.sln` file to open the solution in Visual Studio.
3. Open the `appsettings.json` files in the `VectorSearchExamples` and `VectorSearchCreatePopulateIndex` folders. Update the following values:

- `AZURE_SEARCH_ENDPOINT`: Find the url of your Azure AI Search service in the [Azure portal](#). On the **Overview** page of your search resource, look for the URL field. An example endpoint might look like `https://mydemo.search.windows.net`.
- `AZURE_SEARCH_INDEX_NAME`: Leave the default value provided in the file or enter your own index name.

Create the vector index and upload documents

To run search queries against the Azure AI Search service, you first need to create a search index and upload documents to the service.

1. Open a new terminal in the `VectorSearchCreatePopulateIndex` folder.
2. Run the project using the `dotnet run` command:

```
.NET CLI
```

```
dotnet run
```

The following code executes to create an index:

```
C#
```

```

static async Task CreateSearchIndex(string indexName, SearchIndexClient indexClient)
{
    var addressField = new ComplexField("Address");
    addressField.Fields.Add(new SearchableField("StreetAddress") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft });
    addressField.Fields.Add(new SearchableField("City") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true });
    addressField.Fields.Add(new SearchableField("StateProvince") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true });
    addressField.Fields.Add(new SearchableField("PostalCode") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true });
    addressField.Fields.Add(new SearchableField("Country") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true });

    var allFields = new List<SearchField>()
{
    new SimpleField("HotelId", SearchFieldDataType.String) { IsKey = true,
IsFacetable = true, IsFilterable = true },
    new SearchableField("HotelName") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft },
    new SearchableField("Description") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft },
    new VectorSearchField("DescriptionVector", 1536, "my-vector-profile"),
    new SearchableField("Category") { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true },
    new SearchableField("Tags", collection: true) { AnalyzerName =
LexicalAnalyzerName.EnMicrosoft, IsFacetable = true, IsFilterable = true },
    new SimpleField("ParkingIncluded", SearchFieldDataType.Boolean) { IsFacetable =
true, IsFilterable = true },
    new SimpleField("LastRenovationDate", SearchFieldDataType.DateTimeOffset) {
IsSortable = true },
    new SimpleField("Rating", SearchFieldDataType.Double) { IsFacetable = true,
IsFilterable = true, IsSortable = true },
    addressField,
    new SimpleField("Location", SearchFieldDataType.GeographyPoint) { IsFilterable =
true, IsSortable = true },
};
}

// Create the suggester configuration
var suggester = new SearchSuggester("sg", new[] { "Address/City",
"Address/Country" });

// Create the semantic search
var semanticSearch = new SemanticSearch()
{
    Configurations =
    {
        new SemanticConfiguration(
            name: "semantic-config",
            prioritizedFields: new SemanticPrioritizedFields
            {
                TitleField = new SemanticField("HotelName"),
                KeywordsFields = { new SemanticField("Category") },
                ContentFields = { new SemanticField("Description") }
            }
    }
}

```

```

        })
    };
};

// Add vector search configuration
var vectorSearch = new VectorSearch();
vectorSearch.Algorithms.Add(new HnswAlgorithmConfiguration(name: "my-hnsw-
vector-config-1"));
vectorSearch.Profiles.Add(new VectorSearchProfile(name: "my-vector-profile",
algorithmConfigurationName: "my-hnsw-vector-config-1"));

var definition = new SearchIndex(indexName)
{
    Fields = allFields,
    Suggesters = { suggester },
    VectorSearch = vectorSearch,
    SemanticSearch = semanticSearch
};

// Create or update the index
Console.WriteLine($"Creating or updating index '{indexName}'...");
var result = await indexClient.CreateOrUpdateIndexAsync(definition);
Console.WriteLine($"Index '{result.Value.Name}' updated.");
Console.WriteLine();
}

```

The following code uploads the JSON formatted documents in the `hotel-samples.json` file to the Azure AI Search service:

C#

```

static async Task UploadDocs(SearchClient searchClient)
{
    var jsonPath = Path.Combine(Directory.GetCurrentDirectory(), "HotelData.json");

    // Read and parse hotel data
    var json = await File.ReadAllTextAsync(jsonPath);
    List<Hotel> hotels = new List<Hotel>();
    try
    {
        using var doc = JsonDocument.Parse(json);
        if (doc.RootElement.ValueKind != JsonValueKind.Array)
        {
            Console.WriteLine("HotelData.json root is not a JSON array.");
        }
        // Deserialize all hotel objects
        hotels = doc.RootElement.EnumerateArray()
            .Select(e => JsonSerializer.Deserialize<Hotel>(e.GetRawText()))
            .Where(h => h != null)
            .ToList();
    }
    catch (JsonException ex)
    {

```

```

        Console.WriteLine($"Failed to parse HotelData.json: {ex.Message}");
    }

    try
    {
        // Upload hotel documents to Azure Search
        var result = await searchClient.UploadDocumentsAsync(hotels);
        foreach (var r in result.Value.Results)
        {
            Console.WriteLine($"Key: {r.Key}, Succeeded: {r.Succeeded}");
        }
    }
    catch (Exception ex)
    {
        Console.WriteLine("Failed to upload documents: " + ex);
    }
}

```

After you run the project, the following output is printed:

Output

```

Key: 1, Succeeded: True
Key: 2, Succeeded: True
Key: 3, Succeeded: True
Key: 4, Succeeded: True
Key: 48, Succeeded: True
Key: 49, Succeeded: True
Key: 13, Succeeded: True

```

Key takeaways:

- Your code interacts with a specific search index hosted in your Azure AI Search service through the `SearchClient`, which is the main object provided by the `azure-search-documents` package. The `SearchClient` provides access to index operations such as:
 - **Data ingestion:** `UploadDocuments()`, `MergeDocuments()`, `DeleteDocuments()`
 - **Search operations:** `Search()`, `Autocomplete()`, `Suggest()`
 - **Index management operations:** `CreateOrUpdateIndex()`
- Vector fields contain floating point values. The dimensions attribute has a minimum of 2 and a maximum of 4096 floating point values each. This size of embeddings generated by the Azure OpenAI `text-embedding-3-small` model for this quickstart is 1536.

Run search queries

After the index is created and documents are loaded, you can issue vector queries against them by calling `SearchAsync()` with various parameters.

1. In the `VectorSearchExamples` folder, open the `Program.cs` file.

2. Open a new terminal in the `VectorSearchExamples` folder.

In the following sections, you run queries against the `hotels-vector-quickstart` index. The queries include:

- Single vector search
- Single vector search with filter
- Hybrid search
- Semantic hybrid search with filter

Single vector search

The first example demonstrates a basic scenario where you want to find document descriptions that closely match the search string.

1. In the `Program.cs` file of the `VectorSearchExamples` folder, uncomment the method call `SearchExamples.SearchSingleVector(searchClient, vectorizedResult);`. This method executes the following search function in the `SearchExamples.cs` class:

C#

```
public static async Task SearchSingleVector(SearchClient searchClient,
    ReadOnlyMemory<float> precalculatedVector)
{
    SearchResults<Hotel> response = await searchClient.SearchAsync<Hotel>(
        new SearchOptions
        {
            VectorSearch = new()
            {
                Queries = { new VectorizedQuery(precalculatedVector) {
                    KNearestNeighborsCount = 5, Fields = { "DescriptionVector" } } },
                Select = { "HotelId", "HotelName", "Description", "Category",
                    "Tags" },
            });
}

Console.WriteLine($"Single Vector Search Results:");
await foreach (SearchResult<Hotel> result in response.GetResultsAsync())
{
    Hotel doc = result.Document;
    Console.WriteLine($"Score: {result.Score}, HotelId: {doc.HotelId},
        HotelName: {doc.HotelName}");
}
Console.WriteLine();
}
```

2. Run the project using the `dotnet run` command:

```
.NET CLI
```

```
dotnet run
```

After you run the project, the search results are printed in the output window:

```
Output
```

```
Single Vector Search Results:  
Score: 0.6605852, HotelId: 48, HotelName: Nordick's Valley Motel  
Score: 0.6333684, HotelId: 13, HotelName: Luxury Lion Resort  
Score: 0.605672, HotelId: 4, HotelName: Sublime Palace Hotel  
Score: 0.6026341, HotelId: 49, HotelName: Swirling Currents Hotel  
Score: 0.57902366, HotelId: 2, HotelName: Old Century Hotel
```

Single vector search with filter

You can add filters, but the filters are applied to the nonvector content in your index. In this example, the filter applies to the `Tags` field to filter out any hotels that don't provide free Wi-Fi.

1. In the `Program.cs` file of the `VectorSearchExamples` folder, uncomment the method call `SearchExamples.SearchSingleVectorWithFilter(searchClient, vectorizedResult);`. This method executes the following search function in the `SearchExamples.cs` class:

```
C#
```

```
public static async Task SearchSingleVectorWithFilter(SearchClient searchClient, ReadOnlyMemory<float> precalculatedVector)
{
    SearchResults<Hotel> responseWithFilter = await
    searchClient.SearchAsync<Hotel>(
        new SearchOptions
        {
            VectorSearch = new()
            {
                Queries = { new VectorizedQuery(precalculatedVector) {
                    KNearestNeighborsCount = 5, Fields = { "DescriptionVector" } } }
            },
            Filter = "Tags/any(tag: tag eq 'free wifi')",
            Select = { "HotelId", "HotelName", "Description", "Category",
"Tags" }
        });
    Console.WriteLine($"Single Vector Search With Filter Results:");
    await foreach (SearchResult<Hotel> result in
    responseWithFilter.GetResultsAsync())
    {
        Hotel doc = result.Document;
        Console.WriteLine($"Score: {result.Score}, HotelId: {doc.HotelId},
```

```

        HotelName: {doc.HotelName}, Tags: {string.Join(String.Empty, doc.Tags)}");
    }
    Console.WriteLine();
}

```

2. Run the project again, and the status of each document is printed below it:

Output

```

Single Vector Search With Filter Results:
Score: 0.6605852, HotelId: 48, HotelName: Nordick's Valley Motel, Tags:
continental breakfastair conditioningfree wifi

```

The query was the same as the previous [single vector search example](#), but it includes a post-processing exclusion filter and returns only the two hotels that have free Wi-Fi.

3. The next filter example uses a **geo filter**. In the `Program.cs` file of the

`VectorSearchExamples` folder, uncomment the method call

`SearchExamples.SingleSearchWithGeoFilter(searchClient, vectorizedResult);`. This method executes the following search function in the `SearchExamples.cs` class:

C#

```

public static async Task SingleSearchWithGeoFilter(SearchClient searchClient,
    ReadOnlyMemory<float> precalculatedVector)
{
    SearchResults<Hotel> responseWithGeoFilter = await
    searchClient.SearchAsync<Hotel>(
        new SearchOptions
        {
            VectorSearch = new()
            {
                Queries = { new VectorizedQuery(precalculatedVector) {
                    KNearestNeighborsCount = 5, Fields = { "DescriptionVector" } } }
            },
            Filter = "geo.distance(Location, geography'POINT(-77.03241
38.90166') le 300",
            Select = { "HotelId", "HotelName", "Description", "Address",
"Category", "Tags" },
            Facets = { "Address/StateProvince" },
        });
}

Console.WriteLine($"Vector query with a geo filter:");
await foreach (SearchResult<Hotel> result in
responseWithGeoFilter.GetResultsAsync())
{
    Hotel doc = result.Document;
    Console.WriteLine($"HotelId: {doc.HotelId}");
}

```

```

        Console.WriteLine($"HotelName: {doc.HotelName}");
        Console.WriteLine($"Score: {result.Score}");
        Console.WriteLine($"City/State:
{doc.Address.City}/{doc.Address.StateProvince}");
        Console.WriteLine($"Description: {doc.Description}");
        Console.WriteLine();
    }
    Console.WriteLine();
}

```

The query was the same as the previous [single vector search example](#), but it includes a post-processing exclusion filter and returns only the two hotels within 300 kilometers.

- Run the project again, and the status of each document is printed below it:

Output

```

Vector query with a geo filter:
-HotelId: 48
HotelName: Nordick's Valley Motel
Score: 0.6605852246284485
City/State: Washington D.C./null
Description: Only 90 miles (about 2 hours) from the nation's capital and nearby
most everything the historic valley has to offer. Hiking? Wine Tasting?
Exploring the caverns? It's all nearby and we have specially priced packages to
help make our B&B your home base for fun while visiting the valley.

-HotelId: 49
HotelName: Swirling Currents Hotel
Score: 0.602634072303772
City/State: Arlington/VA
Description: Spacious rooms, glamorous suites and residences, rooftop pool,
walking access to shopping, dining, entertainment and the city center. Each
room comes equipped with a microwave, a coffee maker and a minifridge. In-room
entertainment includes complimentary Wi-Fi and flat-screen TVs.

```

Hybrid search

Hybrid search consists of keyword queries and vector queries in a single search request. This example runs the vector query and full-text search concurrently:

- Search string:** `historic hotel walk to restaurants and shopping`
- Vector query string** (vectorized into a mathematical representation): `Quintessential
lodging near running trails, eateries, retail`

- In the `Program.cs` file of the `VectorSearchExamples` folder, uncomment the method call `SearchExamples.SearchHybridVectorAndText(searchClient, vectorizedResult);`. This method executes the following search function in the `SearchExamples.cs` class:

C#

```
public static async Task<SearchResults<Hotel>>
SearchHybridVectorAndText(SearchClient searchClient, ReadOnlyMemory<float>
precalculatedVector)
{
    SearchResults<Hotel> responseWithFilter = await
searchClient.SearchAsync<Hotel>(
        "historic hotel walk to restaurants and shopping",
        new SearchOptions
    {
        VectorSearch = new()
        {
            Queries = { new VectorizedQuery(precalculatedVector) {
KNearestNeighborsCount = 5, Fields = { "DescriptionVector" } } }
        },
        Select = { "HotelId", "HotelName", "Description", "Category",
"Tags" },
        Size = 5,
    });
}

Console.WriteLine($"Hybrid search results:");
await foreach (SearchResult<Hotel> result in
responseWithFilter.GetResultsAsync())
{
    Hotel doc = result.Document;
    Console.WriteLine($"Score: {result.Score}");
    Console.WriteLine($"HotelId: {doc.HotelId}");
    Console.WriteLine($"HotelName: {doc.HotelName}");
    Console.WriteLine($"Description: {doc.Description}");
    Console.WriteLine($"Category: {doc.Category}");
    Console.WriteLine($"Tags: {string.Join(String.Empty, doc.Tags)}");
    Console.WriteLine();
}
Console.WriteLine();
return responseWithFilter;
}
```

2. Run the project again, and the status of each document is printed below it:

Output

```
Hybrid search results:

Because Reciprocal Rank Fusion (RRF) merges results, it helps to review the inputs. The following results are from only the full-text query. The top two results are Sublime Palace Hotel and History Lion Resort. The Sublime Palace Hotel has a stronger BM25 relevance score.

JSON

```
{  
  "@search.score": 2.2626662,  
  "HotelName": "Sublime Palace Hotel",  
  "Description": "Sublime Palace Hotel is located in the heart of the historic center of Sublime in an extremely vibrant and lively area within short walking
```

```

distance to the sites and landmarks of the city and is surrounded by the
extraordinary beauty of churches, buildings, shops and monuments. Sublime Palace is
part of a lovingly restored 1800 palace."
},
{
    "@search.score": 0.86421645,
    "HotelName": "Luxury Lion Resort",
    "Description": "Unmatched Luxury. Visit our downtown hotel to indulge in luxury
accommodations. Moments from the stadium, we feature the best in comfort"
},

```

In the vector-only query, which uses HNSW for finding matches, the Sublime Palace Hotel drops to fourth position. Historic Lion, which was second in the full-text search and third in the vector search, doesn't experience the same range of fluctuation, so it appears as a top match in a homogenized result set.

Semantic hybrid search with a filter

The hybrid query with semantic ranking is filtered to show only the hotels within a 500-kilometer radius of Washington D.C.

1. In the `Program.cs` file of the `VectorSearchExamples` folder, uncomment the method call `SearchExamples.SearchHybridVectorAndSemantic(searchClient, vectorizedResult);`. This method executes the following search function in the `SearchExamples.cs` class:

C#

```

public static async Task SearchHybridVectorAndSemantic(SearchClient  

searchClient, ReadOnlyMemory<float> precalculatedVector)  

{  

    SearchResults<Hotel> responseWithFilter = await  

searchClient.SearchAsync<Hotel>(  

    "historic hotel walk to restaurants and shopping",  

    new SearchOptions  

{

```

```

        IncludeTotalCount = true,
        VectorSearch = new()
        {
            Queries = { new VectorizedQuery(precalculatedVector) {
                KNearestNeighborsCount = 5, Fields = { "DescriptionVector" } } }
            },
            Select = { "HotelId", "HotelName", "Description", "Category",
"Tags" },
            SemanticSearch = new SemanticSearchOptions
            {
                SemanticConfigurationName = "semantic-config"
            },
            QueryType = SearchQueryType.Semantic,
            Size = 5
        });
    }

    Console.WriteLine($"Hybrid search results:");
    await foreach (SearchResult<Hotel> result in
responseWithFilter.GetResultsAsync())
    {
        Hotel doc = result.Document;
        Console.WriteLine($"Score: {result.Score}");
        Console.WriteLine($"HotelId: {doc.HotelId}");
        Console.WriteLine($"HotelName: {doc.HotelName}");
        Console.WriteLine($"Description: {doc.Description}");
        Console.WriteLine($"Category: {doc.Category}");
        Console.WriteLine();
    }
    Console.WriteLine();
}

```

- Run the project again, and review the output below the cell. The response is three hotels, which are filtered by location and faceted by `StateProvince` and semantically reranked to promote results that are closest to the search string query (`historic hotel walk to restaurants and shopping`).

The Swirling Currents Hotel now moves into the top spot. Without semantic ranking, Nordick's Valley Motel is number one. With semantic ranking, the machine comprehension models recognize that `historic` applies to "hotel, within walking distance to dining (restaurants) and shopping."

Output

```

Key takeaways:

- In a hybrid search, you can integrate vector search with full-text search over keywords. Filters, spell check, and semantic ranking apply to textual content only, and not vectors. In this final query, there's no semantic `answer` because the system didn't produce one that was sufficiently strong.
- Actual results include more detail, including semantic captions and highlights. Results were modified for readability. To get the full structure of the response, run the request in the REST client.

Clean up

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal by using the [All resources](#) or [Resource groups](#) link in the leftmost pane.

Next steps

- Review the repository of code samples for vector search capabilities in Azure AI Search for [.NET](#)
 - Review the other .NET and Azure AI Search code samples in the [azure-search-dotnet-samples repo](#)
-

Last updated on 11/20/2025

Quickstart: Classic generative search (RAG) using grounding data from Azure AI Search

10/15/2025

In this quickstart, you send queries to a chat completion model for a conversational search experience over your indexed content on Azure AI Search. After setting up Azure OpenAI and Azure AI Search resources in the Azure portal, you run code to call the APIs.

ⓘ Note

We now recommend [agentic retrieval](#) for RAG workflows, but classic RAG is simpler. If it meets your application requirements, it's still a good choice.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure OpenAI resource](#).
 - [Choose a region](#) that supports the chat completion model you want to use (gpt-4o, gpt-4o-mini, or an equivalent model).
 - [Deploy the chat completion model](#) in Azure AI Foundry or [use another approach](#).
- An [Azure AI Search resource](#).
 - We recommend using the Basic tier or higher.
 - [Enable semantic ranking](#).
- [Visual Studio Code](#) or [Visual Studio](#).
- [.NET 9.0](#) installed.

Configure access

Requests to the search endpoint must be authenticated and authorized. You can use API keys or roles for this task. Keys are easier to start with, but roles are more secure. This quickstart assumes roles.

You're setting up two clients, so you need permissions on both resources.

Azure AI Search is receiving the query request from your local system. Assign yourself the **Search Index Data Reader** role assignment if the hotels sample index already exists. If it

doesn't exist, assign yourself **Search Service Contributor** and **Search Index Data Contributor** roles so that you can create and query the index.

Azure OpenAI is receiving the query and the search results from your local system. Assign yourself the **Cognitive Services OpenAI User** role on Azure OpenAI.

1. Sign in to the [Azure portal](#).
2. Configure Azure AI Search for role-based access:
 - a. In the Azure portal, find your Azure AI Search service.
 - b. On the left menu, select **Settings > Keys**, and then select either **Role-based access control** or **Both**.
3. Assign roles:
 - a. On the left menu, select **Access control (IAM)**.
 - b. On Azure AI Search, select these roles to create, load, and query a search index, and then assign them to your Microsoft Entra ID user identity:
 - **Search Index Data Contributor**
 - **Search Service Contributor**
 - c. On Azure OpenAI, select **Access control (IAM)** to assign this role to yourself on Azure OpenAI:
 - **Cognitive Services OpenAI User**

It can take several minutes for permissions to take effect.

Create an index

A search index provides grounding data for the chat model. We recommend the **hotels-sample-index**, which can be created in minutes and runs on any search service tier. This index is created using built-in sample data.

1. In the Azure portal, [find your search service](#).
2. On the **Overview** home page, select **Import data** to start the wizard.
3. On the **Connect to your data** page, select **Samples** from the dropdown list.
4. Choose the **hotels-sample**.
5. Select **Next** through the remaining pages, accepting the default values.

6. Once the index is created, select **Search management > Indexes** from the left menu to open the index.
7. Select **Edit JSON**.
8. Scroll to the end of the index, where you can find placeholders for constructs that can be added to an index.

JSON

```
"analyzers": [],
"tokenizers": [],
"tokenFilters": [],
"charFilters": [],
"normalizers": [],
```

9. On a new line after "normalizers", paste in the following semantic configuration. This example specifies a `"defaultConfiguration"`, which is important to the running of this quickstart.

JSON

```
"semantic": {
    "defaultConfiguration": "semantic-config",
    "configurations": [
        {
            "name": "semantic-config",
            "prioritizedFields": {
                "titleField": {
                    "fieldName": "HotelName"
                },
                "prioritizedContentFields": [
                    {
                        "fieldName": "Description"
                    }
                ],
                "prioritizedKeywordsFields": [
                    {
                        "fieldName": "Category"
                    },
                    {
                        "fieldName": "Tags"
                    }
                ]
            }
        }
    ],
}
```

10. Save your changes.

11. Run the following query in [Search Explorer](#) to test your index: complimentary breakfast.

Output should look similar to the following example. Results that are returned directly from the search engine consist of fields and their verbatim values, along with metadata like a search score and a semantic ranking score and caption if you use semantic ranker. We used a [select statement](#) to return just the HotelName, Description, and Tags fields.

        ]
    },
    . . .
}]
}

```

Get service endpoints

In the remaining sections, you set up API calls to Azure OpenAI and Azure AI Search. Get the service endpoints so that you can provide them as variables in your code.

1. Sign in to the [Azure portal](#).

2. [Find your search service](#).
3. On the **Overview** home page, copy the URL. An example endpoint might look like `https://example.search.windows.net.`
4. [Find your Azure OpenAI service](#).
5. On the **Overview** home page, select the link to view the endpoints. Copy the URL. An example endpoint might look like `https://example.openai.azure.com/`.

Sign in to Azure

You're using Microsoft Entra ID and role assignments for the connection. Make sure you're logged in to the same tenant and subscription as Azure AI Search and Azure OpenAI. You can use the Azure CLI on the command line to show current properties, change properties, and to sign in. For more information, see [Connect without keys](#).

Run each of the following commands in sequence.

```
azure-cli  
  
az account show  
  
az account set --subscription <PUT YOUR SUBSCRIPTION ID HERE>  
  
az login --tenant <PUT YOUR TENANT ID HERE>
```

You should now be logged in to Azure from your local device.

Set up the .NET app

To follow along with the steps ahead, you can either clone the completed sample app from GitHub, or create the app yourself.

Clone the sample app

To access the completed sample app for this article:

1. Clone the [azure-search-dotnet-samples](#) repo from GitHub.

```
Bash
```

```
git clone https://github.com/Azure-Samples/azure-search-dotnet-samples
```

2. Navigate into the `quickstart-rag` folder.
3. Open the `quickstart-rag` folder in Visual Studio Code or open the solution file using Visual Studio.

Create the sample app

Complete the following steps to create a .NET console app to connect to an AI model.

1. In an empty directory on your computer, use the `dotnet new` command to create a new console app:

```
.NET CLI  
dotnet new console -o AISearchRag
```

2. Change directory into the app folder:

```
.NET CLI  
cd AISearchRag
```

3. Install the required packages:

```
Bash  
dotnet add package Azure.AI.OpenAI  
dotnet add package Azure.Identity  
dotnet add package Azure.Search.Documents
```

4. Open the app in Visual Studio Code (or your editor of choice).

```
Bash  
code .
```

Set up the query and chat thread

The following example demonstrates how to set up a minimal RAG scenario using Azure AI Search to provide an OpenAI model with contextual resources to improve the generated responses.

1. In the `minimal-query` project of the sample repo, open the `Program.cs` file to view the first example. If you created the project yourself, add the following code to connect to and query the Azure AI Search and Azure OpenAI services.

 Note

Make sure to replace the placeholders for the Azure OpenAI endpoint and model name, as well as the Azure AI Search endpoint and index name.

C#

```
using System;
using System.Collections.Generic;
using System.Threading.Tasks;
using Azure.Identity;
using Azure.Search.Documents;
using Azure.Search.Documents.Models;
using Azure.AI.OpenAI;
using OpenAI.Chat;
using System.Text.Json;
using Microsoft.Extensions.Logging;

// Azure resource endpoints and deployment info
string azureSearchServiceEndpoint = "azure-ai-search-endpoint";
string azureOpenAIEndpoint = "azure-ai-openai-endpoint";
string azureDeploymentModel = "azure-ai-deployment-name";
string indexName = "hotels-sample-index";

// Set up Azure credentials and clients
var credential = new DefaultAzureCredential();
var searchClient = new SearchClient(new Uri(azureSearchServiceEndpoint),
indexName, credential);
var openAIClient = new AzureOpenAIClient(new Uri(azureOpenAIEndpoint),
credential);

// Prompt template for grounding the LLM response in search results
string GROUNDED_PROMPT = @"You are a friendly assistant that recommends
hotels based on activities and amenities.

Answer the query using only the sources provided below in a friendly and
concise bulleted manner

Answer ONLY with the facts listed in the list of sources below.
If there isn't enough information below, say you don't know.
Do not generate answers that don't use the sources below.

Query: {0}
Sources: {1}";

// The user's query
string query = "Can you recommend a few hotels with complimentary
breakfast?";

// Configure search options: top 5 results, select relevant fields
```

```

var options = new SearchOptions { Size = 5 };
options.Select.Add("Description");
options.Select.Add("HotelName");
options.Select.Add("Tags");

// Execute the search
var searchResults = await searchClient.SearchAsync<SearchDocument>(query,
options);
var sources = new List<string>();

await foreach (var result in searchResults.Value.GetResultsAsync())
{
    var doc = result.Document;
    // Format each result as: HotelName:Description:Tags
    sources.Add($"{doc["HotelName"]}:{doc["Description"]}:{doc["Tags"]}");
}
string sourcesFormatted = string.Join("\n", sources);

// Format the prompt with the query and sources
string formattedPrompt = string.Format(GROUNDED_PROMPT, query,
sourcesFormatted);

// Create a chat client for the specified deployment/model
ChatClient chatClient = openAIClient.GetChatClient(azureDeploymentModel);

// Send the prompt to the LLM and stream the response
var chatUpdates = chatClient.CompleteChatStreamingAsync(
    [ new UserChatMessage(formattedPrompt) ]
);

// Print the streaming response to the console
await foreach (var chatUpdate in chatUpdates)
{
    if (chatUpdate.Role.HasValue)
    {
        Console.Write($"{chatUpdate.Role} : ");
    }
    foreach (var contentPart in chatUpdate.ContentUpdate)
    {
        Console.Write(contentPart.Text);
    }
}

```

The preceding code accomplishes the following:

- Searches an Azure Search index for hotels matching a user query about complimentary breakfast, retrieving hotel name, description, and tags.
- Formats the search results into a structured list to serve as contextual sources for the generative AI model.
- Constructs a prompt instructing the Azure OpenAI model to answer using only the provided sources.

- Sends the prompt to the AI model and streams the generated response.
- Outputs the AI's response to the console, displaying both the role and content as it streams.

2. Run the project to initiate a basic RAG scenario. The output from Azure OpenAI consists of recommendations for several hotels, such as the following example:

```
Output

Sure! Here are a few hotels that offer complimentary breakfast:

- **Head Wind Resort**
- Complimentary continental breakfast in the lobby
- Free Wi-Fi throughout the hotel

- **Double Sanctuary Resort**
- Continental breakfast included

- **White Mountain Lodge & Suites**
- Continental breakfast available

- **Swan Bird Lake Inn**
- Continental-style breakfast each morning with a variety of food and drinks
such as caramel cinnamon rolls, coffee, orange juice, milk, cereal,
instant oatmeal, bagels, and muffins
```

To experiment further, change the query and rerun the last step to better understand how the model works with the grounding data. You can also modify the prompt to change the tone or structure of the output.

Troubleshooting

You might receive any of the following errors while testing:

- **Forbidden:** Check Azure AI Search configuration to make sure role-based access is enabled.
- **Authorization failed:** Wait a few minutes and try again. It can take several minutes for role assignments to become operational.
- **Resource not found:** Check the resource URIs and make sure the API version on the chat model is valid.

Send a complex RAG query

Azure AI Search supports [complex types](#) for nested JSON structures. In the hotels-sample-index, `Address` is an example of a complex type, consisting of `Address.StreetAddress`,

`Address.City`, `Address.StateProvince`, `Address.PostalCode`, and `Address.Country`. The index also has complex collection of `Rooms` for each hotel. If your index has complex types, your query can provide those fields if you first convert the search results output to JSON, and then pass the JSON to the chat model.

1. In the `complex-query` project of the sample repo, open the `Program.cs` file. If you created the project yourself, replace your code with the following:

C#

```
using System;
using System.Collections.Generic;
using System.Threading.Tasks;
using Azure.Identity;
using Azure.Search.Documents;
using Azure.Search.Documents.Models;
using Azure.AI.OpenAI;
using OpenAI.Chat;
using System.Text.Json;
using Microsoft.Extensions.Logging;

// Azure resource endpoints and deployment info
string azureSearchServiceEndpoint = "azure-ai-search-endpoint";
string azureOpenAIEndpoint = "azure-ai-openai-endpoint";
string azureDeploymentModel = "azure-ai-deployment-name";
string indexName = "hotels-sample-index";

// Set up Azure credentials and clients
var credential = new DefaultAzureCredential();
var searchClient = new SearchClient(new Uri(azureSearchServiceEndpoint),
indexName, credential);
var openAIClient = new AzureOpenAIClient(new Uri(azureOpenAIEndpoint),
credential);

// Prompt template for the OpenAI model
string groundedPrompt =
    @"You are a friendly assistant that recommends hotels based on activities
and amenities.

    Answer the query using only the sources provided below in a friendly and
concise bulleted manner.

    Answer ONLY with the facts listed in the list of sources below.
    If there isn't enough information below, say you don't know.
    Do not generate answers that don't use the sources below.

Query: {0}
Sources: {1}";

// The user query and fields to select from search
var query = "Can you recommend a few hotels that offer complimentary
breakfast? Tell me their description, address, tags, and the rate for one
room that sleeps 4 people.";
var selectedFields = new[] { "HotelName", "Description", "Address", "Rooms",
"Tags" };
```

```

// Configure search options
var options = new SearchOptions { Size = 5 };
foreach (var field in selectedFields)
{
    options.Select.Add(field);
}

// Run Azure Cognitive Search
var searchResults = await searchClient.SearchAsync<SearchDocument>(query,
options);

// Filter and format search results
var sourcesFiltered = new List<Dictionary<string, object>>();
await foreach (var result in searchResults.Value.GetResultsAsync())
{
    sourcesFiltered.Add(
        selectedFields
            .Where(f => result.Document.TryGetValue(f, out _))
            .ToDictionary(f => f, f => result.Document[f])
    );
}
var sourcesFormatted = string.Join("\n", sourcesFiltered.ConvertAll(source =>
JsonSerializer.Serialize(source)));

// Format the prompt for OpenAI
string formattedPrompt = string.Format(groundedPrompt, query,
sourcesFormatted);

// Get a chat client for the OpenAI deployment
ChatClient chatClient = openAIClient.GetChatClient(azureDeploymentModel);

// Send the prompt to Azure OpenAI and stream the response
var chatUpdates = chatClient.CompleteChatStreamingAsync(
    new[] { new UserChatMessage(formattedPrompt) }
);

// Output the streamed chat response
await foreach (var chatUpdate in chatUpdates)
{
    if (chatUpdate.Role.HasValue)
    {
        Console.Write($"{chatUpdate.Role} : ");
    }
    foreach (var contentPart in chatUpdate.ContentUpdate)
    {
        Console.Write(contentPart.Text);
    }
}

```

2. Run the project to initiate a basic RAG scenario. The output from Azure OpenAI consists of recommendations for several hotels, such as the following example:

Output

1. **Double Sanctuary Resort**
 - **Description**: 5-star luxury hotel with the biggest rooms in the city. Recognized as the #1 hotel in the area by Traveler magazine. Features include free WiFi, flexible check-in/out, a fitness center, and in-room espresso.
 - **Address**: 2211 Elliott Ave, Seattle, WA, 98121, USA
 - **Tags**: view, pool, restaurant, bar, continental breakfast
 - **Room Rate for 4 People**:
 - Suite, 2 Queen Beds: \$254.99 per night
2. **Starlight Suites**
 - **Description**: Spacious all-suite hotel with complimentary airport shuttle and WiFi. Facilities include an indoor/outdoor pool, fitness center, and Florida Green certification. Complimentary coffee and HDTV are also available.
 - **Address**: 19575 Biscayne Blvd, Aventura, FL, 33180, USA
 - **Tags**: pool, coffee in lobby, free wifi
 - **Room Rate for 4 People**:
 - Suite, 2 Queen Beds (Cityside): \$231.99 per night
 - Deluxe Room, 2 Queen Beds (Waterfront View): \$148.99 per night
3. **Good Business Hotel**
 - **Description**: Located one mile from the airport with free WiFi, an outdoor pool, and a complimentary airport shuttle. Close proximity to Lake Lanier and downtown. The business center includes printers, a copy machine, fax, and a work area.
 - **Address**: 4400 Ashford Dunwoody Rd NE, Atlanta, GA, 30346, USA
 - **Tags**: pool, continental breakfast, free parking
 - **Room Rate for 4 People**:
 - Budget Room, 2 Queen Beds (Amenities): \$60.99 per night
 - Deluxe Room, 2 Queen Beds (Amenities): \$139.99 per night

Troubleshooting

If you see output messages while debugging related to `ManagedIdentityCredential` and token acquisition failures, it could be that you have multiple tenants, and your Azure sign-in is using a tenant that doesn't have your search service. To get your tenant ID, search the Azure portal for "tenant properties" or run `az login tenant list`.

Once you have your tenant ID, run `az login --tenant <YOUR-TENANT-ID>` at a command prompt, and then rerun the script.

You can also log errors in your code by creating an instance of `ILogger`:

C#

```
using var loggerFactory = LoggerFactory.Create(builder =>
{
```

```
builder.AddConsole();
});
ILogger logger = loggerFactory.CreateLogger<Program>();
```

Clean up

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal by using the **All resources** or **Resource groups** link in the leftmost pane.

Related content

- [Tutorial: Build a RAG solution in Azure AI Search](#)

Quickstart: Full-text search

In this quickstart, you use the `Azure.Search.Documents` client library to create, load, and query a search index with sample data for [full-text search](#). Full-text search uses Apache Lucene for indexing and queries and the BM25 ranking algorithm for scoring results.

This quickstart uses fictional hotel data from the [azure-search-sample-data](#) repo to populate the index.

💡 Tip

You can download the [source code](#) to start with a finished project or follow these steps to create your own.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) if you don't have one. For this quickstart, you can use a free service.

Microsoft Entra ID prerequisites

For the recommended keyless authentication with Microsoft Entra ID, you must:

- Install the [Azure CLI](#).
- Assign the `Search Service Contributor` and `Search Index Data Contributor` roles to your user account. You can assign roles in the Azure portal under **Access control (IAM)** > **Add role assignment**. For more information, see [Connect to Azure AI Search using roles](#).

Get service information

You need to retrieve the following information to authenticate your application with your Azure AI Search service:

Microsoft Entra ID

[+] [Expand table](#)

Variable name	Value
SEARCH_API_ENDPOINT	This value can be found in the Azure portal. Select your search service and then from the left menu, select Overview . The Url value under Essentials is the endpoint that you need. An example endpoint might look like <code>https://mydemo.search.windows.net.</code>

Learn more about [keyless authentication](#) and [setting environment variables](#).

Set up

1. Create a new folder `full-text-quickstart` to contain the application and open Visual Studio Code in that folder with the following command:

```
shell
mkdir full-text-quickstart && cd full-text-quickstart
```

2. Create a new console application with the following command:

```
shell
dotnet new console
```

3. Install the Azure AI Search client library ([Azure.Search.Documents](#)) for .NET with:

```
Console
dotnet add package Azure.Search.Documents
```

4. For the **recommended** keyless authentication with Microsoft Entra ID, install the [Azure.Identity](#) package with:

```
Console
dotnet add package Azure.Identity
```

5. For the **recommended** keyless authentication with Microsoft Entra ID, sign in to Azure with the following command:

```
Console
az login
```

Create, load, and query a search index

In the prior [set up](#) section, you created a new console application and installed the Azure AI Search client library.

In this section, you add code to create a search index, load it with documents, and run queries. You run the program to see the results in the console. For a detailed explanation of the code, see the [Explaining the code](#) section.

The sample code in this quickstart uses Microsoft Entra ID for the recommended keyless authentication. If you prefer to use an API key, you can replace the `DefaultAzureCredential` object with a `AzureKeyCredential` object.

Microsoft Entra ID

```
C#  
Uri serviceEndpoint = new Uri($"https://<Put your search service NAME here>.search.windows.net/");  
DefaultAzureCredential credential = new();
```

1. In `Program.cs`, paste the following code. Edit the `serviceName` and `apiKey` variables with your search service name and admin API key.

```
C#  
  
using System;  
using Azure;  
using Azure.Identity;  
using Azure.Search.Documents;  
using Azure.Search.Documents.Indexes;  
using Azure.Search.Documents.Indexes.Models;  
using Azure.Search.Documents.Models;  
  
namespace AzureSearch.Quickstart  
  
{  
    class Program  
    {  
        static void Main(string[] args)  
        {  
            // Your search service endpoint  
            Uri serviceEndpoint = new Uri($"https://<Put your search service NAME here>.search.windows.net/");  
  
            // Use the recommended keyless credential instead of the
```

```
AzureKeyCredential credential.  
    DefaultAzureCredential credential = new();  
    //AzureKeyCredential credential = new AzureKeyCredential("Your  
    search service admin key");  
  
    // Create a SearchIndexClient to send create/delete index commands  
    SearchIndexClient searchIndexClient = new  
    SearchIndexClient(serviceEndpoint, credential);  
  
    // Create a SearchClient to load and query documents  
    string indexName = "hotels-quickstart";  
    SearchClient searchClient = new SearchClient(serviceEndpoint,  
indexName, credential);  
  
    // Delete index if it exists  
    Console.WriteLine("{0}", "Deleting index...\\n");  
    DeleteIndexIfExists(indexName, searchIndexClient);  
  
    // Create index  
    Console.WriteLine("{0}", "Creating index...\\n");  
    CreateIndex(indexName, searchIndexClient);  
  
    SearchClient ingestClient =  
searchIndexClient.GetSearchClient(indexName);  
  
    // Load documents  
    Console.WriteLine("{0}", "Uploading documents...\\n");  
    UploadDocuments(ingestClient);  
  
    // Wait 2 seconds for indexing to complete before starting queries  
(for demo and console-app purposes only)  
    Console.WriteLine("Waiting for indexing...\\n");  
    System.Threading.Thread.Sleep(2000);  
  
    // Call the RunQueries method to invoke a series of queries  
    Console.WriteLine("Starting queries...\\n");  
    RunQueries(searchClient);  
  
    // End the program  
    Console.WriteLine("{0}", "Complete. Press any key to end this  
program...\\n");  
    Console.ReadKey();  
}  
  
// Delete the hotels-quickstart index to reuse its name  
private static void DeleteIndexIfExists(string indexName,  
SearchIndexClient searchIndexClient)  
{  
    searchIndexClient.GetIndexNames();  
    {  
        searchIndexClient.DeleteIndex(indexName);  
    }  
}  
// Create hotels-quickstart index

};

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Rating");

response = searchClient.Search<Hotel>("hotels", options);
WriteDocuments(response);

// Query 3
Console.WriteLine("Query #3: Limit search to specific fields (pool
in Tags field)...\\n");

options = new SearchOptions()
{
    SearchFields = { "Tags" }
};

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Tags");

response = searchClient.Search<Hotel>("pool", options);
WriteDocuments(response);

// Query 4 - Use Facets to return a faceted navigation structure
for a given query
    // Filters are typically used with facets to narrow results on
OnClick events
    Console.WriteLine("Query #4: Facet on 'Category'...\\n");

options = new SearchOptions()
{
    Filter = ""
};

options.Facets.Add("Category");

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Category");

response = searchClient.Search<Hotel>("*", options);
WriteDocuments(response);

// Query 5
Console.WriteLine("Query #5: Look up a specific document...\\n");

Response<Hotel> lookupResponse;

```

```

        lookupResponse = searchClient.GetDocument<Hotel>("3");

        Console.WriteLine(lookupResponse.Value.HotelId);

        // Query 6
        Console.WriteLine("Query #6: Call Autocomplete on HotelName...\n");

        var autoresponse = searchClient.Autocomplete("sa", "sg");
        WriteDocuments(autoresponse);

    }

    // Write search results to console
    private static void WriteDocuments(SearchResults<Hotel> searchResults)
    {
        foreach (SearchResult<Hotel> result in searchResults.GetResults())
        {
            Console.WriteLine(result.Document);
        }

        Console.WriteLine();
    }

    private static void WriteDocuments(AutocompleteResults autoResults)
    {
        foreach (AutocompleteItem result in autoResults.Results)
        {
            Console.WriteLine(result.Text);
        }

        Console.WriteLine();
    }
}
}

```

2. In the same folder, create a new file named *Hotel.cs* and paste the following code. This code defines the structure of a hotel document.

C#

```

using System;
using System.Text.Json.Serialization;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;

namespace AzureSearch.Quickstart
{
    public partial class Hotel
    {
        [SimpleField(IsKey = true, IsFilterable = true)]
        public string HotelId { get; set; }
    }
}

```

```

[SearchableField(IsSortable = true)]
public string HotelName { get; set; }

[SearchableField(AnalyzerName = LexicalAnalyzerName.Values.EnLucene)]
public string Description { get; set; }

[SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
public string Category { get; set; }

[SearchableField(IsFilterable = true, IsFacetable = true)]
public string[] Tags { get; set; }

[SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
public bool? ParkingIncluded { get; set; }

[SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
public DateTimeOffset? LastRenovationDate { get; set; }

[SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
public double? Rating { get; set; }

[SearchableField]
public Address Address { get; set; }
}
}

```

3. Create a new file named *Hotel.cs* and paste the following code to define the structure of a hotel document. Attributes on the field determine how it's used in an application. For example, the `IsFilterable` attribute must be assigned to every field that supports a filter expression.

C#

```

using System;
using System.Text.Json.Serialization;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;

namespace AzureSearch.Quickstart
{
    public partial class Hotel
    {
        [SimpleField(IsKey = true, IsFilterable = true)]
        public string HotelId { get; set; }

        [SearchableField(IsSortable = true)]
        public string HotelName { get; set; }
    }
}

```

```

        [SearchableField(AnalyzerName = LexicalAnalyzerName.Values.EnLucene)]
        public string Description { get; set; }

        [SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public string Category { get; set; }

        [SearchableField(IsFilterable = true, IsFacetable = true)]
        public string[] Tags { get; set; }

        [SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public bool? ParkingIncluded { get; set; }

        [SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public DateTimeOffset? LastRenovationDate { get; set; }

        [SimpleField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public double? Rating { get; set; }

        [SearchableField]
        public Address Address { get; set; }
    }
}

```

4. Create a new file named `Address.cs` and paste the following code to define the structure of an address document.

C#

```

using Azure.Search.Documents.Indexes;

namespace AzureSearch.Quickstart
{
    public partial class Address
    {
        [SearchableField(IsFilterable = true)]
        public string StreetAddress { get; set; }

        [SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public string City { get; set; }

        [SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public string StateProvince { get; set; }

        [SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
        public string PostalCode { get; set; }
    }
}

```

```
[SearchableField(IsFilterable = true, IsSortable = true, IsFacetable =
true)]
    public string Country { get; set; }
}
```

5. Create a new file named *Hotel.Methods.cs* and paste the following code to define a `ToString()` override for the `Hotel` class.

C#

```
using System;
using System.Text;

namespace AzureSearch.Quickstart
{
    public partial class Hotel
    {
        public override string ToString()
        {
            var builder = new StringBuilder();

            if (!String.IsNullOrEmpty(HotelId))
            {
                builder.AppendFormat("HotelId: {0}\n", HotelId);
            }

            if (!String.IsNullOrEmpty(HotelName))
            {
                builder.AppendFormat("Name: {0}\n", HotelName);
            }

            if (!String.IsNullOrEmpty(Description))
            {
                builder.AppendFormat("Description: {0}\n", Description);
            }

            if (!String.IsNullOrEmpty(Category))
            {
                builder.AppendFormat("Category: {0}\n", Category);
            }

            if (Tags != null && Tags.Length > 0)
            {
                builder.AppendFormat("Tags: [ {0} ]\n", String.Join(", ",
Tags));
            }

            if (ParkingIncluded.HasValue)
            {
                builder.AppendFormat("Parking included: {0}\n",
ParkingIncluded.Value ? "yes" : "no");
            }
        }
    }
}
```

```

        if (LastRenovationDate.HasValue)
        {
            builder.AppendFormat("Last renovated on: {0}\n",
LastRenovationDate);
        }

        if (Rating.HasValue)
        {
            builder.AppendFormat("Rating: {0}\n", Rating);
        }

        if (Address != null && !Address.IsEmpty)
        {
            builder.AppendFormat("Address: \n{0}\n", Address.ToString());
        }

        return builder.ToString();
    }
}
}

```

6. Create a new file named `Address.Methods.cs` and paste the following code to define a `ToString()` override for the `Address` class.

C#

```

using System;
using System.Text;
using System.Text.Json.Serialization;

namespace AzureSearch.Quickstart
{
    public partial class Address
    {
        public override string ToString()
        {
            var builder = new StringBuilder();

            if (!IsEmpty)
            {
                builder.AppendFormat("{0}\n{1}, {2} {3}\n{4}", StreetAddress,
City, StateProvince, PostalCode, Country);
            }

            return builder.ToString();
        }

        [JsonIgnore]
        public bool IsEmpty => String.IsNullOrEmpty(StreetAddress) &&
                           String.IsNullOrEmpty(City) &&
                           String.IsNullOrEmpty(StateProvince) &&
                           String.IsNullOrEmpty(PostalCode) &&

```

```
        String.IsNullOrEmpty(Country));
    }
}
```

7. Build and run the application with the following command:

```
shell  
dotnet run
```

Output includes messages from `Console.WriteLine`, with the addition of query information and results.

Explaining the code

In the previous sections, you created a new console application and installed the Azure AI Search client library. You added code to create a search index, load it with documents, and run queries. You ran the program to see the results in the console.

In this section, we explain the code you added to the console application.

Create a search client

In `Program.cs`, you created two clients:

- `SearchIndexClient` creates the index.
- `SearchClient` loads and queries an existing index.

Both clients need the search service endpoint and credentials described previously in the [Get service information](#) section.

The sample code in this quickstart uses Microsoft Entra ID for the recommended keyless authentication. If you prefer to use an API key, you can replace the `DefaultAzureCredential` object with a `AzureKeyCredential` object.

Microsoft Entra ID

C#

```
Uri serviceEndpoint = new Uri($"https://<Put your search service NAME  
here>.search.windows.net/");  
DefaultAzureCredential credential = new();
```

C#

```
static void Main(string[] args)
{
    // Your search service endpoint
    Uri serviceEndpoint = new Uri($"https://<Put your search service NAME here>.search.windows.net/");

    // Use the recommended keyless credential instead of the AzureKeyCredential
    // credential.
    DefaultAzureCredential credential = new();
    //AzureKeyCredential credential = new AzureKeyCredential("Your search service
    admin key");

    // Create a SearchIndexClient to send create/delete index commands
    SearchIndexClient searchIndexClient = new SearchIndexClient(serviceEndpoint,
    credential);

    // Create a SearchClient to load and query documents
    string indexName = "hotels-quickstart";
    SearchClient searchClient = new SearchClient(serviceEndpoint, indexName,
    credential);

    // REDACTED FOR BREVITY . . .
}
```

Create an index

This quickstart builds a Hotels index that you load with hotel data and execute queries against. In this step, you define the fields in the index. Each field definition includes a name, data type, and attributes that determine how the field is used.

In this example, synchronous methods of the *Azure.Search.Documents* library are used for simplicity and readability. However, for production scenarios, you should use asynchronous methods to keep your app scalable and responsive. For example, you would use [CreateIndexAsync](#) instead of [CreateIndex](#).

Define the structures

You created two helper classes, *Hotel.cs* and *Address.cs*, to define the structure of a hotel document and its address. The `Hotel` class includes fields for a hotel ID, name, description, category, tags, parking, renovation date, rating, and address. The `Address` class includes fields for street address, city, state/province, postal code, and country/region.

In the *Azure.Search.Documents* client library, you can use [SearchableField](#) and [SimpleField](#) to streamline field definitions. Both are derivatives of a [SearchField](#) and can potentially simplify your code:

- `SimpleField` can be any data type, is always non-searchable (ignored for full text search queries), and is retrievable (not hidden). Other attributes are off by default, but can be enabled. You might use a `SimpleField` for document IDs or fields used only in filters, facets, or scoring profiles. If so, be sure to apply any attributes that are necessary for the scenario, such as `IsKey = true` for a document ID. For more information, see [SimpleFieldAttribute.cs](#) in source code.
- `SearchableField` must be a string, and is always searchable and retrievable. Other attributes are off by default, but can be enabled. Because this field type is searchable, it supports synonyms and the full complement of analyzer properties. For more information, see the [SearchableFieldAttribute.cs](#) in source code.

Whether you use the basic `SearchField` API or either one of the helper models, you must explicitly enable filter, facet, and sort attributes. For example, `IsFilterable`, `IsSortable`, and `IsFacetable` must be explicitly attributed, as shown in the previous sample.

Create the search index

In `Program.cs`, you create a `SearchIndex` object, and then call the `CreateIndex` method to express the index in your search service. The index also includes a `SearchSuggester` to enable autocomplete on the specified fields.

C#

```
// Create hotels-quickstart index
private static void CreateIndex(string indexName, SearchIndexClient
searchIndexClient)
{
    FieldBuilder fieldBuilder = new FieldBuilder();
    var searchFields = fieldBuilder.Build(typeof(Hotel));

    var definition = new SearchIndex(indexName, searchFields);

    var suggester = new SearchSuggester("sg", new[] { "HotelName", "Category",
"Address/City", "Address/StateProvince" });
    definition.Suggesters.Add(suggester);

    searchIndexClient.CreateOrUpdateIndex(definition);
}
```

Load documents

Azure AI Search searches over content stored in the service. In this step, you load JSON documents that conform to the hotel index you created.

In Azure AI Search, search documents are data structures that are both inputs to indexing and outputs from queries. As obtained from an external data source, document inputs might be rows in a database, blobs in Blob storage, or JSON documents on disk. In this example, we're taking a shortcut and embedding JSON documents for four hotels in the code itself.

When uploading documents, you must use an [IndexDocumentsBatch](#) object. An [IndexDocumentsBatch](#) object contains a collection of [Actions](#), each of which contains a document and a property telling Azure AI Search what action to perform ([upload](#), [merge](#), [delete](#), and [mergeOrUpload](#)).

In *Program.cs*, you create an array of documents and index actions, and then pass the array to [IndexDocumentsBatch](#). The following documents conform to the `hotels-quickstart` index, as defined by the `Hotel` class.

C#

```
// Upload documents in a single Upload request.
private static void UploadDocuments(SearchClient searchClient)
{
    IndexDocumentsBatch<Hotel> batch = IndexDocumentsBatch.Create(
        IndexDocumentsAction.Upload(
            new Hotel()
            {
                HotelId = "1",
                HotelName = "Stay-Kay City Hotel",
                Description = "This classic hotel is fully-refurbished and ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Times Square and the historic centre of the city, as well as other places of interest that make New York one of America's most attractive and cosmopolitan cities.",
                Category = "Boutique",
                Tags = new[] { "view", "air conditioning", "concierge" },
                ParkingIncluded = false,
                LastRenovationDate = new DateTimeOffset(2022, 1, 18, 0, 0, 0,
TimeSpan.Zero),
                Rating = 3.6,
                Address = new Address()
                {
                    StreetAddress = "677 5th Ave",
                    City = "New York",
                    StateProvince = "NY",
                    PostalCode = "10022",
                    Country = "USA"
                }
            ),
            // REDACTED FOR BREVITY
        )
    );
}
```

Once you initialize the [IndexDocumentsBatch](#) object, you can send it to the index by calling [IndexDocuments](#) on your [SearchClient](#) object.

You load documents using `SearchClient` in `Main()`, but the operation also requires admin rights on the service, which is typically associated with `SearchIndexClient`. One way to set up this operation is to get `SearchClient` through `SearchIndexClient` (`searchIndexClient` in this example).

C#

```
SearchClient ingestorClient = searchIndexClient.GetSearchClient(indexName);

// Load documents
Console.WriteLine("{0}", "Uploading documents...\n");
UploadDocuments(ingesterClient);
```

Because we have a console app that runs all commands sequentially, we add a 2-second wait time between indexing and queries.

C#

```
// Wait 2 seconds for indexing to complete before starting queries (for demo and
// console-app purposes only)
Console.WriteLine("Waiting for indexing...\n");
System.Threading.Thread.Sleep(2000);
```

The 2-second delay compensates for indexing, which is asynchronous, so that all documents can be indexed before the queries are executed. Coding in a delay is typically only necessary in demos, tests, and sample applications.

Search an index

You can get query results as soon as the first document is indexed, but actual testing of your index should wait until all documents are indexed.

This section adds two pieces of functionality: query logic, and results. For queries, use the `Search` method. This method takes search text (the query string) and other [options](#).

The `SearchResults` class represents the results.

In `Program.cs`, the `WriteDocuments` method prints search results to the console.

C#

```
// Write search results to console
private static void WriteDocuments(SearchResults<Hotel> searchResults)
{
    foreach (SearchResult<Hotel> result in searchResults.GetResults())
    {
```

```

        Console.WriteLine(result.Document);
    }

    Console.WriteLine();
}

private static void WriteDocuments(AutocompleteResults autoResults)
{
    foreach (AutocompleteItem result in autoResults.Results)
    {
        Console.WriteLine(result.Text);
    }

    Console.WriteLine();
}

```

Query example 1

The `RunQueries` method executes queries and returns results. Results are Hotel objects. This sample shows the method signature and the first query. This query demonstrates the `Select` parameter that lets you compose the result using selected fields from the document.

C#

```

// Run queries, use WriteDocuments to print output
private static void RunQueries(SearchClient searchClient)
{
    SearchOptions options;
    SearchResults<Hotel> response;

    // Query 1
    Console.WriteLine("Query #1: Search on empty term '*' to return all documents,
showing a subset of fields...\n");

    options = new SearchOptions()
    {
        IncludeTotalCount = true,
        Filter = "",
        OrderBy = { "" }
    };

    options.Select.Add("HotelId");
    options.Select.Add("HotelName");
    options.Select.Add("Address/City");

    response = searchClient.Search<Hotel>("*", options);
    WriteDocuments(response);
    // REDACTED FOR BREVITY
}

```

Query example 2

In the second query, search on a term, add a filter that selects documents where *Rating* is greater than 4, and then sort by Rating in descending order. Filter is a boolean expression that is evaluated over [IsFilterable](#) fields in an index. Filter queries either include or exclude values. As such, there's no relevance score associated with a filter query.

```
C#
```

```
// Query 2
Console.WriteLine("Query #2: Search on 'hotels', filter on 'Rating gt 4', sort by
Rating in descending order...\n");

options = new SearchOptions()
{
    Filter = "Rating gt 4",
    OrderBy = { "Rating desc" }
};

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Rating");

response = searchClient.Search<Hotel>("hotels", options);
WriteDocuments(response);
```

Query example 3

The third query demonstrates `searchFields`, used to scope a full text search operation to specific fields.

```
C#
```

```
// Query 3
Console.WriteLine("Query #3: Limit search to specific fields (pool in Tags
field)...\\n");

options = new SearchOptions()
{
    SearchFields = { "Tags" }
};

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Tags");

response = searchClient.Search<Hotel>("pool", options);
WriteDocuments(response);
```

Query example 4

The fourth query demonstrates `facets`, which can be used to structure a faceted navigation structure.

```
C#
```

```
// Query 4
Console.WriteLine("Query #4: Facet on 'Category'...\n");

options = new SearchOptions()
{
    Filter = ""
};

options.Facets.Add("Category");

options.Select.Add("HotelId");
options.Select.Add("HotelName");
options.Select.Add("Category");

response = searchClient.Search<Hotel>("*", options);
WriteDocuments(response);
```

Query example 5

In the fifth query, return a specific document. A document lookup is a typical response to `OnClick` event in a result set.

```
C#
```

```
// Query 5
Console.WriteLine("Query #5: Look up a specific document...\n");

Response<Hotel> lookupResponse;
lookupResponse = searchClient.GetDocument<Hotel>("3");

Console.WriteLine(lookupResponse.Value.HotelId);
```

Query example 6

The last query shows the syntax for autocomplete, simulating a partial user input of `sa` that resolves to two possible matches in the `sourceFields` associated with the suggester you defined in the index.

```
C#
```

```
// Query 6
Console.WriteLine("Query #6: Call Autocomplete on HotelName that starts with
'sa'...\n");

var autoreponse = searchClient.Autocomplete("sa", "sg");
WriteDocuments(autoreponse);
```

Summary of queries

The previous queries show multiple [ways of matching terms in a query](#): full-text search, filters, and autocomplete.

Full text search and filters are performed using the `SearchClient.Search` method. A search query can be passed in the `searchText` string, while a filter expression can be passed in the `Filter` property of the `SearchOptions` class. To filter without searching, just pass `"*"` for the `searchText` parameter of the `Search` method. To search without filtering, leave the `Filter` property unset, or don't pass in a `SearchOptions` instance at all.

Clean up resources

When working in your own subscription, it's a good idea to finish a project by determining whether you still need the resources you created. Resources that are left running can cost you money. You can delete resources individually, or you can delete the resource group to delete the entire set of resources.

In the [Azure portal](#), you can find and manage resources by selecting **All resources** or **Resource groups** from the left pane.

If you're using a free service, remember that you're limited to three indexes, indexers, and data sources. You can delete individual items in the Azure portal to stay under the limit.

Quickstart: Semantic ranking

In this quickstart, you learn how to use [semantic ranking](#) by adding a semantic configuration to a search index and adding semantic parameters to a query. You can use the `hotels-sample-index` or one of your own.

In Azure AI Search, semantic ranking is query-side functionality that uses machine reading comprehension from Microsoft to rescore search results, promoting the most semantically relevant matches to the top of the list. Depending on the content and the query, semantic ranking can [significantly improve search relevance](#) with minimal developer effort.

You can add a semantic configuration to an existing index with no rebuild requirement. Semantic ranking is most effective on text that's informational or descriptive.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#) with [semantic ranker enabled](#).
- A [new or existing index](#) with descriptive or verbose text fields that are attributed as retrievable. This quickstart assumes the [hotels-sample-index](#).

Configure access

You can connect to your Azure AI Search service using API keys or Microsoft Entra ID with role assignments. Keys are easier to start with, but roles are more secure. For more information, see [Connect to Azure AI Search using roles](#).

To configure role-based access:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Settings > Keys**.
3. Under **API Access control**, select **Role-based access control** or **Both** if you need time to transition clients to role-based access.
4. From the left pane, select **Access control (IAM)**.
5. Select **Add > Add role assignment**.
6. Assign the **Search Service Contributor** and **Search Index Data Contributor** roles to your user account.

Start with an index

This quickstart assumes an existing index and modifies it to include a semantic configuration. We recommend the [hotels-sample-index](#) that you can create in minutes using an Azure portal wizard.

To start with an existing index:

1. Sign in to the [Azure portal](#) and find your search service.
2. Under **Search management > Indexes**, select the hotels-sample-index.
3. Select **Semantic configurations** to ensure the index doesn't have a semantic configuration.

You haven't created any semantic configurations

Create

4. Select **Search explorer**, and then select the **JSON view**.
5. Paste the following JSON into the query editor.

```
JSON
{
  "search": "walking distance to live music",
  "select": "HotelId, HotelName, Description",
```

```
        "count": true  
    }
```

The screenshot shows the Microsoft Azure portal interface for the 'hotels-sample-index' search service. At the top, there's a navigation bar with 'Microsoft Azure', a search bar, and a 'Copilot' button. Below the navigation, the service name 'hotels-sample-index' is displayed. A toolbar with various actions like 'Save', 'Discard', 'Refresh', 'Create demo app', 'Edit JSON', 'Delete', and 'Encryption' is visible. Key statistics are shown: 'Documents' (50), 'Total storage' (561.25 KB), 'Vector index quota usage' (0 Bytes), and 'Max storage' (15 GB). Below these, tabs for 'Search explorer', 'Fields', 'CORS', 'Scoring profiles', 'Semantic configurations', and 'Vector profiles' are present. A dropdown menu shows the date '2025-05-01-preview' and a 'View' option. The main area is a 'JSON query editor' containing the following code:

```
1 {  
2     "search": "walking distance to live music",  
3     "select": "HotelId, HotelName, Description",  
4     "count": true  
5 }
```

To the right of the editor, a 'Results' section is partially visible. A dropdown menu on the right side of the interface shows three options: 'Query view', 'Image view', and 'JSON view'. The 'JSON view' option is highlighted with a red box.

6. Select **Search** to run the query.

This query is a keyword search. The response should be similar to the following example, as scored by the default BM25 L1 ranker for full-text search.

For readability, the example only selects the `HotelId`, `HotelName`, and `Description` fields. The results contain verbatim matches on the query terms (`walking`, `distance`, `live`, `music`) or linguistic variants (`walk`, `living`).

The screenshot shows the 'JSON' results panel. It displays a single document from the search results. The document contains the following fields and their values:

```
"@odata.count": 13,  
"value": [  
    {  
        "@search.score": 5.5153193,  
        "HotelId": "2",  
        "HotelName": "Old Century Hotel",

    }  
]
```

This query shows how the response looks *before* semantic ranking is applied. Later, you can run the same query after semantic ranking is configured to see how the response changes.

 **Tip**

You can add a semantic configuration in the Azure portal. However, if you want to learn how to add a semantic configuration programmatically, continue with this quickstart.

Set up the client

In this quickstart, you use an IDE and the [Azure.Search.Documents](#) client library to add semantic ranking to an existing search index.

We recommend [Visual Studio](#) for this quickstart.

 **Tip**

You can download the [source code](#) to start with a finished project or follow these steps to create your own.

Install libraries

1. Start Visual Studio and open the [quickstart-semantic-search.sln](#) or create a new project using a console application template.
2. In **Tools > NuGet Package Manager**, select **Manage NuGet Packages for Solution....**
3. Select **Browse**.
4. Search for the [Azure.Search.Documents package](#) and select the latest stable version.
5. Search for the [Azure.Identity package](#) and select the latest stable version.
6. Select **Install** to add the assembly to your project and solution.

Sign in to Azure

If you signed in to the [Azure portal](#), you're signed into Azure. If you aren't sure, use the Azure CLI or Azure PowerShell to log in: `az login` or `az connect`. If you have multiple tenants

and subscriptions, see [Quickstart: Connect without keys](#) for help on how to connect.

Update the index

In this section, you update a search index to include a semantic configuration. The code gets the index definition from the search service and adds a semantic configuration.

1. Open the [BuildIndex project](#) in Visual Studio. The program consists of the following code.

This code uses a `SearchIndexClient` to update an index on your search service.

C#

```
class BuildIndex
{
    static async Task Main(string[] args)
    {
        string searchServiceName = "PUT-YOUR-SEARCH-SERVICE-NAME-HERE";
        string indexName = "hotels-sample-index";
        string endpoint = $"https://{{searchServiceName}}.search.windows.net";
        var credential = new Azure.Identity.DefaultAzureCredential();

        await ListIndexesAsync(endpoint, credential);
        await UpdateIndexAsync(endpoint, credential, indexName);
    }

    // Print a list of all indexes on the search service
    // You should see hotels-sample-index in the list
    static async Task ListIndexesAsync(string endpoint,
        Azure.Core.TokenCredential credential)
    {
        try
        {
            var indexClient = new
                Azure.Search.Documents.Indexes.SearchIndexClient(
                    new Uri(endpoint),
                    credential
                );

            var indexes = indexClient.GetIndexesAsync();

            Console.WriteLine("Here's a list of all indexes on the search
service. You should see hotels-sample-index:");
            await foreach (var index in indexes)
            {
                Console.WriteLine(index.Name);
            }
            Console.WriteLine(); // Add an empty line for readability
        }
        catch (Exception ex)
```

```

        {
            Console.WriteLine($"Error listing indexes: {ex.Message}");
        }
    }

    static async Task UpdateIndexAsync(string endpoint,
Azure.Core.TokenCredential credential, string indexName)
{
    try
    {
        var indexClient = new
Azure.Search.Documents.Indexes.SearchIndexClient(
            new Uri(endpoint),
            credential
        );

        // Get the existing definition of hotels-sample-index
        var indexResponse = await indexClient.GetIndexAsync(indexName);
        var index = indexResponse.Value;

        // Add a semantic configuration
        const string semanticConfigName = "semantic-config";
        AddSemanticConfiguration(index, semanticConfigName);

        // Update the index with the new information
        var updatedIndex = await
indexClient.CreateOrUpdateIndexAsync(index);
        Console.WriteLine("Index updated successfully.");

        // Print the updated index definition as JSON
        var refreshedIndexResponse = await
indexClient.GetIndexAsync(indexName);
        var refreshedIndex = refreshedIndexResponse.Value;
        var jsonOptions = new JsonSerializerOptions { WriteIndented = true
};

        string indexJson = JsonSerializer.Serialize(refreshedIndex,
jsonOptions);
        Console.WriteLine($"Here is the revised index
definition:\n{indexJson}");
    }
    catch (Exception ex)
    {
        Console.WriteLine($"Error updating index: {ex.Message}");
    }
}

// This is the semantic configuration definition
static void AddSemanticConfiguration(SearchIndex index, string
semanticConfigName)
{
    if (index.SemanticSearch == null)
    {
        index.SemanticSearch = new SemanticSearch();
    }
    var configs = index.SemanticSearch.Configurations;
}

```

```

    if (configs == null)
    {
        throw new InvalidOperationException("SemanticSearch.Configurations
is null and cannot be assigned. Your service must be Basic tier or higher.");
    }
    if (!configs.Any(c => c.Name == semanticConfigName))
    {
        var prioritizedFields = new SemanticPrioritizedFields
        {
            TitleField = new SemanticField("HotelName"),
            ContentFields = { new SemanticField("Description") },
            KeywordsFields = { new SemanticField("Tags") }
        };

        configs.Add(
            new SemanticConfiguration(
                semanticConfigName,
                prioritizedFields
            )
        );
        Console.WriteLine($"Added new semantic configuration
'{semanticConfigName}' to the index definition.");
    }
    else
    {
        Console.WriteLine($"Semantic configuration '{semanticConfigName}'
already exists in the index definition.");
    }
    index.SemanticSearch.DefaultConfigurationName = semanticConfigName;
}
}

```

2. Replace the search service URL with a valid endpoint.
3. Run the program.
4. Output is logged to a console window from `Console.WriteLine`. You should see messages for each step, including the JSON of the index schema with the new semantic configuration included.

Run semantic queries

In this section, the program runs several semantic queries in sequence.

1. Open the [QueryIndex project](#) in Visual Studio. The program consists of the following code.

This code uses a `SearchClient` for sending queries to an index.

C#

```
class SemanticQuery
{
    static async Task Main(string[] args)
    {
        string searchServiceName = "PUT-YOUR-SEARCH-SERVICE-NAME-HERE";
        string indexName = "hotels-sample-index";
        string endpoint = $"https://'{searchServiceName}'.search.windows.net";
        var credential = new Azure.Identity.DefaultAzureCredential();

        var client = new SearchClient(new Uri(endpoint), indexName,
        credential);

        // Query 1: Simple query
        string searchText = "walking distance to live music";
        Console.WriteLine("\nQuery 1: Simple query using the search string
'walking distance to live music'.");
        await RunQuery(client, searchText, new SearchOptions
        {
            Size = 5,
            QueryType = SearchQueryType.Simple,
            IncludeTotalCount = true,
            Select = { "HotelId", "HotelName", "Description" }
        });
        Console.WriteLine("Press Enter to continue to the next query...");
        Console.ReadLine();

        // Query 2: Semantic query (no captions, no answers)
        Console.WriteLine("\nQuery 2: Semantic query (no captions, no answers)");
        for ('walking distance to live music'.);
        var semanticOptions = new SearchOptions
        {
            Size = 5,
            QueryType = SearchQueryType.Semantic,
            SemanticSearch = new SemanticSearchOptions
            {
                SemanticConfigurationName = "semantic-config"
            },
            IncludeTotalCount = true,
            Select = { "HotelId", "HotelName", "Description" }
        };
        await RunQuery(client, searchText, semanticOptions);
        Console.WriteLine("Press Enter to continue to the next query...");
        Console.ReadLine();

        // Query 3: Semantic query with captions
        Console.WriteLine("\nQuery 3: Semantic query with captions.");
        var captionsOptions = new SearchOptions
        {
            Size = 5,
            QueryType = SearchQueryType.Semantic,
            SemanticSearch = new SemanticSearchOptions
            {
                SemanticConfigurationName = "semantic-config",
                QueryCaption = new QueryCaption(QueryCaptionType.Extractive)
            }
        };
    }
}
```

```

        {
            HighlightEnabled = true
        }
    },
    IncludeTotalCount = true,
    Select = { "HotelId", "HotelName", "Description" }
);
// Add the field(s) you want captions for to the QueryCaption.Fields
collection
captionsOptions.HighlightFields.Add("Description");
await RunQuery(client, searchText, captionsOptions, showCaptions:
true);
Console.WriteLine("Press Enter to continue to the next query...");
Console.ReadLine();

// Query 4: Semantic query with answers
// This query uses different search text designed for an answers
scenario
string searchText2 = "what's a good hotel for people who like to read";
searchText = searchText2; // Update searchText for the next query
Console.WriteLine("\nQuery 4: Semantic query with a verbatim answer
from the Description field for 'what's a good hotel for people who like to
read'.");
var answersOptions = new SearchOptions
{
    Size = 5,
    QueryType = SearchQueryType.Semantic,
    SemanticSearch = new SemanticSearchOptions
    {
        SemanticConfigurationName = "semantic-config",
        QueryAnswer = new QueryAnswer(QueryAnswerType.Extractive)
    },
    IncludeTotalCount = true,
    Select = { "HotelId", "HotelName", "Description" }
};
await RunQuery(client, searchText2, answersOptions, showAnswers: true);

static async Task RunQuery(
SearchClient client,
string searchText,
SearchOptions options,
bool showCaptions = false,
bool showAnswers = false)
{
    try
    {
        var response = await client.SearchAsync<SearchDocument>
(searchText, options);

        if (showAnswers && response.Value.SemanticSearch?.Answers !=
null)
        {
            Console.WriteLine("Extractive Answers:");
            foreach (var answer in
response.Value.SemanticSearch.Answers)

```

```
        {
            Console.WriteLine($"  {answer.Highlights}");
        }
        Console.WriteLine(new string('-', 40));
    }

    await foreach (var result in response.Value.GetResultsAsync())
    {
        var doc = result.Document;
        // Print captions first if available
        if (showCaptions && result.SemanticSearch?.Captions != null)
        {
            foreach (var caption in result.SemanticSearch.Captions)
            {
                Console.WriteLine($"Caption: {caption.Highlights}");
            }
            Console.WriteLine($"HotelId: {doc.GetString("HotelId")}");
            Console.WriteLine($"HotelName: {doc.GetString("HotelName")}");
            Console.WriteLine($"Description: {doc.GetString("Description")}");
            Console.WriteLine($"@search.score: {result.Score}");

            // Print @search.rerankerScore if available
            if (result.SemanticSearch != null && result.SemanticSearch.RerankerScore.HasValue)
            {
                Console.WriteLine($"@search.rerankerScore: {result.SemanticSearch.RerankerScore.Value}");
            }
            Console.WriteLine(new string('-', 40));
        }
    }
    catch (Exception ex)
    {
        Console.WriteLine($"Error querying index: {ex.Message}");
    }
}
}
```

2. Replace the search service URL with a valid endpoint.
 3. Run the program.
 4. Output is logged to a console window from `Console.WriteLine`. You should see search results for each query.

Output for semantic query (no captions or answers)

This output is from the semantic query, with no captions or answers. The query string is 'walking distance to live music'.

Here, the initial results from the term query are rescored using the semantic ranking models. For this particular dataset and query, the first several results are in similar positions. The effects of semantic ranking are more pronounced in the remainder of the results.

Press Enter to continue to the next query...

Output for semantic answers

The final query returns a semantic answer. Notice that we changed the query string for this example: 'what's a good hotel for people who like to read'.

Semantic ranker can produce an answer to a query string that has the characteristics of a question. The generated answer is extracted verbatim from your content so it won't include composed content like what you might expect from a chat completion model. If the semantic answer isn't useful for your scenario, you can omit `semantic_answers` from your code.

To produce a semantic answer, the question and answer must be closely aligned, and the model must find content that clearly answers the question. If potential answers fail to meet a confidence threshold, the model doesn't return an answer. For demonstration purposes, the question in this example is designed to get a response so that you can see the syntax.

Recall that answers are *verbatim content* pulled from your index and might be missing phrases that a user would expect to see. To get *composed answers* as generated by a chat completion model, considering using a [RAG pattern](#) or [agentic retrieval](#).

Clean up resources

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the **All resources** or **Resource groups** link in the left-navigation pane.

Related content

In this quickstart, you learned how to invoke semantic ranking on an existing index. We recommend trying semantic ranking on your own indexes as a next step. The following articles can help you get started.

- [Semantic ranking overview](#)
- [Configure semantic ranker](#)
- [Add query rewrite to semantic ranking](#)
- [Use scoring profiles and semantic ranking together](#)

Last updated on 11/20/2025

Quickstart: Chat with Azure OpenAI models using your own data

ⓘ Note

This document refers to the [Microsoft Foundry \(classic\)](#) portal.

 [View the Microsoft Foundry \(new\) documentation](#) to learn about the new portal.

In this quickstart, you use your own data with Azure OpenAI models to create a powerful, conversational AI platform that enables faster and more accurate communication.

ⓘ Important

There are new ways to build conversational solutions with your own data. For the latest recommended approach, see [Quickstart: Use agentic retrieval in Azure AI Search](#).

Prerequisites

- Download the example data from [GitHub](#) if you don't have your own data.

Add your data using Microsoft Foundry portal

💡 Tip

Alternatively, you can [use the Azure Developer CLI](#) to programmatically create the resources needed for Azure OpenAI On Your Data.

To add your data using the portal:

1. Sign in to [Microsoft Foundry](#). Make sure the **New Foundry** toggle is off. These steps refer to **Foundry (classic)**.

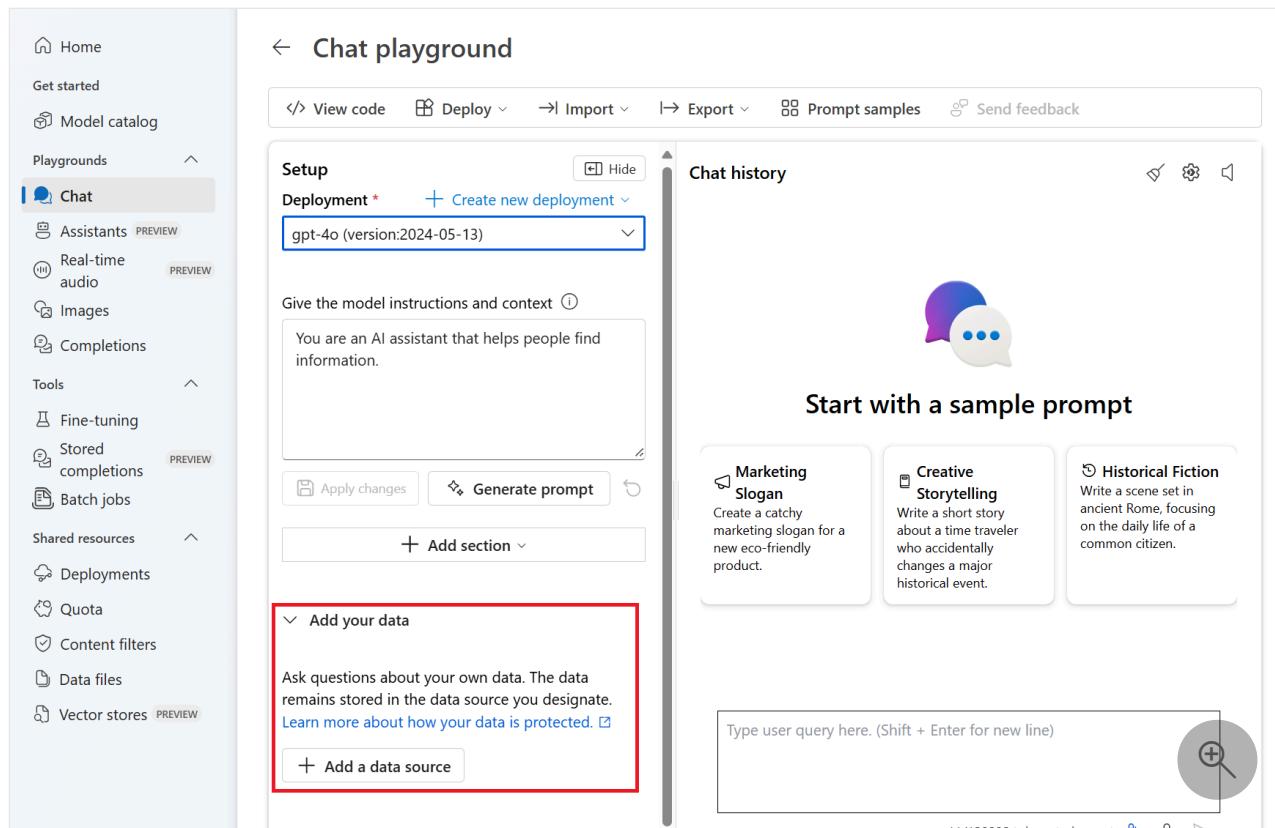

New Foundry

2. Select your Azure OpenAI resource. If you have a Foundry resource, you can [create a Foundry project](#).
3. From the left pane, select **Playgrounds > Chat**.

4. In the **Setup** pane, select your model deployment.

5. Select **Add your data > Add a data source**.

6. On the **Data source** page:

a. Under **Select data source**, select **Upload files (preview)**.

Tip

- This option requires an Azure Blob Storage resource and Azure AI Search resource to access and index your data. For more information, see [Data source options](#) and [Supported file types and formats](#).
- For documents and datasets with long text, we recommend that you use the [data preparation script](#).

b. [Cross-origin resource sharing](#) (CORS) is required for Azure OpenAI to access your storage account. If CORS isn't already enabled for your Azure Blob Storage resource, select **Turn on CORS**.

c. Select your Azure AI Search resource.

d. Enter a name for your new index.

e. Select the checkbox that acknowledges the billing effects of using Azure AI Search.

f. Select Next.

The screenshot shows the 'Add data' wizard with the title 'Select or add data source'. On the left, a sidebar lists steps: 'Data source' (selected), 'Upload files', 'Data management', and 'Review and finish'. The main area contains fields for 'Subscription' (dropdown), 'Select Azure Blob storage resource' (dropdown), 'Select Azure AI Search resource' (dropdown), 'Enter the index name' (text input), and a checkbox for 'Add vector search to this search resource'. At the bottom are 'Next' and 'Cancel' buttons.

7. On the **Upload files** page:

- Select **Browse for a file**, and then select your own data or the sample data you downloaded from the [prerequisites](#).
- Select **Upload files**.
- Select **Next**.

8. On the **Data management** page:

- Choose whether to enable [semantic search](#) or [vector search](#) for your index.

Important

- [Semantic search](#) and [vector search](#) are subject to additional pricing. Your Azure AI Search resource must be on the Basic tier or higher to enable semantic search or vector search. For more information, see [Choose a tier](#) and [Service limits](#).

- To help improve the quality of the information retrieval and model response, we recommend that you enable [semantic search](#) for the following data source languages: English, French, Spanish, Portuguese, Italian, Germany, Chinese(Zh), Japanese, Korean, Russian, and Arabic.

b. Select **Next**.

9. On the **Data connection** page:

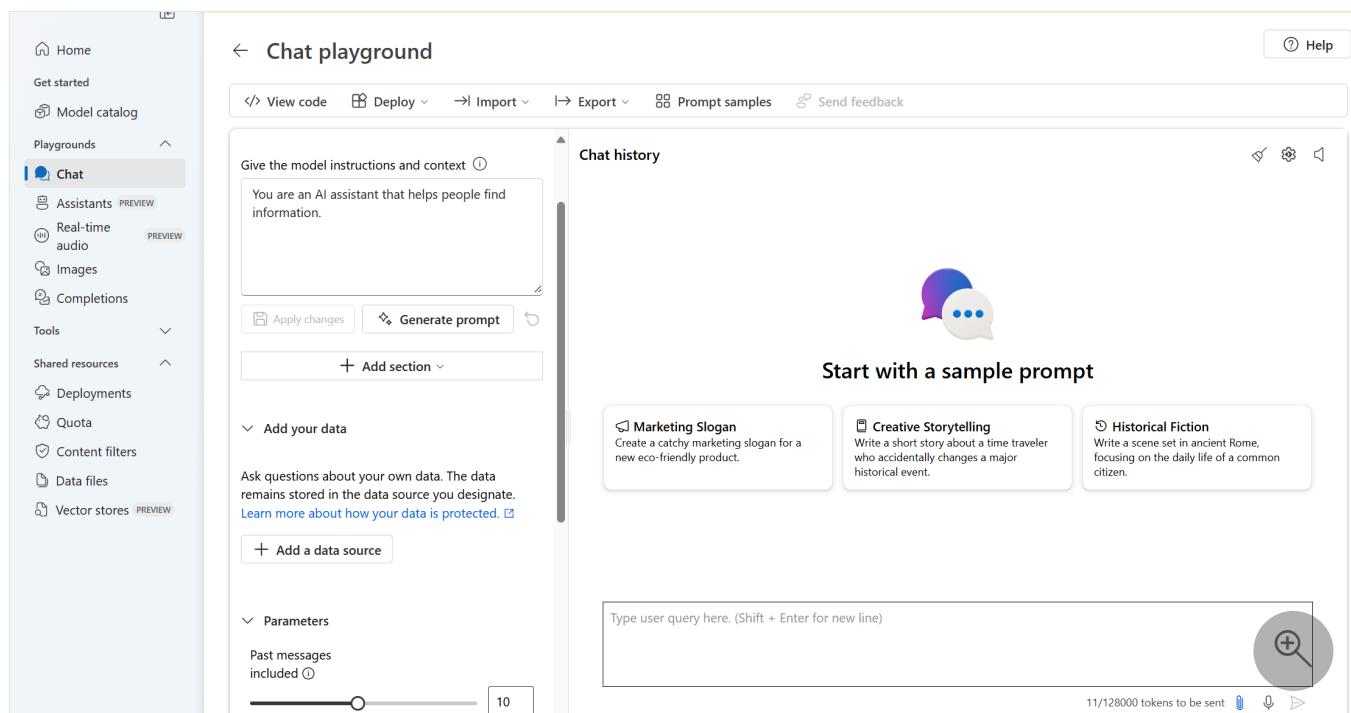

- Choose whether to authenticate using a **System assigned managed identity** or an **API key**.
- Select **Next**.

10. Review your configurations, and then select **Save and close**.

You can now chat with the model, which uses your data to construct the response.

Chat playground

Start exploring Azure OpenAI capabilities with a no-code approach through the chat playground. It's simply a text box where you can submit a prompt to generate a completion. From this page, you can quickly iterate and experiment with the capabilities.

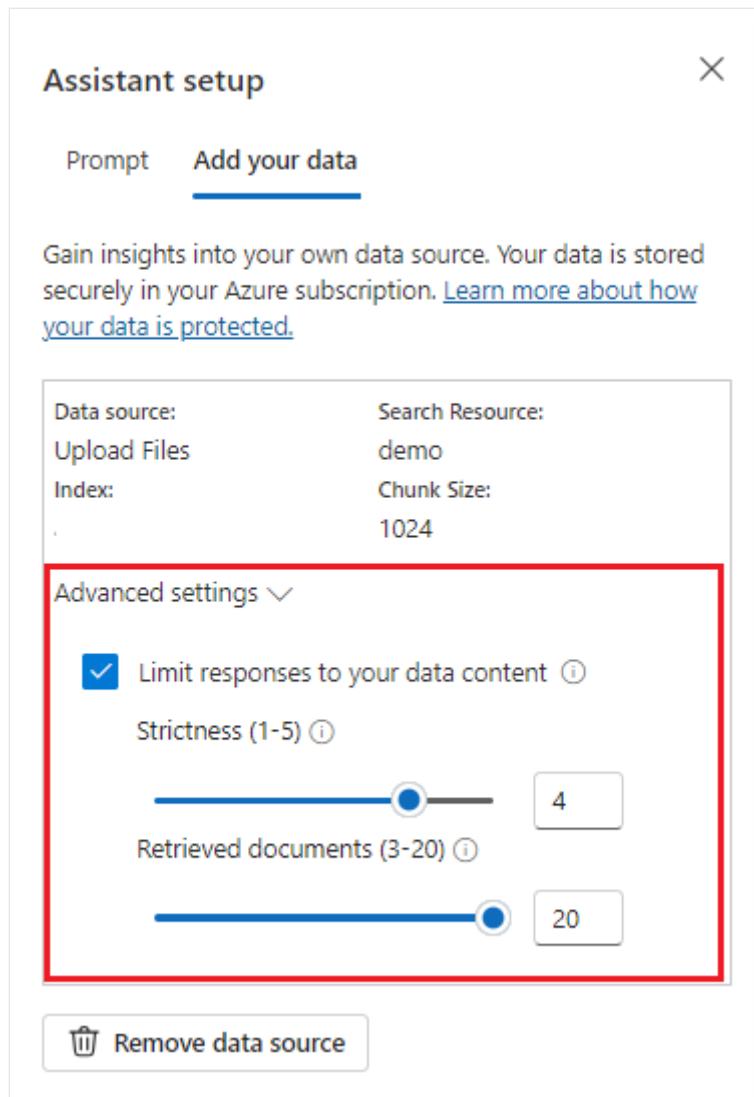

The playground gives you options to tailor your chat experience. On the top menu, you can select **Deploy** to determine which model generates a response using the search results from your index. You choose the number of past messages to include as conversation history for

future generated responses. [Conversation history](#) gives context to generate related responses but also consumes [token usage](#). The input token progress indicator keeps track of the token count of the question you submit.

The **Advanced settings** on the left are [runtime parameters](#), which give you control over retrieval and search relevant information from your data. A good use case is when you want to make sure responses are generated only based on your data or you find the model cannot generate a response based on existed information on your data.

- **Strictness** determines the system's aggressiveness in filtering search documents based on their similarity scores. Setting strictness to 5 indicates that the system will aggressively filter out documents, applying a very high similarity threshold. [Semantic search](#) can be helpful in this scenario because the ranking models do a better job of inferring the intent of the query. Lower levels of strictness produce more verbose answers, but might also include information that isn't in your index. This is set to 3 by default.
- **Retrieved documents** is an integer that can be set to 3, 5, 10, or 20, and controls the number of document chunks provided to the large language model for formulating the final response. By default, this is set to 5.
- When **Limit responses to your data** is enabled, the model attempts to only rely on your documents for responses. This is set to true by default.

Send your first query. The chat models perform best in question and answer exercises. For example, "*What are my available health plans?*" or "*What is the health plus option?*".

Queries that require data analysis would probably fail, such as "*Which health plan is most popular?*". Queries that require information about all of your data will also likely fail, such as "*How many documents have I uploaded?*". Remember that the search engine looks for chunks having exact or similar terms, phrases, or construction to the query. And while the model might understand the question, if search results are chunks from the data set, it's not the right information to answer that kind of question.

Chats are constrained by the number of documents (chunks) returned in the response (limited to 3-20 in Foundry portal playground). As you can imagine, posing a question about "all of the titles" requires a full scan of the entire vector store.

Deploy your model

Once you're satisfied with the experience, you can deploy a web app directly from the portal by selecting the **Deploy to** button.

← Chat playground

The screenshot shows the Microsoft Foundry Models Chat playground interface. At the top, there's a navigation bar with 'View code', 'Deploy' (with a dropdown menu showing '...as a web app'), 'Import', and 'Export'. Below the navigation is a text input field containing the placeholder 'Give the model instructions and context'. A tooltip above the input field says '...as a web app'. To the right of the input field is a button with a magnifying glass icon. The main area contains the text 'You are an AI assistant that helps people find'.

This gives you the option to either deploy to a standalone web application, or a copilot in Copilot Studio (preview) if you're [using your own data](#) on the model.

As an example, if you choose to deploy a web app:

The first time you deploy a web app, you should select **Create a new web app**. Choose a name for the app, which will become part of the app URL. For example,

`https://<appname>.azurewebsites.net`.

Select your subscription, resource group, location, and pricing plan for the published app. To update an existing app, select **Publish to an existing web app** and choose the name of your previous app from the dropdown menu.

If you choose to deploy a web app, see the [important considerations](#) for using it.

Clean up resources

If you want to clean up and remove an Azure OpenAI or Azure AI Search resource, you can delete the resource or resource group. Deleting the resource group also deletes any other resources associated with it.

- [Azure AI Search resources](#)
- [Azure app service resources](#)

Last updated on 11/18/2025

Quickstart: Use agentic retrieval in the Azure portal

!Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In this quickstart, you use [agentic retrieval](#) in the Azure portal to create a conversational search experience powered by documents indexed in Azure AI Search and large language models (LLMs) from Azure OpenAI in Foundry Models.

The portal guides you through the process of creating the following objects:

- A *knowledge source* that references a container in Azure Blob Storage. When you create a blob knowledge source, Azure AI Search automatically generates an index and other pipeline objects to ingest and enrich your content for agentic retrieval.
- A *knowledge base* that uses agentic retrieval to infer the underlying information need, plan and execute subqueries, and formulate a natural-language answer using the optional answer synthesis output mode.

Afterwards, you test the knowledge base by submitting a complex query that requires information from multiple documents and reviewing the synthesized answer.

!Important

Because the portal uses the 2025-08-01-preview REST API version for agentic retrieval, the knowledge source and knowledge base created in this quickstart aren't compatible with the latest 2025-11-01-preview. For help with breaking changes, see [Migrate your agentic retrieval code](#).

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#) in any region that provides agentic retrieval.
- An [Azure Blob Storage account](#).

- A Microsoft Foundry project and resource. When you create a project, the resource is automatically created.
- For text-to-vector conversion, an embedding model [deployed to your project](#). You can use any `text-embedding` model, such as `text-embedding-3-large`.
- For query planning and answer generation, an LLM [deployed to your project](#). You can use any [portal-supported LLM](#).

Supported LLMs

Although agentic retrieval [programmatically supports several LLMs](#), the portal currently supports the following LLMs:

- `gpt-4o`
- `gpt-4o-mini`
- `gpt-5`
- `gpt-5-mini`
- `gpt-5-nano`

Configure access

Before you begin, make sure you have permissions to access content and operations. We recommend Microsoft Entra ID for authentication and role-based access for authorization. You must be an **Owner** or **User Access Administrator** to assign roles. If roles aren't feasible, use [key-based authentication](#) instead.

To configure access for this quickstart, select each of the following tabs.

Azure AI Search

Azure AI Search provides the agentic retrieval pipeline. Configure access for yourself and your search service to read and write data, interact with other Azure services, and run the pipeline.

On your Azure AI Search service:

1. [Enable role-based access](#).
2. [Configure a system-assigned managed identity](#).
3. [Assign the following roles](#) to yourself.

- Search Service Contributor
- Search Index Data Contributor
- Search Index Data Reader

Important

Agentic retrieval has two token-based billing models:

- Billing from Azure AI Search for agentic retrieval.
- Billing from Azure OpenAI for query planning and answer synthesis.

For more information, see [Availability and pricing of agentic retrieval](#).

Prepare sample data

This quickstart uses sample JSON documents from NASA's Earth at Night e-book, but you can also use your own files. The documents describe general science topics and images of Earth at night as observed from space.

To prepare the sample data for this quickstart:

1. Sign in to the [Azure portal](#) and select your Azure Blob Storage account.
2. From the left pane, select **Data storage > Containers**.
3. Create a container named **earth-at-night-data**.
4. Upload the [sample JSON documents](#) to the container.

Create a knowledge source

A knowledge source is a reusable reference to your source data. In this section, you create a [blob knowledge source](#), which triggers the creation of a *data source*, *skillset*, *index*, and *indexer* to automate data indexing and enrichment. You review these objects in a later section.

You also configure a *vectorizer*, which uses your deployed embedding model to convert text into vectors and match documents based on semantic similarity. The vectorizer, vector fields, and vectors will be added to the auto-generated index.

To create the knowledge source for this quickstart:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Knowledge retrieval > Knowledge sources**.
3. Select **Add knowledge source > Add knowledge source**.
4. Enter **earth-at-night-ks** for the name.
5. Select **Azure blob**, and then select your subscription, storage account, and container with the sample data.
6. Select the **Authenticate using managed identity** checkbox. Leave the identity type as **System-assigned**.
7. Select **Add vectorizer**.
8. Select **Microsoft Foundry** for the kind, and then select your subscription, project, and embedding model deployment.
9. Select **System managed identity** for the authentication type.
10. Create the knowledge source.

[Create](#)

[Back](#)

Create a knowledge base

⚠ Note

The portal uses the 2025-08-01-preview, which refers to "knowledge bases" as "knowledge agents." Although the portal UI uses the latest terminology, the underlying REST API objects and JSON payloads still use "knowledge agents."

A knowledge base uses your knowledge source and deployed LLM to orchestrate agentic retrieval. When a user submits a complex query, the LLM generates subqueries that are sent simultaneously to your knowledge source. Azure AI Search then semantically ranks the results for relevance and combines the best results into a single, unified response.

The output mode determines how the knowledge base formulates answers. You can either use extractive data for verbatim content or [answer synthesis](#) for natural-language answer generation. By default, the portal uses answer synthesis.

To create the knowledge base for this quickstart:

1. From the left pane, select **Knowledge retrieval > Knowledge bases**.
2. Select **Add knowledge base > Add knowledge base**.
3. Enter **earth-at-night-kb** for the name.
4. Under **Model deployment**, select **Add model deployment**.
5. Select **Foundry** for the kind, and then select your subscription, project, and LLM deployment.
6. Select **System assigned identity** for the authentication type.
7. Save the model deployment.
8. Under **Knowledge sources**, select **earth-at-night-ks**.
9. Create the knowledge base.

Test agentic retrieval

The portal provides a chat playground where you can submit `retrieve` requests to the knowledge base, whose responses include references to your knowledge sources and debug information about the retrieval process.

To query the knowledge base:

1. Use the chat box to send the following query.

Why do suburban belts display larger December brightening than urban cores even though absolute light levels are higher downtown? Why is the Phoenix nighttime

street grid is so sharply visible from space, whereas large stretches of the interstate between midwestern cities remain comparatively dim?

2. Review the synthesized, citation-backed answer, which should be similar to the following example.

The suburban belts exhibit larger December brightening compared to urban cores due to the increased use of decorative and festive lighting in residential areas, which are more prevalent in suburban regions. In contrast, urban cores, despite having higher absolute light levels, experience less seasonal variation in lighting. The Phoenix nighttime street grid is sharply visible from space because of its regular grid layout and the extensive use of street lighting, which creates a consistent and bright pattern. Conversely, large stretches of interstate highways between Midwestern cities are less illuminated, as they primarily serve as transit routes with minimal lighting infrastructure, resulting in comparatively dim visibility from space.

3. Select the debug icon to review the activity log, which should be similar to the following example.

```
[  
 {  
   "type": "modelQueryPlanning",  
   "id": 0,  
   "inputTokens": 2081,  
   "outputTokens": 128,  
   "elapsedMs": 1577  
 },  
 {  
   "type": "azureBlob",  
   "id": 1,  
   "knowledgeSourceName": "earth-at-night-ks",  
   "queryTime": "2025-11-03T15:09:28.172Z",  
   "count": 0,  
   "elapsedMs": 731,

    "type": "modelAnswerSynthesis",  
    "id": 4,  
    "inputTokens": 3938,  
    "outputTokens": 136,  
    "elapsedMs": 1963  
}  
]  
]
```

The activity log offers insight into the steps taken during retrieval, including query planning and execution, semantic ranking, and answer synthesis. For more information, see [Review the activity array](#).

Review the created objects

Azure AI Search automatically generates a data source, skillset, index, and indexer for each blob knowledge source. These objects form an end-to-end pipeline for data ingestion, enrichment, chunking, and vectorization. You can review these objects to learn how your data is processed for agentic retrieval.

To review the auto-generated objects:

1. From the left pane, select **Search management**.
2. Check the data source to verify the connection to your blob storage container.
3. Check the skillset to see how your content is chunked and vectorized using your embedding model.
4. Check the index to see how your content is indexed and exposed for retrieval, including which fields are searchable and filterable and which fields store vectors for similarity search.
5. Check the indexer for success or failure messages. Connection or quota errors appear here.

Clean up resources

When you work in your own subscription, it's a good idea to finish a project by determining whether you still need the resources you created. Resources that are left running can cost you money.

In the Azure portal, you can manage your Azure AI Search, Azure Blob Storage, and Foundry resources by selecting **All resources** or **Resource groups** from the left pane.

You can also delete the knowledge source and knowledge base on their respective portal pages. When you delete the knowledge source, the portal prompts you to delete the associated data source, skillset, index, and indexer.

Next step

[Learn more about agentic retrieval](#)

Last updated on 11/18/2025

Quickstart: Create a search index in the Azure portal

Important

The **Import data (new)** wizard now supports keyword search, which was previously only available in the **Import data** wizard. We recommend the new wizard for an improved search experience. For more information about how we're consolidating the wizards, see [Import data wizards in the Azure portal](#).

In this quickstart, you use the **Import data (new)** wizard and sample data about fictitious hotels to create your first search index. The wizard requires no code to create an index, helping you write interesting queries within minutes.

The wizard creates multiple objects on your search service, including a searchable [index](#), an [indexer](#), and a data source connection for automated data retrieval. At the end of this quickstart, you review each object.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription. You can use a free service for this quickstart.
- An [Azure Storage account](#). Use Azure Blob Storage or Azure Data Lake Storage Gen2 (storage account with a hierarchical namespace) on a standard performance (general-purpose v2) account. To avoid bandwidth charges, use the same region as Azure AI Search.

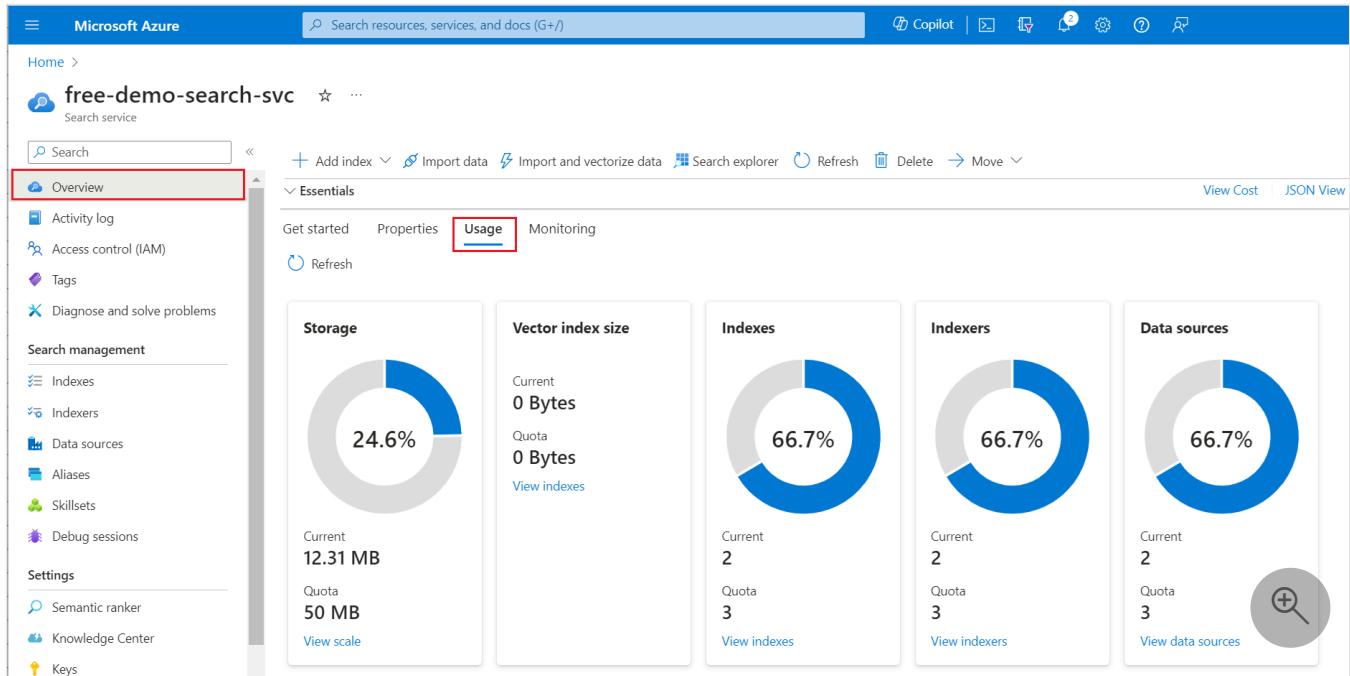

Check for network access

For this quickstart, all of the preceding resources must have public access enabled so that the Azure portal nodes can access them. Otherwise, the wizard fails. After the wizard runs, you can enable firewalls and private endpoints on the integration components for security. For more information, see [Secure connections in the import wizards](#).

Check for space

Many customers start with a free search service, which is limited to three indexes, three indexers, and three data sources. This quickstart creates one of each, so before you begin, make sure you have room for extra objects.

On the **Overview** page, select **Usage** to see how many indexes, indexers, and data sources you currently have.

Prepare sample data

This quickstart uses a JSON document that contains metadata for 50 fictitious hotels, but you can also use your own files.

To prepare the sample data for this quickstart:

1. Download the [sample JSON document](#).
2. Sign in to the [Azure portal](#) and select your Azure Storage account.
3. From the left pane, select **Data storage > Containers**.
4. Create a container named **hotels-sample**.
5. Upload the **HotelsData_toAzureBlobs.json** file to the container.

Start the wizard

To start the wizard for this quickstart:

1. Sign in to the [Azure portal](#) and select your search service.

2. On the **Overview** page, select **Import data (new)**.

3. Select your data source: **Azure Blob Storage** or **Azure Data Lake Storage Gen2**.

A screenshot of the 'Select your data source' interface. It shows a grid of data source options. The first two options, 'Azure Blob Storage' and 'Azure Data Lake Storage Gen2', are highlighted with red boxes. Other options include: Azure SQL Database, Azure Table Storage, Azure Cosmos DB, SharePoint, OneDrive, OneDrive for Business, Azure File Storage, Azure Queues, Service Bus, Amazon S3, Dropbox, and SFTP - SSH. A search bar at the top says 'Let's start by picking a data source...' and 'Available options are listed below. Learn more'. A magnifying glass icon is in the bottom right corner.

4. Select **Keyword search**.

A screenshot of the 'Select Keyword search' interface. It shows three scenarios: 'Keyword search' (highlighted with a red box), 'RAG', and 'Multimodal RAG'. Each scenario has a description and an icon. The 'Keyword search' box says: 'Ingest text for keyword search. Optionally, add AI skills to extract, infer, or create new searchable content.' The 'RAG' box says: 'Ingest text and simple images containing text (via OCR) to enable AI-powered answers.' The 'Multimodal RAG' box says: 'Ingest text and complex images (diagrams, charts, workflows) where interpreting visual elements is necessary for insights.' A magnifying glass icon is in the bottom right corner.

Create and load a search index

In this section, you create and load an index in five steps.

Connect to a data source

Azure AI Search requires a connection to a data source for content ingestion and indexing. In this case, the data source is your Azure Storage account.

To connect to the sample data:

1. On the **Connect to your data** page, select your Azure subscription.

2. Select your storage account, and then select the **hotels-sample** container.

3. Select **JSON array** for the parsing mode.

Configure your Azure Blob Storage

Connect to Azure Blob Storage to access your structured and unstructured data files, including PDFs. [Learn more](#)

Subscription *	my-subscription
Storage account *	mystorageaccount
Blob container * ⓘ	hotels-sample
Blob folder ⓘ	your/folder/here
Parsing mode	JSON array
Document Root ⓘ	/level1/level2

Enable deletion tracking. ⓘ

Authenticate using managed identity. [Learn more](#)

4. Select **Next**.

Skip configuration for skills

The wizard supports skillset creation and **AI enrichment** during indexing, which are beyond the scope of this quickstart. Skip this step by selecting **Next**.

💡 Tip

For a similar walkthrough that focuses on AI enrichment, see [Quickstart: Create a skillset in the Azure portal](#).

Configure the index

Based on the structure and content of the sample hotel data, the wizard infers a schema for your search index.

To configure the index:

1. For each of the following fields, select **Configure field**, and then set the respective attributes.

[Expand table](#)

StateProvince	StateProvince	Edm.String
PostalCode	PostalCode	Edm.String
Country	Country	Edm.String
Location	Location	Edm.GeographyPoint

2. Select Next.

At a minimum, the index requires a name and a collection of fields. The wizard scans for unique string fields and marks one as the document key, which uniquely identifies each document in the index.

Each field has a name, [data type](#), and attributes that control how the field is used in the index. You can enable or disable the following attributes:

[Expand table

Attribute	Description	Applicable data types
Retrievable	Fields returned in a query response.	Strings and integers
Filterable	Fields that accept a filter expression.	Strings and integers
Sortable	Fields that accept an orderby expression.	Strings and integers
Facetable	Fields used in a faceted navigation structure.	Strings and integers
Searchable	Fields used in full-text search. Strings are searchable, but numeric and Boolean fields are often marked as not searchable.	Strings

Attributes affect storage in different ways. For example, filterable fields consume extra storage, while retrievable fields don't. For more information about attributes and data types, see [Configure field definitions](#).

If you want autocomplete or suggested queries, specify [Suggesters](#).

Skip advanced settings

The wizard offers advanced settings for semantic ranking and index scheduling, which are beyond the scope of this quickstart. Skip this step by selecting [Next](#).

Review and create the objects

The last step is to review your configuration and create the index, indexer, and data source on your search service. The indexer automates the process of extracting content from your data source and loading it into the index, enabling keyword search.

To review and create the objects:

1. Change the object name prefix to **hotels-sample**.

2. Review the object configurations.

Based on your configuration, the wizard will create an index, an indexer, a data source, and a skillset on your search service. You can view and manage these objects after they're created, but their names and many other properties are fixed. To customize the name, change the object name prefix.

Objects name prefix

Review your configuration

Data source	Azure Blob Storage - hotels-sample
AI enrichments	Disabled
Semantic ranker	Enabled
Indexer run schedule	Once

AI enrichment, semantic ranker, and indexer scheduling are either disabled or set to their default values because you skipped their wizard steps.

3. Select **Create** to simultaneously create the objects and run the indexer.

Monitor indexer progress

You can monitor the creation of the indexer and index in the Azure portal. The **Overview** page provides links to the objects created on your search service.

To monitor the progress of the indexer:

1. From the left pane, select **Indexes**.
2. Find **hotels-sample-indexer** in the list.

Home > free-demo-search-svc

 **free-demo-search-svc** | Indexers  

Search service

Overview Activity log Access control (IAM) Tags Diagnose and solve problems

Search management

Indexes Indexers Data sources Aliases Skillsets Debug sessions

Add indexer Refresh Delete

Filter by name...

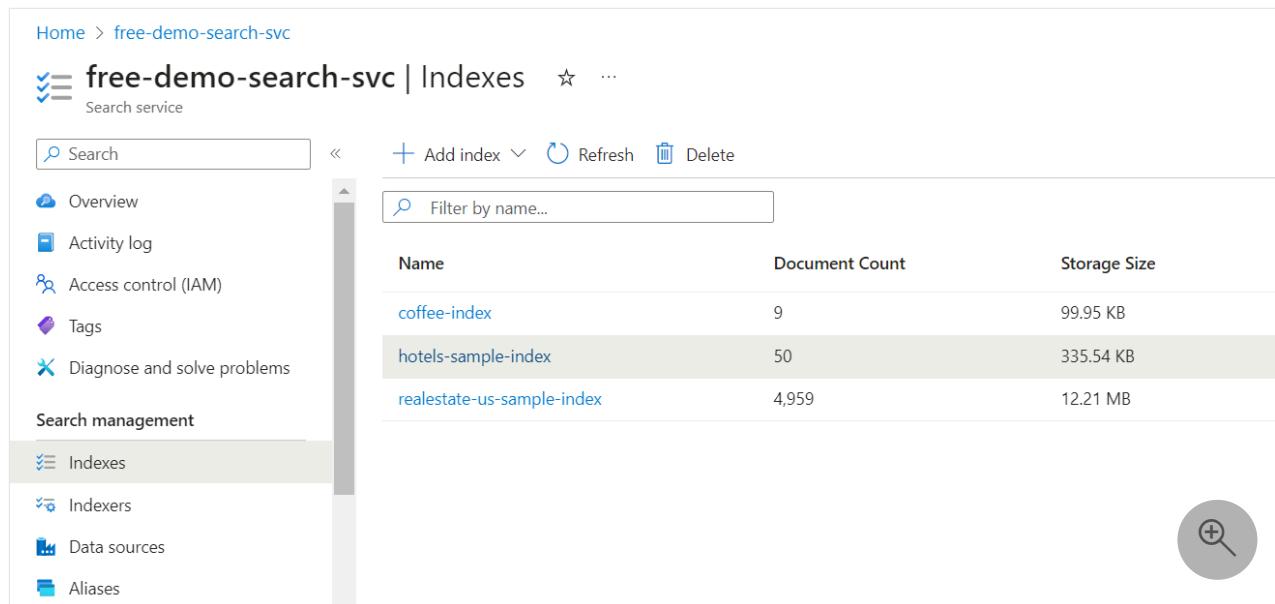

Status	Name	Last run	Docs succeeded	Errors/Warnings
Success	coffee-indexer	1 year ago	9/9	0/0
In progress	hotels-sample-indexer	2 seconds ago	0/0	0/0
Success	realestate-us-sample-in...	3 hours ago	4959/4959	0/0

It can take a few minutes for the results to update. You should see the newly created indexer with a status of **In progress** or **Success**. The list also shows the number of documents indexed.

Check search index results

1. From the left pane, select **Indexes**.
2. Select **hotels-sample-index**. If the index has zero documents or storage, wait for the Azure portal to refresh.

The screenshot shows the Azure portal interface for a search service named "free-demo-search-svc". The left sidebar includes options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Search management, Indexes (which is selected and highlighted in grey), Indexers, Data sources, and Aliases. The main content area displays the "Indexes" page with a table showing three entries:

Name	Document Count	Storage Size
coffee-index	9	99.95 KB
hotels-sample-index	50	335.54 KB
realestate-us-sample-index	4,959	12.21 MB

A search bar at the top allows filtering by name. A large circular button with a magnifying glass icon is located in the bottom right corner of the main content area.

3. Select the **Fields** tab to view the index schema.
4. Check which fields are **Filterable** or **Sortable** so that you know what queries to write.

Add or change fields

On the **Fields** tab, you can create a field by selecting **Add field** and specifying a name, [supported data type](#), and attributes.

Changing existing fields is more difficult. Existing fields have a physical representation in the search index, so they aren't modifiable, not even in code. To fundamentally change an existing field, you must create a new field to replace the original. You can add other constructs, such as scoring profiles and CORS options, to an index at any time.

Review the index definition options to understand what you can and can't edit during index design. If an option appears dimmed, you can't modify or delete it.

Query with Search explorer

You now have a search index that can be queried using [Search explorer](#), which sends REST calls that conform to [Documents - Search Post \(REST API\)](#). This tool supports [simple query syntax](#) and [full Lucene query syntax](#) for keyword search.

To query your search index:

1. On the [Search explorer](#) tab, enter text to search on.

```

Example queries for hotels-sample index

The following examples assume the JSON view and the latest preview REST API version.

Tip

The JSON view supports intellisense for parameter name completion. Place your cursor inside the JSON view and enter a space character to see a list of all query parameters. You can also enter a letter, like `s`, to see only the query parameters that begin with that letter.

Intellisense doesn't exclude invalid parameters, so use your best judgment.

Filter examples

Parking, tags, renovation date, rating, and location are filterable.

JSON

```
{
  "search": "beach OR spa",
  "select": "HotelId, HotelName, Description, Rating",
  "count": true,
  "top": 10,
  "filter": "Rating gt 4"
}
```

Boolean filters assume "true" by default.

JSON

```
{
  "search": "beach OR spa",
  "select": "HotelId, HotelName, Description, Rating",
  "count": true,
```

```
"top": 10,  
"filter": "ParkingIncluded"  
}
```

Geospatial search is filter based. The `geo.distance` function filters all results for positional data based on the specified `Location` and `geography'POINT` coordinates. The query seeks hotels within five kilometers of the latitude and longitude coordinates `-122.12 47.67`, which is "Redmond, Washington, USA." The query displays the total number of matches `&$count=true` with the hotel names and address locations.

JSON

```
{  
  "search": "*",  
  "select": "HotelName, Address/City, Address/StateProvince",  
  "count": true,  
  "top": 10,  
  "filter": "geo.distance(Location, geography'POINT(-122.12 47.67)') le 5"  
}
```

Full Lucene syntax examples

The default syntax is [simple syntax](#), but if you want fuzzy search, term boosting, or regular expressions, specify the [full syntax](#).

JSON

```
{  
  "queryType": "full",  
  "search": "seattle~",  
  "select": "HotelId, HotelName,Address/City, Address/StateProvince",  
  "count": true  
}
```

Misspelled query terms, like `seattle` instead of `Seattle`, don't return matches in a typical search. The `queryType=full` parameter invokes the full Lucene query parser, which supports the tilde (`~`) operand. When you use these parameters, the query performs a fuzzy search for the specified keyword and matches on terms that are similar but not an exact match.

Take a minute to try these example queries on your index. For more information, see [Querying in Azure AI Search](#).

Clean up resources

When you work in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

In the Azure portal, you can find and manage resources by selecting **All resources** or **Resource groups** from the left pane.

 **Note**

If you're using a free search service, remember that the limit is three indexes, three indexers, and three data sources. You can delete individual objects in the Azure portal to stay under the limit.

Next step

Try an Azure portal wizard to generate a ready-to-use web app that runs in a browser. Use this wizard on the small index you created in this quickstart, or use [sample data](#) for a richer search experience.

[Quickstart: Create a demo search app in the Azure portal](#)

Last updated on 12/05/2025

Quickstart: Vectorize text in the Azure portal

In this quickstart, you use the [Import data \(new\)](#) wizard in the Azure portal to get started with [integrated vectorization](#). The wizard chunks your content and calls an embedding model to vectorize the chunks at indexing and query time.

This quickstart uses text-based PDFs from the [azure-search-sample-data](#) repo. However, you can use images and still complete this quickstart.

Prerequisites

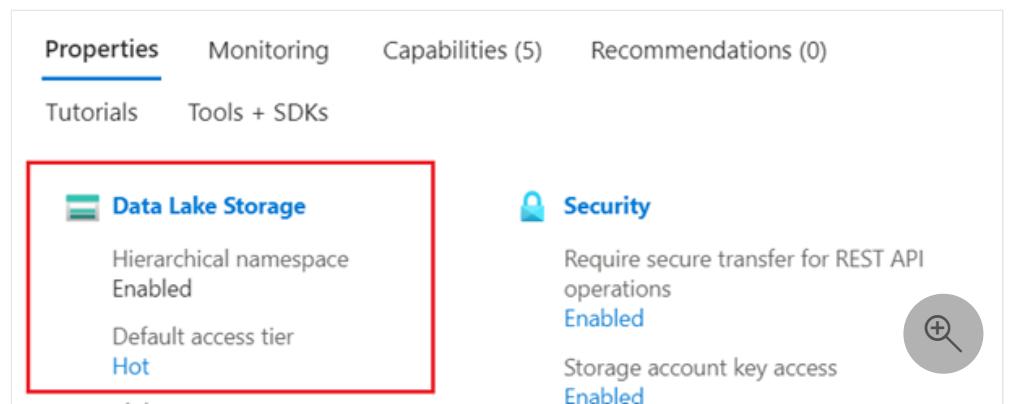

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#). We recommend the Basic tier or higher.
- A [supported data source](#).
- A [supported embedding model](#).
- Familiarity with the wizard. See [Import data wizards in the Azure portal](#).

Supported data sources

The wizard [supports a wide range of Azure data sources](#). However, this quickstart only covers the data sources that work with whole files, which are described in the following table.

 [Expand table](#)

Supported data source	Description
Azure Blob Storage	This data source works with blobs and tables. You must use a standard performance (general-purpose v2) account. Access tiers can be hot, cool, or cold.
Azure Data Lake Storage (ADLS) Gen2	This is an Azure Storage account with a hierarchical namespace enabled. To confirm that you have Data Lake Storage, check the Properties tab on the Overview page.

Supported data source	Description
	<p>Microsoft OneLake</p>

Supported embedding models

For integrated vectorization, use one of the following embedding models. Deployment instructions are provided in a [later section](#).

 Expand table

Provider	Supported models
Azure OpenAI in Azure AI Foundry Models resource ¹ ²	For text: text-embedding-ada-002 text-embedding-3-small text-embedding-3-large
Azure AI Foundry project	For text: text-embedding-ada-002 text-embedding-3-small text-embedding-3-large
Azure AI Foundry hub-based project	For text: text-embedding-ada-002 text-embedding-3-small text-embedding-3-large
Azure AI services multi-service resource ⁴	For text and images: Cohere-embed-v3-english ³ Cohere-embed-v3-multilingual ³
Azure AI services multi-service resource ⁴ ⁵	For text and images: Azure AI Vision multimodal

¹ The endpoint of your Azure OpenAI resource must have a [custom subdomain](#), such as `https://my-unique-name.openai.azure.com`. If you created your resource in the [Azure portal](#), this subdomain was automatically generated during resource setup.

² Azure OpenAI resources (with access to embedding models) that were created in the [Azure AI Foundry portal](#) aren't supported. You must create an Azure OpenAI resource in the Azure portal.

³ To use this model in the wizard, you must [deploy it as a serverless API deployment](#).

⁴ For billing purposes, you must [attach your Azure AI multi-service resource](#) to the skillset in your Azure AI Search service. Unless you use a [keyless connection \(preview\)](#) to create the skillset, both resources must be in the same region.

⁵ The Azure AI Vision multimodal embeddings APIs are available in [select regions](#).

Public endpoint requirements

For this quickstart, all of the preceding resources must have public access enabled so that the Azure portal nodes can access them. Otherwise, the wizard fails. After the wizard runs, you can enable firewalls and private endpoints on the integration components for security. For more information, see [Secure connections in the import wizards](#).

If private endpoints are already present and you can't disable them, the alternative option is to run the respective end-to-end flow from a script or program on a virtual machine. The virtual machine must be on the same virtual network as the private endpoint. Here's a [Python code sample](#) for integrated vectorization. The same [GitHub repo](#) has samples in other programming languages.

Role-based access

You can use Microsoft Entra ID with role assignments or key-based authentication with full-access connection strings. For Azure AI Search connections to other resources, we recommend role assignments. This quickstart assumes roles.

Free search services support role-based connections to Azure AI Search. However, they don't support managed identities on outbound connections to Azure Storage or Azure AI Vision. This lack of support requires key-based authentication on connections between free search services and other Azure resources. For more secure connections, use the Basic tier or higher, and then enable roles and configure a managed identity.

To configure the recommended role-based access:

1. On your search service, [enable roles](#) and [configure a system-assigned managed identity](#).
2. [Assign the following roles](#) to yourself.
 - **Search Service Contributor**
 - **Search Index Data Contributor**
 - **Search Index Data Reader**
3. On your data source and embedding model provider, create role assignments that allow your search service to access data and models. See [Prepare sample data](#) and [Prepare embedding models](#).

 **Note**

If you can't progress through the wizard because options aren't available (for example, you can't select a data source or an embedding model), revisit the role assignments. Error messages indicate that models or deployments don't exist, when the real cause is that the search service doesn't have permission to access them.

Check for space

If you're starting with the free service, you're limited to three indexes, data sources, skillsets, and indexers. Basic limits you to 15. This quickstart creates one of each object, so make sure you have room for extra items before you begin.

Prepare sample data

In this section, you use a [supported data source](#) to prepare sample data. Before you proceed, make sure you completed the prerequisites for [role-based access](#).

Azure Blob Storage

1. Sign in to the [Azure portal](#) and select your Azure Storage account.
2. From the left pane, select **Data storage > Containers**.
3. Create a container, and then upload the [health-plan PDF documents](#) used for this quickstart.
4. To assign roles:

- a. From the left pane, select **Access Control (IAM)**.
 - b. Select **Add > Add role assignment**.
 - c. Under **Job function roles**, select **Storage Blob Data Reader**, and then select **Next**.
 - d. Under **Members**, select **Managed identity**, and then select **Select members**.
 - e. Select your subscription and the managed identity of your search service.
5. (Optional) Synchronize deletions in your container with deletions in the search index.
To configure your indexer for deletion detection:
- a. [Enable soft delete](#) on your storage account. If you're using [native soft delete](#), the next step isn't required.
 - b. [Add custom metadata](#) that an indexer can scan to determine which blobs are marked for deletion. Give your custom property a descriptive name. For example, you can name the property "IsDeleted" and set it to false. Repeat this step for every blob in the container. When you want to delete the blob, change the property to true. For more information, see [Change and delete detection when indexing from Azure Storage](#).

Prepare embedding model

In this section, you deploy a [supported embedding model](#) for later use in this quickstart. Before you proceed, make sure you completed the prerequisites for [role-based access](#).

Azure OpenAI

The wizard supports several embedding models. Internally, the wizard calls the [Azure OpenAI Embedding skill](#) to connect to Azure OpenAI.

1. To assign roles:
 - a. Sign in to the [Azure portal](#) and select your Azure OpenAI resource.
 - b. From the left pane, select **Access control (IAM)**.
 - c. Select **Add > Add role assignment**.
 - d. Under **Job function roles**, select **Cognitive Services OpenAI User**, and then select **Next**.

- e. Under **Members**, select **Managed identity**, and then select **Select members**.
 - f. Select your subscription and the managed identity of your search service.
2. To deploy an embedding model:
- a. Sign in to the [Azure AI Foundry portal](#) and select your Azure OpenAI resource.
 - b. From the left pane, select **Model catalog**.
 - c. Deploy a [supported embedding model](#).

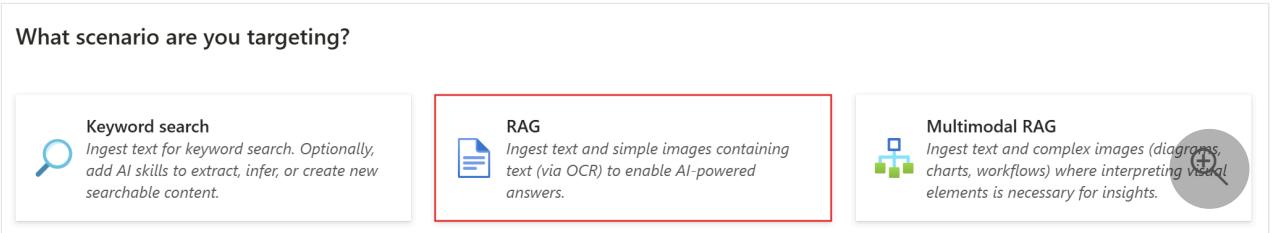

Start the wizard

To start the wizard for vector search:

1. Sign in to the [Azure portal](#) and select your Azure AI Search service.
2. On the **Overview** page, select **Import data (new)**.

3. Select your data source: **Azure Blob Storage**, **ADLS Gen2**, or **OneLake**.
4. Select **RAG**.

Connect to your data

In this step, you connect Azure AI Search to your chosen [data source](#) for content ingestion and indexing.

Azure Blob Storage

1. On the **Connect to your data** page, select your Azure subscription.
2. Select the storage account and container that provide the sample data.

3. If you enabled soft delete and added custom metadata in [Prepare sample data](#), select the **Enable deletion tracking** checkbox.

- On subsequent indexing runs, the search index is updated to remove any search documents based on soft-deleted blobs on Azure Storage.
- Blobs support either **Native blob soft delete** or **Soft delete using custom metadata**.
- If you configured your blobs for soft delete, provide the metadata property name-value pair. We recommend **IsDeleted**. If **IsDeleted** is set to **true** on a blob, the indexer drops the corresponding search document on the next indexer run.
- The wizard doesn't check Azure Storage for valid settings or throw an error if the requirements aren't met. Instead, deletion detection doesn't work, and your search index is likely to collect orphaned documents over time.

4. Select the **Authenticate using managed identity** checkbox. Leave the identity type as **System-assigned**.

Configure your Azure Blob Storage

Connect to your Azure Blob Storage containing PDFs and other unstructured data files. [Learn more](#)

Subscription *	My Azure Subscription
Storage account *	My Azure Storage Account
Blob container * ⓘ	health-plan-pdfs
Blob folder ⓘ	your/folder/here
<input checked="" type="checkbox"/> Enable deletion tracking ⓘ	
<input type="radio"/> Native blob soft delete	
<input checked="" type="radio"/> Soft delete using custom metadata	
Soft delete column *	IsDeleted
Delete marker value *	true
<input checked="" type="checkbox"/> Authenticate using managed identity. Learn more	
Managed identity type ⓘ	System-assigned

5. Select **Next**.

Vectorize your text

During this step, the wizard uses your chosen [embedding model](#) to vectorize chunked data. Chunking is built in and nonconfigurable. The effective settings are:

JSON

```
"textSplitMode": "pages",
"maximumPageLength": 2000,
"pageOverlapLength": 500,
"maximumPagesToTake": 0, #unlimited
"unit": "characters"
```

Azure OpenAI

1. On the **Vectorize your text** page, select **Azure OpenAI** for the kind.
2. Select your Azure subscription.
3. Select your Azure OpenAI resource, and then select the model you deployed in [Prepare embedding model](#).
4. For the authentication type, select **System assigned identity**.
5. Select the checkbox that acknowledges the billing effects of using these resources.

Vectorize your text

Connect to an Azure OpenAI, AI Studio or an Azure AI service and select an embedding model or multi-service account for vector generation. [Learn more](#)

Kind	<input type="text" value="Azure OpenAI"/>
Subscription *	<input type="text" value="Contoso Developer Division"/>
Azure OpenAI service * ⓘ	<input type="text" value="contosoazureopenaieastus"/>  Create a new Azure OpenAI service
Model deployment * ⓘ	<input type="text" value="text-embedding-3-large"/>
Authentication type ⓘ	<input type="radio"/> API key <input checked="" type="radio"/> System assigned identity <input type="radio"/> User assigned identity
<input checked="" type="checkbox"/> I acknowledge that connecting to an Azure OpenAI service will incur additional costs to my account. View pricing 	

6. Select **Next**.

Vectorize and enrich your images

The health-plan PDFs include a corporate logo, but otherwise, there are no images. You can skip this step if you're using the sample documents.

However, if your content includes useful images, you can apply AI in one or both of the following ways:

- Use a supported image embedding model from the Azure AI Foundry model catalog or the Azure AI Vision multimodal embeddings API (via an Azure AI multi-service resource) to vectorize images.
- Use optical character recognition (OCR) to extract text from images. This option invokes the [OCR skill](#).

Vectorize images

1. On the **Vectorize and enrich your images** page, select the **Vectorize images** checkbox.
2. For the kind, select your model provider: **AI Foundry Hub catalog models** or **AI Vision vectorization**.
If Azure AI Vision is unavailable, make sure your search service and multi-service resource are both in a [region that supports the Azure AI Vision multimodal APIs](#).
3. Select your Azure subscription, resource, and embedding model deployment (if applicable).
4. For the authentication type, select **System assigned identity** if you're not using a hub-based project. Otherwise, leave it as **API key**.
5. Select the checkbox that acknowledges the billing effects of using these resources.

Vectorize your images
Specify an embedding model that can create embeddings for image content.

Vectorize images ⓘ

Kind: AI Vision vectorization (Preview)

Create new AI service ⓘ

Authentication type *: ⓘ API key System assigned identity

I acknowledge that including Azure AI services involves a Pay-as-you-go pricing model. [View pricing](#) ⓘ

6. Select **Next**.

Add semantic ranking

On the [Advanced settings](#) page, you can optionally add [semantic ranking](#) to rerank results at the end of query execution. Reranking promotes the most semantically relevant matches to the top.

Map new fields

Key points about this step:

- The index schema provides vector and nonvector fields for chunked data.
- You can add fields, but you can't delete or modify generated fields.
- Document parsing mode creates chunks (one search document per chunk).

On the [Advanced settings](#) page, you can optionally add new fields, assuming the data source provides metadata or fields that aren't picked up on the first pass. By default, the wizard generates the fields described in the following table.

[] [Expand table](#)

Field	Applies to	Description
chunk_id	Text and image vectors	Generated string field. Searchable, retrievable, and sortable. This is the document key for the index.
parent_id	Text vectors	Generated string field. Retrievable and filterable. Identifies the parent document from which the chunk originates.
chunk	Text and image vectors	String field. Human readable version of the data chunk. Searchable and retrievable, but not filterable, facetable, or sortable.
title	Text and image vectors	String field. Human readable document title or page title or page number. Searchable and retrievable, but not filterable, facetable, or sortable.
text_vector	Text vectors	Collection(Edm.single). Vector representation of the chunk. Searchable and retrievable, but not filterable, facetable, or sortable.

You can't modify the generated fields or their attributes, but you can add new fields if your data source provides them. For example, Azure Blob Storage provides a collection of metadata fields.

1. Select **Add field**.

2. Select a source field from the available fields, enter a field name for the index, and accept (or override) the default data type.

 **Note**

Metadata fields are searchable but not retrievable, filterable, facetable, or sortable.

3. If you want to restore the schema to its original version, select **Reset**.

Schedule indexing

On the **Advanced settings** page, you can also specify an optional [run schedule](#) for the indexer. After you choose an interval from the dropdown list, select **Next**.

Finish the wizard

1. On the **Review your configuration** page, specify a prefix for the objects that the wizard creates. A common prefix helps you stay organized.
2. Select **Create**.

When the wizard completes the configuration, it creates the following objects:

- A data source connection.
- An index with vector fields, vectorizers, vector profiles, and vector algorithms. You can't design or modify the default index during the wizard workflow. Indexes conform to the [2024-05-01-preview REST API](#).
- A skillset with the [Text Split skill](#) for chunking and an embedding skill for vectorization. The embedding skill is either the [Azure OpenAI Embedding skill](#), [AML skill](#), or [Azure AI Vision multimodal embeddings skill](#). The skillset also has the [index projections](#) configuration, which maps data from one document in the data source to its corresponding chunks in a "child" index.
- An indexer with field mappings and output field mappings (if applicable).

 **Tip**

Wizard-created objects have configurable JSON definitions. To view or modify these definitions, select **Search management** from the left pane, where you can view your indexes, indexers, data sources, and skillsets.

Check results

Search Explorer accepts text strings as input and then vectorizes the text for vector query execution.

1. In the Azure portal, go to **Search Management > Indexes**, and then select your index.
2. Select **Query options**, and then select **Hide vector values in search results**. This step makes the results more readable.

3. From the **View** menu, select **JSON view** so you can enter text for your vector query in the `text` vector query parameter.

2    "@odata.context": "https://free-demo-search-svc.search.windows.net/indexes('vector-1701309912002')/$metadata#items",
3    "value": [
4      {
5        "@search.score": 0.835181,
6        "chunk": "year deductible is the same for \n\nall members of the plan and is reset each year on the plan",
7        "title": "Northwind_Health_Plus_Benefits_Details.pdf"
8      },

```

Search

The default query is an empty search ("*") but includes parameters for returning the number matches. It's a hybrid query that runs text and vector queries in parallel. It also includes semantic ranking and specifies which fields to return in the results through the `select` statement.

JSON

```

{
  "search": "*",
  "count": true,
  "vectorQueries": [
    {
      "kind": "text",
      "text": "*",
      "fields": "text_vector,image_vector"
    }
  ],
  "queryType": "semantic",
  "semanticConfiguration": "my-demo-semantic-configuration",
  "captions": "extractive",
  "answers": "extractive|count-3",
  "queryLanguage": "en-us",
  "select": "chunk_id,text_parent_id,chunk,title,image_parent_id"
}

```

- Replace both asterisk (*) placeholders with a question related to health plans, such as `Which plan has the lowest deductible?`.

JSON

```
{  
  "search": "Which plan has the lowest deductible?",  
  "count": true,  
  "vectorQueries": [  
    {  
      "kind": "text",  
      "text": "Which plan has the lowest deductible?",  
      "fields": "text_vector,image_vector"  
    }  
  ],  
  "queryType": "semantic",  
  "semanticConfiguration": "my-demo-semantic-configuration",  
  "captions": "extractive",  
  "answers": "extractive|count-3",  
  "queryLanguage": "en-us",  
  "select": "chunk_id,text_parent_id,chunk,title"  
}
```

5. To run the query, select Search.

The screenshot shows a search interface with a search bar containing the query "Which plan has the lowest deductible?". Below the search bar is a "Results" section. The results are presented as a list of JSON documents, each representing a chunk from a PDF. The first document in the list has the following structure:

```
33  "value": [  
34    {  
35      "@search.score": 0.017200259491801262,  
36      "@search.rerankerScore": 2.550845146179199,  
37      "@search.captions": [  
38        {  
39          "text": "the plan will pay towards the cost of care. The Allowed Amount may vary depending on the type of service.",  
40          "highlights": ""  
41        }  
42      ],  
43      "chunk_id": "62e612d57ba3_aHR0cHM6Ly9oZWIkaXN0c3RvcFmFnZWR1bW91YXN0dXMuYmxvYi5jb3JlLndpbmRvd3MubmV0L2h1YWxG",  
44      "text_parent_id": "aHR0cHM6Ly9oZWIkaXN0c3RvcFmFnZWR1bW91YXN0dXMuYmxvYi5jb3JlLndpbmRvd3MubmV0L2h1YWx0aC1wbG",  
45      "chunk": "the plan will pay towards the \ncost of care. The Allowed Amount may vary depending on the type",  
46      "title": "Northwind_Health_Plus_Benefits_Details.pdf",  
47      "image_parent_id": null  
48    },  
49    {  
50      "@search.score": 0.022132549434900284,  
51      "@search.rerankerScore": 2.492180347442627,  
52      "@search.captions": [  
53        {  
54          "text": "care physicians, specialists, hospitals, and pharmacies. This allows you to choose a provider",  
55          "highlights": ""  
56        }  
57      ],  
58      "chunk_id": "62e612d57ba3_aHR0cHM6Ly9oZWIkaXN0c3RvcFmFnZWR1bW91YXN0dXMuYmxvYi5jb3JlLndpbmRvd3MubmV0L2h1YWxG",  
59      "text_parent_id": "aHR0cHM6Ly9oZWIkaXN0c3RvcFmFnZWR1bW91YXN0dXMuYmxvYi5jb3JlLndpbmRvd3MubmV0L2h1YWx0aC1wbG",  
60      "chunk": "care physicians, specialists, hospitals, and pharmacies. This allows you to choose a provider",  
61      "title": "Northwind_Standard_Benefits_Details.pdf",  
62      "image_parent_id": null
```

Each document is a chunk of the original PDF. The `title` field shows which PDF the chunk comes from. Each `chunk` is long. You can copy and paste one into a text editor to read the entire value.

6. To see all of the chunks from a specific document, add a filter for the `title_parent_id` field for a specific PDF. You can check the **Fields** tab of your index to confirm the field is filterable.

JSON

```
{  
    "select": "chunk_id, text_parent_id, chunk, title",  
    "filter": "text_parent_id eq  
'aHR0cHM6Ly9oZWlkaXN0c3RvcnFnZWR1bW91YXN0dXMuYmxvYi5jb3JlLndpbmRvd3MubmV0L2h1YW  
x0aC1wbGFuLXBkZnMvTm9ydGh3aW5kX1N0YW5kYXJkX0J1bmVmaXRzX0R1dGFpbHMucGRm0'",  
    "count": true,  
    "vectorQueries": [  
        {  
            "kind": "text",  
            "text": "*",  
            "k": 5,  
            "fields": "text_vector"  
        }  
    ]  
}
```

Clean up resources

This quickstart uses billable Azure resources. If you no longer need the resources, delete them from your subscription to avoid charges.

Next step

This quickstart introduced you to the **Import data (new)** wizard, which creates all of the necessary objects for integrated vectorization. To explore each step in detail, see [Set up integrated vectorization in Azure AI Search](#).

Last updated on 10/24/2025

Quickstart: Search for multimodal content in the Azure portal

In this quickstart, you use the [Import data \(new\)](#) wizard in the Azure portal to get started with [multimodal search](#). The wizard simplifies the process of extracting, chunking, vectorizing, and loading both text and images into a searchable index.

Unlike [Quickstart: Vector search in the Azure portal](#), which processes simple text-containing images, this quickstart supports advanced image processing for multimodal RAG scenarios.

This quickstart uses a multimodal PDF from the [azure-search-sample-data](#) repo. However, you can use different files and still complete this quickstart.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#). We recommend the Basic tier or higher.
- An [Azure Storage account](#). Use Azure Blob Storage or Azure Data Lake Storage Gen2 (storage account with a hierarchical namespace) on a standard performance (general-purpose v2) account. Access tiers can be hot, cool, or cold.
- A [supported extraction method](#).
- A [supported embedding method](#).
- Familiarity with the wizard. See [Import data wizards in the Azure portal](#).

Supported extraction methods

For content extraction, you can choose either default extraction via Azure AI Search or enhanced extraction via [Azure Document Intelligence in Foundry Tools](#). The following table describes both extraction methods.

[] [Expand table](#)

Method	Description
Default extraction	Extracts location metadata from PDF images only. Doesn't require another Azure AI resource.
Enhanced	Extracts location metadata from text and images for multiple document types. Requires

Method	Description
extraction	a Microsoft Foundry resource ¹ in a supported region .

¹ For billing purposes, you must [attach your Foundry resource](#) to the skillset in your Azure AI Search service. Unless you use a [keyless connection](#) to create the skillset, both resources must be in the same region.

Supported embedding methods

For content embedding, choose one of the following methods:

- **Image verbalization:** Uses an LLM to generate natural-language descriptions of images, and then uses an embedding model to vectorize plain text and verbalized images.
- **Multimodal embeddings:** Uses an embedding model to directly vectorize both text and images.

The following table lists the supported providers and models for each method. Deployment instructions for the models are provided in a [later section](#).

[] [Expand table](#)

Provider	Models for image verbalization	Models for multimodal embeddings
Azure OpenAI in Foundry Models resource ^{1, 2}	LLMs: gpt-4o gpt-4o-mini gpt-5 gpt-5-mini gpt-5-nano Embedding models: text-embedding-ada-002 text-embedding-3-small text-embedding-3-large	
Foundry project	LLMs: phi-4 gpt-4o gpt-4o-mini gpt-5 gpt-5-mini gpt-5-nano Embedding models:	

Provider	Models for image verbalization	Models for multimodal embeddings
	text-embedding-ada-002 text-embedding-3-small text-embedding-3-large	
Foundry hub-based project	LLMs: phi-4 gpt-4o gpt-4o-mini gpt-5 gpt-5-mini gpt-5-nano Embedding models: text-embedding-ada-002 text-embedding-3-small text-embedding-3-large Cohere-embed-v3-english ³ Cohere-embed-v3-multilingual ³	Cohere-embed-v3-english ³ Cohere-embed-v3-multilingual ³
Foundry resource ⁴	Embedding model: Azure Vision in Foundry Tools multimodal ⁵	Azure Vision multimodal ⁵

¹ The endpoint of your Azure OpenAI resource must have a [custom subdomain](#), such as <https://my-unique-name.openai.azure.com>. If you created your resource in the [Azure portal](#) , this subdomain was automatically generated during resource setup.

² Azure OpenAI resources (with access to embedding models) that were created in the [Foundry portal](#)  aren't supported. You must create an Azure OpenAI resource in the Azure portal.

³ To use this model in the wizard, you must [deploy it as a serverless API deployment](#).

⁴ For billing purposes, you must [attach your Foundry resource](#) to the skillset in your Azure AI Search service. Unless you use a [keyless connection \(preview\)](#) to create the skillset, both resources must be in the same region.

⁵ The Azure Vision multimodal embeddings APIs are available in [select regions](#).

Public endpoint requirements

All of the preceding resources must have public access enabled so that the Azure portal nodes can access them. Otherwise, the wizard fails. After the wizard runs, you can enable firewalls and private endpoints on the integration components for security. For more information, see [Secure connections in the import wizards](#).

If private endpoints are already present and you can't disable them, the alternative is to run the respective end-to-end flow from a script or program on a virtual machine. The virtual machine must be on the same virtual network as the private endpoint. [Here's a Python code sample](#) for integrated vectorization. The same [GitHub repo](#) has samples in other programming languages.

Check for space

If you're starting with the free service, you're limited to three indexes, three data sources, three skillsets, and three indexers. Make sure you have room for extra items before you begin. This quickstart creates one of each object.

Configure access

Before you begin, make sure you have permissions to access content and operations. We recommend Microsoft Entra ID authentication and role-based access for authorization. You must be an **Owner** or **User Access Administrator** to assign roles. If roles aren't feasible, you can use [key-based authentication](#) instead.

Configure the [required roles](#) and [conditional roles](#) identified in this section.

Required roles

Azure AI Search and Azure Storage are required for all multimodal search scenarios.

Azure AI Search

Azure AI Search provides the multimodal pipeline. Configure access for yourself and your search service to read data, run the pipeline, and interact with other Azure resources.

On your Azure AI Search service:

1. [Enable role-based access](#).
2. [Configure a system-assigned managed identity](#).
3. [Assign the following roles](#) to yourself.
 - **Search Service Contributor**
 - **Search Index Data Contributor**

- Search Index Data Reader

Conditional roles

The following tabs cover all wizard-compatible resources for multimodal search. Select only the tabs that apply to your chosen [extraction method](#) and [embedding method](#).

Azure OpenAI

Azure OpenAI provides LLMs for image verbalization and embedding models for text and image vectorization. Your search service requires access to call the [GenAI Prompt skill](#) and [Azure OpenAI Embedding skill](#).

On your Azure OpenAI resource:

- Assign [Cognitive Services OpenAI User](#) to your [search service identity](#).

Prepare sample data

This quickstart uses a sample multimodal PDF, but you can also use your own files. If you're on a free search service, use fewer than 20 files to stay within the free quota for enrichment processing.

To prepare the sample data for this quickstart:

1. Sign in to the [Azure portal](#) and select your Azure Storage account.
2. From the left pane, select **Data storage > Containers**.
3. Create a container, and then upload the [sample PDF](#) to the container.
4. Create another container to store images extracted from the PDF.

Deploy models

The wizard offers several options for content embedding. Image verbalization requires an LLM to describe images and an embedding model to vectorize text and image content, while direct multimodal embeddings only require an embedding model. These models are available through Azure OpenAI and Foundry.

(!) Note

If you're using Azure Vision, skip this step. The multimodal embeddings are built into your Foundry resource and don't require model deployment.

To deploy the models for this quickstart:

1. Sign in to the [Foundry portal](#).
2. Select your Azure OpenAI resource or Foundry project.
3. Deploy the models required for your chosen [embedding method](#).

Start the wizard

To start the wizard for multimodal search:

1. Sign in to the [Azure portal](#) and select your Azure AI Search service.
2. On the **Overview** page, select **Import data (new)**.

3. Select your data source: **Azure Blob Storage** or **Azure Data Lake Storage Gen2**.

A screenshot of the 'Import data (new)' wizard. The top bar says 'Let's start by picking a data source...'. Below it is a 'Filter by name...' input field. A list of data sources is shown in a grid:

- Azure Blob Storage** (Built-in indexer)
- Azure Data Lake Storage Gen2** (Built-in indexer)
- Azure Cosmos DB** (Built-in indexer)
- Azure SQL Database** (Built-in indexer)
- Azure Table Storage** (Built-in indexer)
- Fabric OneLake files (Preview)** (Built-in indexer)
- SharePoint** (Logic Apps indexer)
- OneDrive** (Logic Apps indexer)
- OneDrive for Business** (Logic Apps indexer)
- Azure File Storage** (Logic Apps indexer)
- Azure Queues** (Logic Apps indexer)
- Service Bus** (Logic Apps indexer)
- Amazon S3** (Logic Apps indexer)
- Dropbox** (Logic Apps indexer)
- SFTP - SSH** (Logic Apps indexer)

A magnifying glass icon is in the bottom right corner of the grid.

4. Select **Multimodal RAG**.

Connect to your data

Azure AI Search requires a connection to a data source for content ingestion and indexing. In this case, the data source is your Azure Storage account.

To connect to your data:

1. On the **Connect to your data** page, select your Azure subscription.
2. Select the storage account and container to which you uploaded the sample data.
3. Select the **Authenticate using managed identity** checkbox. Leave the identity type as **System-assigned**.

Configure your Azure Blob Storage

Connect to your Azure Blob Storage containing PDFs, other unstructured data files, and structured data files. [Learn more](#)

Subscription *	my-subscription
Storage account *	mystorageaccount
Blob container * ⓘ	my-container
Blob folder ⓘ	your/folder/here

Enable deletion tracking ⓘ

Authenticate using managed identity. [Learn more](#)

Managed identity type ⓘ System-assigned

4. Select **Next**.

Extract your content

Depending on your chosen [extraction method](#), the wizard provides configuration options for document cracking and chunking.

Default extraction

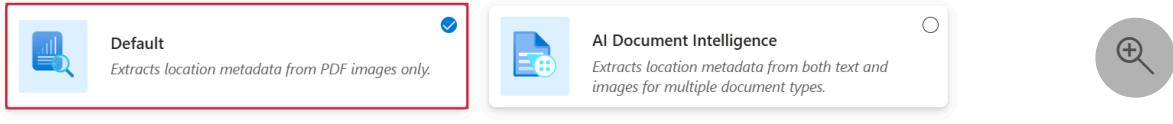

The default method calls the [Document Extraction skill](#) to extract text content and generate normalized images from your documents. The [Text Split skill](#) is then called to split the extracted text content into pages.

To use the Document Extraction skill:

1. On the Content extraction page, select Default.

Content extraction

Choose a content extraction path that suits your scenario. These paths extract location metadata such as page numbers, bounding polygons, annotations; and other metadata and content from text and images. Learn more about the pricing options for [default content extraction](#) and [AI Document Intelligence](#).

2. Select Next.

Embed your content

During this step, the wizard uses your chosen [embedding method](#) to generate vector representations of both text and images.

Image verbalization

The wizard calls one skill to create descriptive text for images (image verbalization) and another skill to create vector embeddings for both text and images.

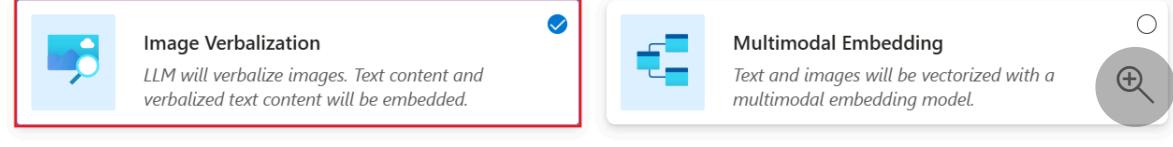

For image verbalization, the [GenAI Prompt skill](#) uses your deployed LLM to analyze each extracted image and produce a natural-language description.

For embeddings, the [Azure OpenAI Embedding skill](#), [AML skill](#), or [Azure Vision multimodal embeddings skill](#) uses your deployed embedding model to convert text chunks and verbalized descriptions into high-dimensional vectors. These vectors enable similarity and hybrid retrieval.

To use the skills for image verbalization:

1. On the Content embedding page, select Image Verbalization.

Choose your content embedding strategy

2. On the Image Verbalization tab:

- a. For the kind, select your LLM provider: **Azure OpenAI** or **Foundry Hub catalog models**.
- b. Select your Azure subscription, resource, and LLM deployment.
- c. For the authentication type, select **System assigned identity** if you're not using a hub-based project. Otherwise, leave it as **API key**.
- d. Select the checkbox that acknowledges the billing effects of using these resources.

① Image Verbalization ② Text Vectorization

(i) Please complete the text vectorization step to proceed.

4. Select Next.

Store the extracted images

The next step is to send images extracted from your documents to Azure Storage. In Azure AI Search, this secondary storage is known as a [knowledge store](#).

To store the extracted images:

1. On the **Image output** page, select your Azure subscription.
2. Select the storage account and blob container you created to store the images.
3. Select the **Authenticate using managed identity** checkbox. Leave the identity type as **System-assigned**.

Image output location

Select a storage account to store the images extracted from your documents.

Managed identity type ⓘ	System-assigned

4. Select Next.

Map new fields

On the **Advanced settings** page, you can optionally add fields to the index schema. By default, the wizard generates the fields described in the following table.

[+] Expand table

Field	Applies to	Description	Attributes
content_id	Text and image vectors	String field. Document key for the index.	Retrievable, sortable, and searchable.
document_title	Text and image vectors	String field. Human-readable document title.	Retrievable and searchable.
text_document_id	Text vectors	String field. Identifies the parent document from which the text chunk originates.	Retrievable and filterable.
image_document_id	Image vectors	String field. Identifies the parent document from which the image originates.	Retrievable and filterable.
content_text	Text vectors	String field. Human-readable version of the text chunk.	Retrievable and searchable.
content_embedding	Text and image vectors	Collection(Edm.Single). Vector representation of text and images.	Retrievable and searchable.
content_path	Text and image vectors	String field. Path to the content in the storage container.	Retrievable and searchable.
locationMetadata	Image vectors	Edm.ComplexType. Contains metadata about the image's location in the documents.	Varies by field.

You can't modify the generated fields or their attributes, but you can add fields if your data source provides them. For example, Azure Blob Storage provides a collection of metadata fields.

To add fields to the index schema:

1. Under **Index fields**, select **Preview and edit**.
2. Select **Add field**.
3. Select a source field from the available fields, enter a field name for the index, and accept (or override) the default data type.

4. If you want to restore the schema to its original version, select **Reset**.

Schedule indexing

For data sources where the underlying data is volatile, you can [schedule indexing](#) to capture changes at specific intervals or specific dates and times.

To schedule indexing:

1. On the **Advanced settings** page, under **Schedule indexing**, specify a run schedule for the indexer. We recommend **Once** for this quickstart.

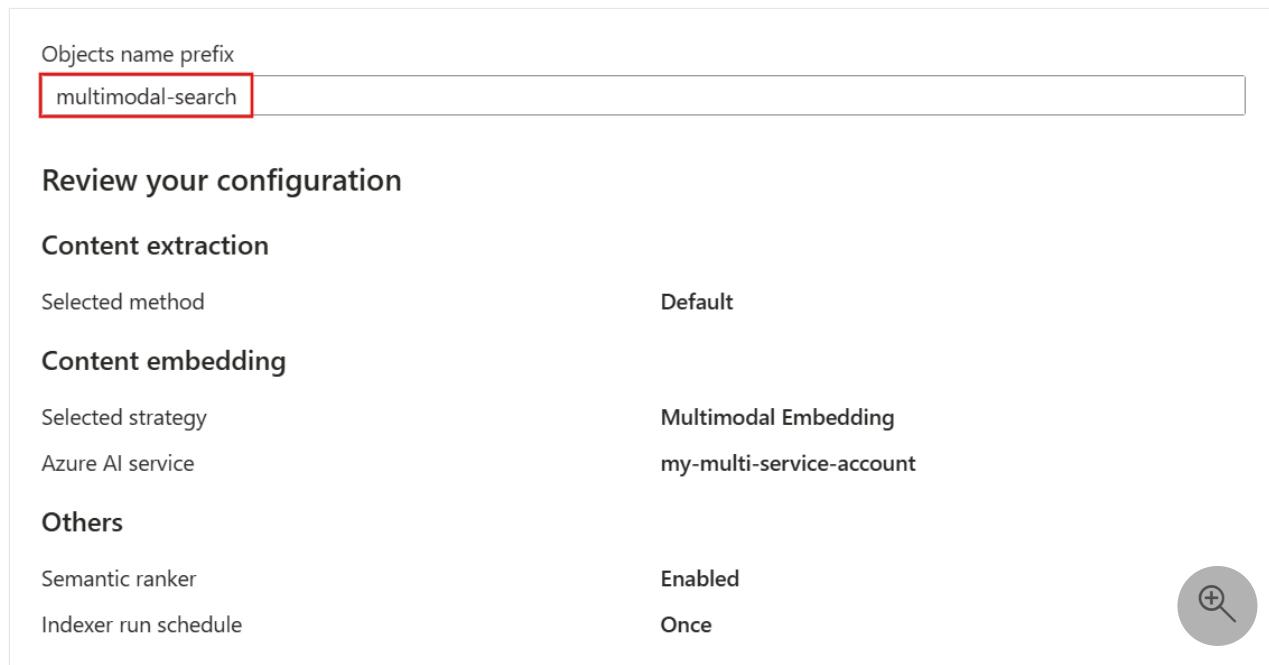

2. Select **Next**.

Finish the wizard

The final step is to review your configuration and create the necessary objects for multimodal search. If necessary, return to the previous pages in the wizard to adjust your configuration.

To finish the wizard:

1. On the **Review and create** page, specify a prefix for the objects the wizard will create. A common prefix helps you stay organized.

2. Select **Create**.

When the wizard completes the configuration, it creates the following objects:

- An indexer that drives the indexing pipeline.
- A data source connection to Azure Blob Storage.
- An index with text fields, vector fields, vectorizers, vector profiles, and vector algorithms. During the wizard workflow, you can't modify the default index. Indexes conform to the [2024-05-01-preview REST API](#) so that you can use preview features.
- A skillset with the following skills:
 - The [Document Extraction skill](#) or [Document Layout skill](#) extracts text and images from source documents. The [Text Split skill](#) accompanies the Document Extraction skill for data chunking, while the Document Layout skill has built-in chunking.
 - The [GenAI Prompt skill](#) verbalizes images in natural language. If you're using direct multimodal embeddings, this skill is absent.
 - The [Azure OpenAI Embedding skill](#), [AML skill](#), or [Azure Vision multimodal embeddings skill](#) is called once for text vectorization and once for image vectorization.
 - The [Shaper skill](#) enriches the output with metadata and creates new images with contextual information.

Tip

Wizard-created objects have configurable JSON definitions. To view or modify these definitions, select **Search management** from the left pane, where you can view your indexes, indexers, data sources, and skillsets.

Check results

This quickstart creates a multimodal index that supports [hybrid search](#) over both text and images. Unless you use direct multimodal embeddings, the index doesn't accept images as query inputs, which requires the [AML skill](#) or [Azure Vision multimodal embeddings skill](#) with an equivalent vectorizer. For more information, see [Configure a vectorizer in a search index](#).

Hybrid search combines full-text queries and vector queries. When you issue a hybrid query, the search engine computes the semantic similarity between your query and the indexed

vectors and ranks the results accordingly. For the index created in this quickstart, the results surface content from the `content_text` field that closely aligns with your query.

To query your multimodal index:

1. Sign in to the [Azure portal](#) and select your Azure AI Search service.
2. From the left pane, select **Search management > Indexes**.
3. Select your index.
4. Select **Query options**, and then select **Hide vector values in search results**. This step makes the results more readable.

The screenshot shows the Azure AI Search service interface for the 'multimodal-index'. The 'Search explorer' tab is active. At the top, there are buttons for Save, Discard, Refresh, Create demo app, Edit JSON, Delete, and Encryption. Below that, it shows document statistics: 105 documents, 4.5 MB total storage, 1.24 MB vector index quota usage, and 15 GB max storage. There are also tabs for Fields, CORS, Scoring profiles, Semantic configurations, and Vector profiles. On the right side, there are 'Query options' and 'View' buttons, with 'Query options' being highlighted by a red box. Below the tabs is a search bar containing 'energy'.

5. Enter text for which you want to search. Our example uses `energy`.

6. To run the query, select **Search**.

The screenshot shows the 'Search explorer' interface. The search bar at the bottom contains the text 'energy'. To the right of the search bar are 'Query options' and 'View' buttons, with 'View' having a dropdown arrow. Below the search bar is a 'Search' button, which is highlighted with a red box.

The JSON results should include text and image content related to `energy` in your index. If you enabled semantic ranker, the `@search.answers` array provides concise, high-confidence [semantic answers](#) to help you quickly identify relevant matches.

The screenshot shows the JSON results for the search query 'energy'. The results are displayed in a JSON editor. The first result under the `@search.answers` array is shown in red. It includes a key and a value. The value is a long string of alphanumeric characters followed by '_normalized_images_7'. Below this, there is another object with a 'text' field containing a detailed description of AI's role in sustainability.

```

Clean up resources

This quickstart uses billable Azure resources. If you no longer need the resources, delete them from your subscription to avoid charges.

Next steps

This quickstart introduced you to the **Import data (new)** wizard, which creates all of the necessary objects for multimodal search. To explore each step in detail, see the following tutorials:

- [Tutorial: Verbalize images using generative AI](#)
 - [Tutorial: Verbalize images from a structured document layout](#)
 - [Tutorial: Vectorize images and text](#)
 - [Tutorial: Vectorize from a structured document layout](#)
-

Last updated on 11/18/2025

Quickstart: Create a demo search app in the Azure portal

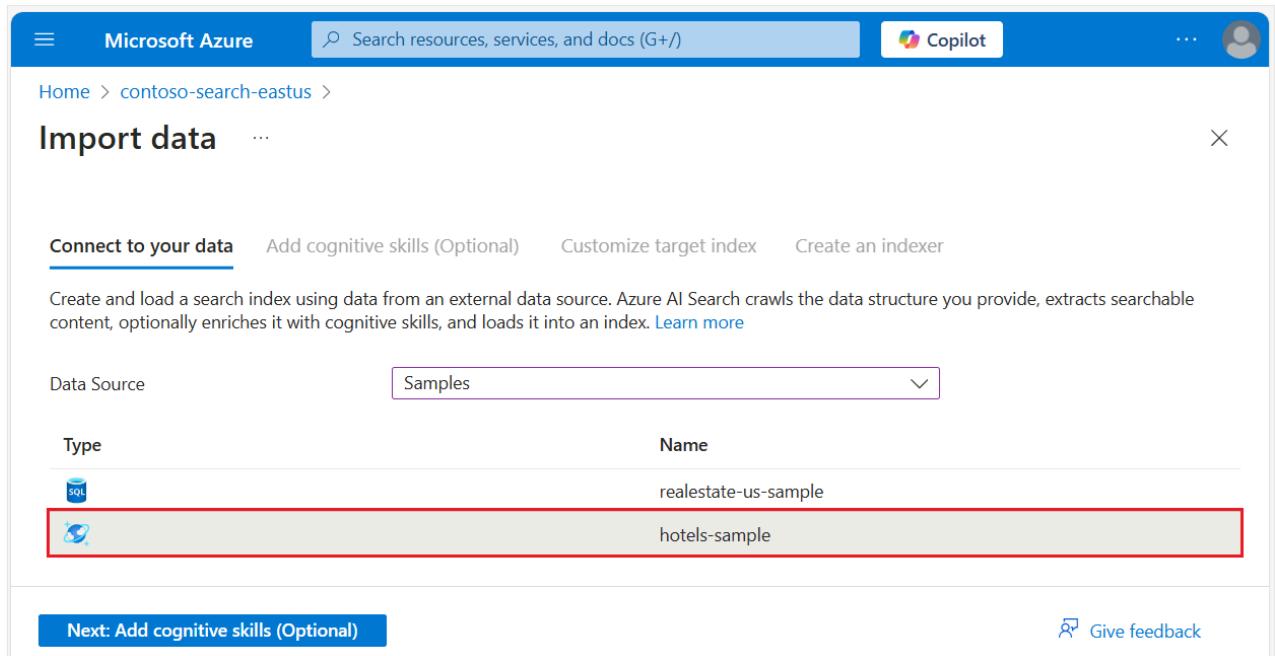

In this quickstart, you use the [Create demo app](#) wizard in the Azure portal to generate a downloadable, "localhost"-style web app that runs in a browser. Depending on how you configure it, the generated app is operational on first use, with a live read-only connection to an index on your search service. A default app can include a search box, results area, sidebar filters, and typeahead support.

A demo app can help you visualize how an index functions in a client app, but it isn't intended for production scenarios. Production apps should include security, error handling, and hosting logic that the demo app doesn't provide.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription. For this quickstart, you can use a free service.
- A [search index](#) to use as the basis of your generated application.

This quickstart uses the hotels-sample index. Follow the instructions in [this quickstart](#) to create the index.

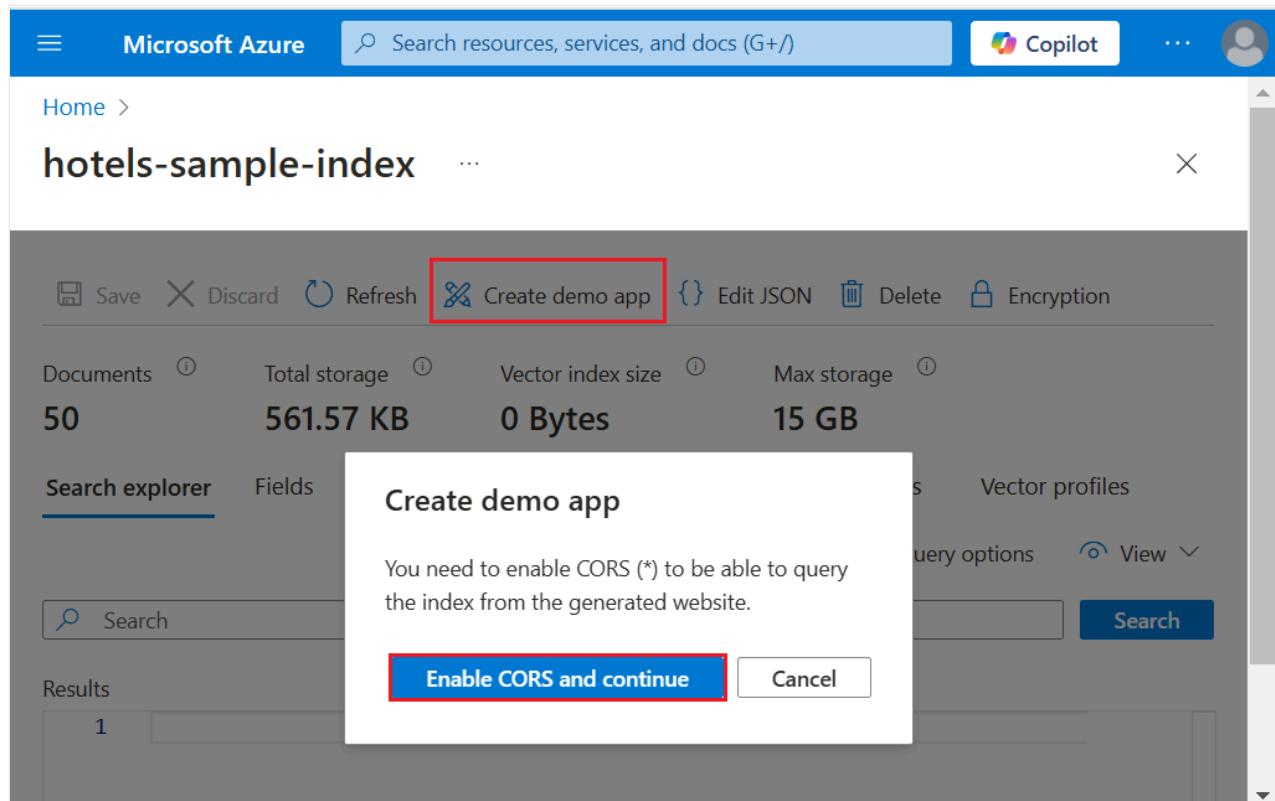

The screenshot shows the Microsoft Azure portal interface with the following details:

- Header:** Microsoft Azure, Search resources, services, and docs (G+), Copilot, and a user profile icon.
- Breadcrumb:** Home > contoso-search-eastus >
- Title:** Import data
- Subtitles:** Connect to your data, Add cognitive skills (Optional), Customize target index, Create an indexer.
- Description:** Create and load a search index using data from an external data source. Azure AI Search crawls the data structure you provide, extracts searchable content, optionally enriches it with cognitive skills, and loads it into an index. [Learn more](#)
- Data Source:** Samples (selected)
- Type:** SQL (selected)
- Name:** realestate-us-sample
- Recent Data Sources:** hotels-sample (highlighted with a red border)
- Buttons:** Next: Add cognitive skills (Optional) and Give feedback.

Start the wizard

To start the wizard for this quickstart:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Search management > Indexes**.
3. Select **hotels-sample-index** from the list.
4. At the top of the index page, select **Create demo app**.
5. Select **Enable CORS** and continue to add CORS support to your index definition.

Configure search results

The wizard provides a basic layout for the rendered search results, including space for a thumbnail image, title, and description. Each element is backed by a field in your index that provides the necessary data.

To configure the search results:

1. Skip **Thumbnail** because the index doesn't have image URLs.

However, if your index contains a field populated with URLs that resolve to publicly available images, you should specify that field for the thumbnail.

2. For **Title**, choose a field that conveys the uniqueness of each document. Our example uses **HotelName**.

3. For **Description**, choose a field that might help someone decide whether to drill down to that particular document. Our example uses **Description**.

4. Select **Next**.

The screenshot shows the Microsoft Azure portal interface. At the top, there's a blue header bar with the Microsoft Azure logo, a search bar containing 'Search resources, services, and docs (G+)', and a 'Copilot' button. Below the header, the URL 'Home > contoso-search-eastus | Indexes > hotels-sample-index >' is visible. The main content area has a title 'Create demo app' with a close button. On the left, a vertical list of options is shown: 'Customize individual result' (selected, indicated by a blue dot), 'Customize sidebar', and 'Customize suggestions'. To the right of this list is a preview window showing a simple search result card with a placeholder 'Thumbnail' and dropdown menus for 'Title' (set to 'HotelName') and 'Description'. Below the preview are buttons for 'Previous' and 'Next', and a magnifying glass icon. A descriptive text block above the preview says: 'Customize how individual results will be displayed.' and 'An individual result: Choose the look and feel for each search result below. The layout corresponds to how each result will be rendered.'

Add a sidebar

The search service supports faceted navigation, which is often rendered as a sidebar. Facets are based on fields attributed as filterable and facetable in your index schema.

Tip

To view field attributes, select the **Fields** tab on the index page in the Azure portal. Only fields marked as filterable and facetable can be used in the sidebar.

In Azure AI Search, faceted navigation is a cumulative filtering experience. Within a category, selecting multiple filters expands the results, such as selecting both `Seattle` and `Bellevue` within the `city` filter. Across categories, selecting multiple filters narrows the results.

To customize the sidebar:

1. Review the list of filterable and facetable fields in the index.

2. To shorten the sidebar and prevent scrolling in the finished app, delete some fields.

3. Select **Next**.

The screenshot shows the Microsoft Azure portal interface for creating a demo app. The top navigation bar includes 'Microsoft Azure', a search bar, and a user profile icon. Below the navigation, the breadcrumb trail shows 'Home > contoso-search-eastus | Indexes > hotels-sample-index'. The main title is 'Create demo app' with a '...' button. On the left, there's a vertical navigation menu with three items: 'Customize individual result' (selected, indicated by a checked checkbox), 'Customize sidebar' (indicated by a blue circle), and 'Customize suggestions' (indicated by an empty circle). The main content area is titled 'UI components of sidebar' with the sub-instruction 'Choose which fields are displayed in the filter sidebar. Only fields that are "filterable" and "facetable" can be used.' It features a diagram of a sidebar with a list of items. Below this is a table where users can map fields to filtering components. The table has two columns: 'Field name' and 'Filtering component'. The fields listed are HotelId, Category, Tags, Rating, Address/City, Address/StateProvince, Address/PostalCode, Address/Country, and Rooms/Type. Each field is mapped to a 'Checkbox' component. There are also 'Add', 'Delete', and '...' buttons for each row. At the bottom of the table are 'Previous' and 'Next' buttons, and a magnifying glass icon.

Add suggestions

Suggestions are automated query prompts that appear in the search box. The demo app supports suggestions that provide a dropdown list of potential matching documents based on partial text inputs.

To customize the suggestions:

1. Choose the fields you want to display as suggested queries. Use shorter string fields instead of verbose fields, such as descriptions.
2. Use the **Show Field Name** checkbox to include or exclude labels for the suggestions.

Microsoft Azure Search resources, services, and docs (G+/)

Home > contoso-search-eastus | Indexes > hotels-sample-index >

Create demo app

Customize individual result

Customize sidebar

Customize suggestions

Choose and customize which fields will be displayed as suggestion in search box dropdown.

Suggestions of search box

Choose the look and feel for each search suggestion below. The order of the table corresponds to the order that the fields are displayed for each result.

+ Add Delete

Style	Field name	Show Field Name
Normal	HostName	<input checked="" type="checkbox"/>
Normal	Category	<input type="checkbox"/>
Normal	Address.City	<input type="checkbox"/>

Previous Create demo app

The screenshot shows the 'Create demo app' wizard in the Microsoft Azure portal. On the left, there's a vertical list of customization steps: 'Customize individual result' (checked), 'Customize sidebar' (checked), and 'Customize suggestions' (unchecked). The 'Customize sidebar' section contains a placeholder window icon and a note about choosing fields for the search box dropdown. The 'Customize suggestions' section is titled 'Suggestions of search box' and includes a table for setting styles and field names. The table has three rows: 'Normal' style for 'HostName' with 'Show Field Name' checked; 'Normal' style for 'Category' with it unchecked; and 'Normal' style for 'Address.City' with it unchecked. At the bottom are 'Previous' and 'Create demo app' buttons, and a magnifying glass icon.

Create, download, and execute

To finish the wizard and use the demo app:

1. Select **Create demo app** to generate the HTML file.
2. When prompted, select **Download** to download the file.
3. Open the file in a browser.
4. Select the search button to run an empty query (*) that returns an arbitrary result set.
5. Enter a term in the search box and use the sidebar filters to narrow the results.

The screenshot shows a search interface for 'OCEAN WATER RESORT & SPA' and 'HOTEL ON THE HARBOR'. On the left, there are filter panels for 'Category' (Resort and Spa, Suite, Luxury, Boutique) and 'Tags' (pool, bar, continental breakfast, free wifi, air conditioning, free parking, 24-hour front desk service). A search bar at the top right contains a magnifying glass icon. A sidebar on the right includes a 'Tip' section with a lightbulb icon.

💡 Tip

If you don't see suggested queries, check your browser settings or try a different browser.

Clean up resources

When you work in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

In the Azure portal, you can find and manage resources by selecting **All resources** or **Resource groups** from the left pane.

Remember that a free search service is limited to three indexes, three indexers, and three data sources. To stay under the limit, you can delete these items individually in the Azure portal.

Next step

The demo app is useful for prototyping because it simulates the end-user experience without requiring JavaScript or front-end code. As you approach the proof-of-concept stage of your

own project, review the end-to-end code samples that more closely resemble a real-world app:

[Add search to web apps](#)

Last updated on 12/05/2025

Quickstart: Create a skillset in the Azure portal

09/16/2025

ⓘ Important

The **Import data (new)** wizard now supports keyword search, which was previously only available in the **Import data** wizard. We recommend the new wizard for an improved search experience. For more information about how we're consolidating the wizards, see [Import data wizards in the Azure portal](#).

In this quickstart, you learn how a skillset in Azure AI Search adds optical character recognition (OCR), image analysis, language detection, text merging, and entity recognition to generate text-searchable content in an index.

You can run the **Import data (new)** wizard in the Azure portal to apply skills that create and transform textual content during indexing. The input is your raw data, usually blobs in Azure Storage. The output is a searchable index containing AI-generated image text, captions, and entities. You can then query generated content in the Azure portal using [Search explorer](#).

Before you run the wizard, you create a few resources and upload sample files.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription. You can use a free service for this quickstart.
- An [Azure Storage account](#). Use Azure Blob Storage on a standard performance (general-purpose v2) account. To avoid bandwidth charges, use the same region as Azure AI Search.

ⓘ Note

This quickstart uses [Azure AI services](#) for AI enrichment. Because the workload is small, Azure AI services is tapped behind the scenes for free processing up to 20 transactions. Therefore, you don't need to create an Azure AI services multi-service resource.

Prepare sample data

In this section, you create an Azure Storage container to store sample data consisting of various file types, including images and application files that aren't full-text searchable in their native formats.

To prepare the sample data for this quickstart:

1. Sign in to the [Azure portal](#) and select your Azure Storage account.
2. From the left pane, select **Data storage > Containers**.
3. Create a container, and then upload the [sample data](#) to the container.

Run the wizard

To run the wizard:

1. Sign in to the [Azure portal](#) and select your search service.
2. On the **Overview** page, select **Import data (new)**.

3. Select **Azure Blob Storage** for the data source.

A screenshot of the 'Choose a data source' dialog box. It lists various data sources with their icons and descriptions. The 'Azure Blob Storage' option is highlighted with a red box. Other options include 'Azure Data Lake Storage Gen2', 'Azure Cosmos DB', 'Azure SQL Database', 'Fabric OneLake files (Preview)', 'SharePoint', 'OneDrive', 'OneDrive for Business', 'Azure File Storage', 'Azure Queues', 'Service Bus', 'Amazon S3', 'Dropbox', and 'SFTP - SSH'. A search bar at the top says 'Filter by name...'. A magnifying glass icon is in the bottom right corner of the dialog.

4. Select **Keyword search**.

What scenario are you targeting?

Keyword search

Ingest text for keyword search. Optionally, add AI skills to extract, infer, or create new searchable content.

RAG

Ingest text and simple images containing text (via OCR) to enable AI-powered answers.

Multimodal RAG

Ingest text and complex images (diagrams, charts, workflows) where interpreting visual elements is necessary for insights.

Step 1: Create a data source

Azure AI Search requires a connection to a data source for content ingestion and indexing. In this case, the data source is your Azure Storage account.

To create the data source:

1. On the [Connect to your data](#) page, select your Azure subscription.
2. Select your storage account, and then select the container you created.

Configure your Azure Blob Storage

Connect to Azure Blob Storage to access your structured and unstructured data files, including PDFs. [Learn more](#)

Subscription *

my-subscription

Storage account *

mystorageaccount

Blob container * ⓘ

my-container

Blob folder ⓘ

your/folder/here

Parsing mode

Default

Enable deletion tracking. ⓘ

Authenticate using managed identity. [Learn more](#)

3. Select **Next**.

If you get `Error detecting index schema from data source`, the indexer that powers the wizard can't connect to your data source. The data source most likely has security protections. Try the following solutions, and then rerun the wizard.

Expand table

Security feature	Solution
Resource requires Azure roles, or its access keys are disabled.	Connect as a trusted service or connect using a managed identity .

Security feature	Solution
Resource is behind an IP firewall.	Create an inbound rule for Azure AI Search and the Azure portal.
Resource requires a private endpoint connection.	Connect over a private endpoint.

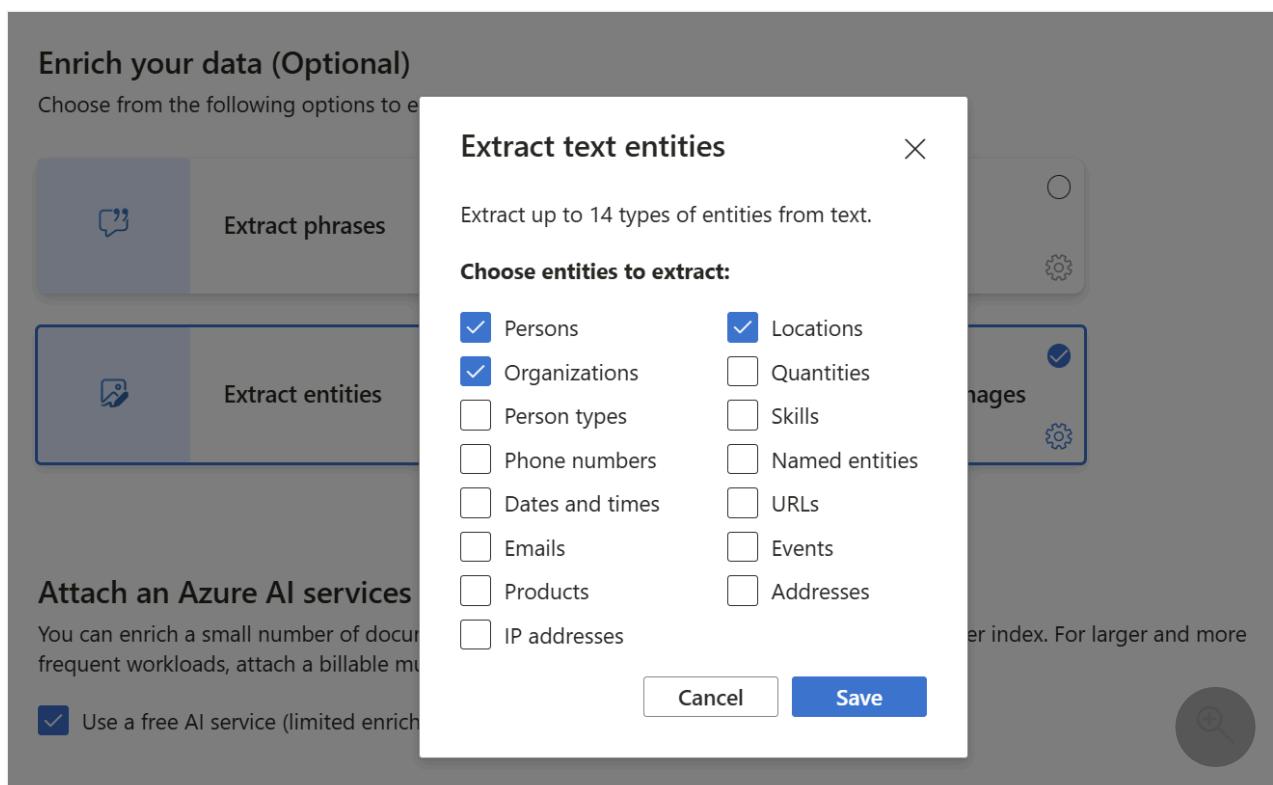

Step 2: Add cognitive skills

The next step is to configure AI enrichment to invoke OCR, image analysis, and entity recognition.

OCR and image analysis are available for blobs in Azure Blob Storage and Azure Data Lake Storage (ADLS) Gen2 and for image content in Microsoft OneLake. Images can be standalone files or embedded images in a PDF or other files.

To add the skills:

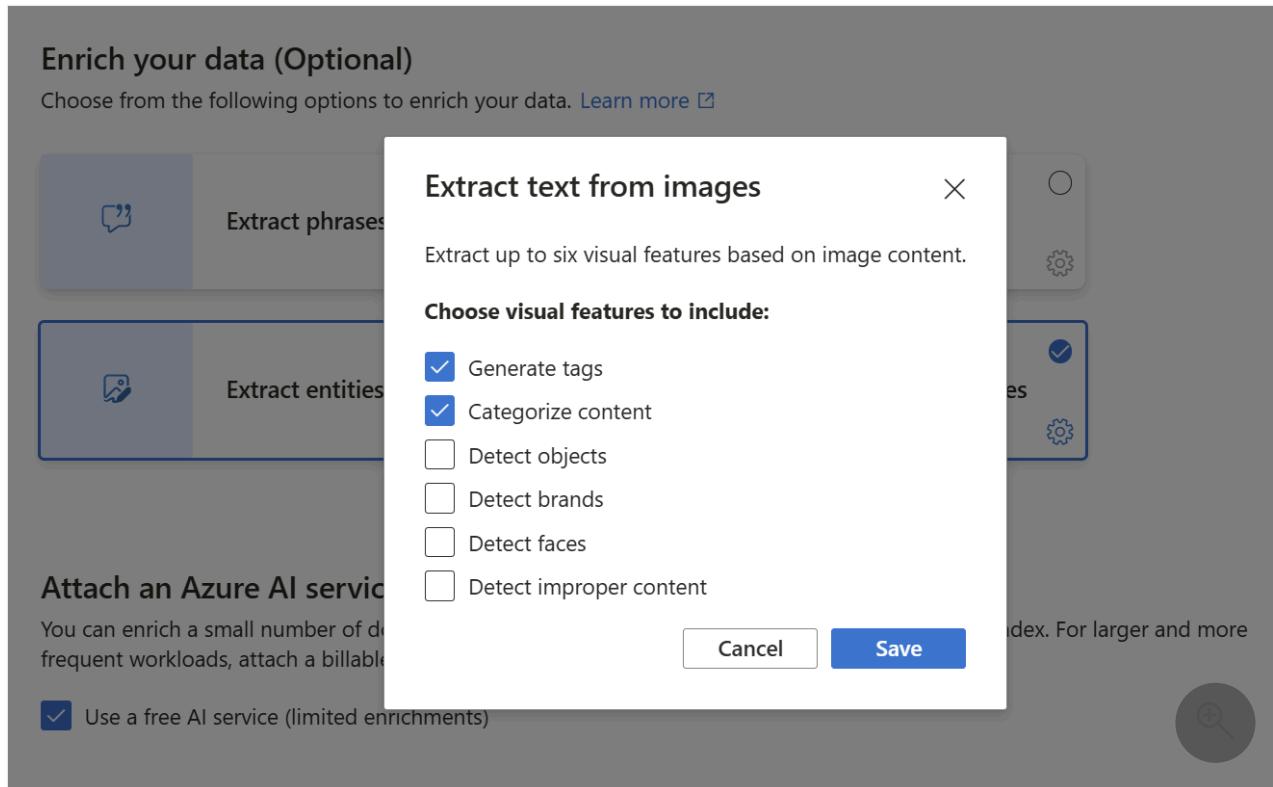

1. Select **Extract entities**, and then select the gear icon.
2. Select and save the following checkboxes:
 - **Persons**
 - **Locations**
 - **Organizations**

3. Select **Extract text from images**, and then select the gear icon.

4. Select and save the following checkboxes:

- **Generate tags**
- **Categorize content**

5. Leave the **Use a free AI service (limited enrichments)** checkbox selected.

The sample data consists of 14 files, so the free allotment of 20 transactions on Azure AI services is sufficient.

6. Select **Next**.

Step 3: Configure the index

An index contains your searchable content. The wizard can usually create the schema by sampling the data source. In this step, you review the generated schema and potentially revise any settings.

For this quickstart, the wizard sets reasonable defaults:

- Default fields are based on metadata properties of existing blobs and new fields for the enrichment output, such as `persons`, `locations`, and `organizations`. Data types are inferred from metadata and by data sampling.

Preview index fields

Review the fields that will be included in your index. Index fields can obtain values from your data source and from skill outputs if you added enrichments in the previous step. [Learn more](#)

Source column	Target index field name	Target index field type
<content + normalized_images>	→ merged_content	Edm.String
metadata_storage_name	→ title	Edm.String
metadata_storage_path	→ id	Edm.String
merged_content	→ persons	Collection(Edm.String)
merged_content	→ locations	Collection(Edm.String)
merged_content	→ organizations	Collection(Edm.String)
normalized_images	→ text	Collection(Edm.String)
normalized_images	→ layoutText	Collection(Edm.String)
normalized_images	→ tags	Collection(Edm.ComplexType)
normalized_images	→ name	Edm.String
normalized_images	→ hint	Edm.String
normalized_images	→ confidence	Edm.Double

- Default document key is `metadata_storage_path`, which is selected because the field contains unique values.
- Default field attributes are based on the skills you selected. For example, fields created by the Entity Recognition skill (`persons`, `locations`, and `organizations`) are **Retrievable**, **Filterable**, **Facetable**, and **Searchable**. To view and change these attributes, select a field, and then select **Configure field**.

Retrievable fields can be returned in results, while **Searchable** fields support full-text search. Use **Filterable** if you want to use fields in a filter expression.

Marking a field as **Retrievable** doesn't mean that the field *must* appear in search results. You can control which fields are returned by using the `select` query parameter.

After you review the index schema, select **Next**.

Step 4: Skip advanced settings

The wizard offers advanced settings for semantic ranking and index scheduling, which are beyond the scope of this quickstart. Skip this step by selecting **Next**.

Step 5: Review and create objects

The last step is to review your configuration and create the index, indexer, and data source on your search service. The indexer automates the process of extracting content from your data source, loading the index, and driving skillset execution.

To review and create the objects:

1. Accept the default Objects name prefix.

2. Review the object configurations.

Based on your configuration, the wizard will create an index, an indexer, a data source, and a skillset on your search service. You can view and manage these objects after they're created, but their names and many other properties are fixed. To customize the name, change the object name prefix.

Objects name prefix

search-1757520343372

Review your configuration

Data source

Azure Blob Storage - my-container

AI enrichments

Disabled

Semantic ranker

Enabled

Indexer run schedule

Once

AI enrichment, semantic ranker, and indexer scheduling are either disabled or set to their default values because you skipped their wizard steps.

3. Select **Create** to simultaneously create the objects and run the indexer.

Monitor status

You can monitor the creation of the indexer in the Azure portal. Skills-based indexing takes longer than text-based indexing, especially OCR and image analysis.

To monitor the progress of the indexer:

1. From the left pane, select **Indexers**.
2. Select your indexer from the list.
3. Select **Success** (or **Failed**) to view execution details.

Search icon

In this quickstart, there are a few warnings, including `Could not execute skill because one or more skill input was invalid.` This warning tells you that a PNG file in the data source doesn't provide a text input to Entity Recognition. It occurs because the upstream OCR skill didn't recognize any text in the image and couldn't provide a text input to the downstream Entity Recognition skill.

Warnings are common in skillset execution. As you become familiar with how skills iterate over your data, you might begin to notice patterns and learn which warnings are safe to ignore.

Query in Search explorer

To query your index:

1. From the left pane, select **Indexes**.
2. Select your index from the list. If the index has zero documents or storage, wait for the Azure portal to refresh.
3. On the **Search explorer** tab, enter a search string, such as `satya nadella`.

The search bar accepts keywords, quote-enclosed phrases, and operators. For example: `"Satya Nadella" +"Bill Gates" +"Steve Ballmer"`

Results are returned as verbose JSON, which can be hard to read, especially in large documents. Here are tips for searching in this tool:

- Switch to the JSON view to specify parameters that shape results.
- Add `select` to limit the fields in results.
- Add `count` to show the number of matches.
- Use Ctrl-F to search within the JSON for specific properties or terms.

my-index

The screenshot shows the Azure Search interface for the index "my-index". At the top, there are navigation links: Save, Discard, Refresh, Create demo app, Edit JSON, Delete, and Encryption. Below that, it displays the number of documents (14), total storage (395 KB), vector index quota usage (0 Bytes), and max storage (160 GB). The "Search explorer" tab is selected. On the right, there's a "View" dropdown menu with options: Query view, Image view, and JSON view, with "JSON view" highlighted by a red box. A search bar at the top right contains the query "satya nadella". The results section shows a JSON response with 3 items found. The JSON code in the editor is:

```
1 {  
2   "search": "\"Satya Nadella\" +\"Bill Gates\" +\"Steve Ballmer\"",  
3   "count": true,  
4   "select": "merged_content, persons"  
5 }
```

The search results table has columns for @odata.context, @odata.count, and value. The value column shows the merged content and a list of persons: Bill Gates, Steve Ballmer, Satya Nadella, and Reid Hoffman.

Here's some JSON you can paste into the view:

A JSON query editor window is shown. The JSON code is identical to the one in the previous screenshot:

```
{  
  "search": "\"Satya Nadella\" +\"Bill Gates\" +\"Steve Ballmer\"",  
  "count": true,  
  "select": "merged_content, persons"  
}
```

💡 Tip

Query strings are case sensitive, so if you get an "unknown field" message, check **Fields** or **Index Definition (JSON)** to verify the name and case.

Takeaways

You've created your first skillset and learned the basic steps of skills-based indexing.

Some key concepts that we hope you picked up include the dependencies. A skillset is bound to an indexer, and indexers are Azure and source-specific. Although this quickstart uses Azure

Blob Storage, other Azure data sources are available. For more information, see [Indexers in Azure AI Search](#).

Another important concept is that skills operate over content types, and when you use heterogeneous content, some inputs are skipped. Also, large files or fields might exceed the indexer limits of your service tier. It's normal to see warnings when these events occur.

The output is routed to a search index, and there's a mapping between name-value pairs created during indexing and individual fields in your index. Internally, the wizard sets up [an enrichment tree](#) and defines a [skillset](#), establishing the order of operations and general flow. These steps are hidden in the wizard, but when you start writing code, these concepts become important.

Finally, you learned that you can verify content by querying the index. Ultimately, Azure AI Search provides a searchable index that you can query using either [simple](#) or [fully extended query syntax](#). An index containing enriched fields is like any other. You can incorporate standard or [custom analyzers](#), [scoring profiles](#), [synonyms](#), [faceted navigation](#), geo-search, and other Azure AI Search features.

Clean up resources

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal by selecting [All resources](#) or [Resource groups](#) from the left pane.

If you used a free service, remember that you're limited to three indexes, indexers, and data sources. You can delete individual items in the Azure portal to stay under the limit.

Next step

You can use the Azure portal, REST APIs, or an Azure SDK to create skillsets. Try the REST APIs by using a REST client and more sample data:

[Tutorial: Use skillsets to generate searchable content in Azure AI Search](#)

Quickstart: Create a knowledge store in the Azure portal

(!) Note

Knowledge stores are secondary storage that exists in Azure Storage and contain the outputs of Azure AI Search skillsets. They're separate from knowledge sources and knowledge bases, which are used in [agentic retrieval](#) workflows.

In this quickstart, you create a [knowledge store](#) that serves as a repository for output generated from an [AI enrichment pipeline](#) in Azure AI Search. A knowledge store makes generated content available in Azure Storage for workloads other than search.

First, you set up sample data in Azure Storage. Next, you run the **Import data** wizard to create an enrichment pipeline that also generates a knowledge store. The knowledge store contains original source content pulled from the data source (customer reviews of a hotel), plus AI-generated content that includes a sentiment label, key phrase extraction, and text translation of non-English customer comments.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription. For this quickstart, you can use a free service.
- An Azure Storage account. [Create an account](#) or [find an existing account](#). The account type must be **StorageV2 (general purpose V2)**.
- Sample data hosted in Azure Storage:
 - [Download HotelReviews_Free.csv](#), which contains 19 pieces of customer feedback about a single hotel (originates from Kaggle.com). This CSV is in a repo with other sample data. If you don't want the whole repo, copy the raw content and paste it into a spreadsheet app on your device.
 - [Upload the file to a blob container](#) in Azure Storage.

(!) Note

This quickstart uses [Foundry Tools](#) for AI enrichment. Because the workload is so small, Foundry Tools is tapped behind the scenes for free processing for up to 20 transactions. This means that you can complete this exercise without having to create an extra Microsoft Foundry resource.

Start the wizard

1. Sign in to the [Azure portal](#) with your Azure account.
2. [Find your search service](#) and on the Overview page, select **Import data** on the command bar to create a knowledge store in four steps.

Step 1: Create a data source

Because the data is multiple rows in one CSV file, set the *parsing mode* to get one search document for each row.

1. In **Connect to your data**, choose **Azure Blob Storage**.
2. For the **Name**, enter "hotel-reviews-ds".
3. For **Data to extract**, choose **Content and Metadata**.
4. For **Parsing mode**, select **Delimited text**, and then select the **First Line Contains Header** checkbox. Make sure the **Delimiter character** is a comma (,).
5. In **Connection String**, choose an existing connection if the storage account is in the same subscription. Otherwise, paste in a connection string to your Azure Storage account.

A connection string can be full access, having the following format:

```
DefaultEndpointsProtocol=https;AccountName=<YOUR-ACCOUNT-NAME>;AccountKey=<YOUR-  
ACCOUNT-KEY>;EndpointSuffix=core.windows.net
```

Or, a connection string can reference a managed identity, assuming it's [configured and assigned a role](#) in Azure Storage: `ResourceId=/subscriptions/<YOUR-SUBSCRIPTION-ID>/resourceGroups/<YOUR-RESOURCE-GROUP-NAME>/providers/Microsoft.Storage/storageAccounts/<YOUR-ACCOUNT-NAME>;`

6. In **Containers**, enter the name of the blob container holding the data ("hotel-reviews").

Your page should look similar to the following screenshot.

7. Continue to the next page.

Step 2: Add skills

In this wizard step, add skills for AI enrichment. The source data consists of customer reviews in English and French. Skills that are relevant for this data set include key phrase extraction, sentiment detection, and text translation. In a later step, these enrichments are "projected" into a knowledge store as Azure tables.

1. Expand **Attach Foundry Tools**. **Free (Limited enrichments)** is selected by default. You can use this resource because the number of records in HotelReviews-Free.csv is 19 and this free resource allows up to 20 transactions a day.
2. Expand **Add enrichments**.
3. For **Skillset name**, enter "hotel-reviews-ss".
4. For **Source data field**, select **reviews_text**.
5. For **Enrichment granularity level**, select **Pages (5000 characters chunks)**.
6. For **Text Cognitive Skills**, select the following skills:
 - Extract key phrases
 - Translate text
 - Language detection
 - Detect sentiment

Your page should look like the following screenshot:

Skillset name * ⓘ

Enable OCR and merge all text into **merged_content** field ⓘ

Source data field *

<input type="text" value="reviews_text"/>	▼
---	---

Enrichment granularity level ⓘ

<input type="text" value="Pages (5000 characters chunks)"/>	▼
---	---

Checked items below require a field name.

Parameter	Field name
<input type="checkbox"/> Text Cognitive Skills	
<input type="checkbox"/> Extract people names	people
<input type="checkbox"/> Extract organization names	organizations
<input type="checkbox"/> Extract location names	locations
<input checked="" type="checkbox"/> Extract key phrases	<input type="text" value="keyphrases"/>
<input checked="" type="checkbox"/> Detect language	language
<input checked="" type="checkbox"/> Translate text	Target Language <input type="button" value="English"/> translated_text
<input type="checkbox"/> Extract personally identifiable infor...	pii_entities
<input checked="" type="checkbox"/> Detect sentiment	sentiment

7. Scroll down and expand **Save enrichments to knowledge store**.

8. Select **Choose an existing connection** and then select an Azure Storage account. The **Containers** page appears so that you can create a container for projections. We recommend adopting a prefix naming convention, such as "kstore-hotel-reviews" to distinguish between source content and knowledge store content.

9. Returning to the Import data wizard, select the following **Azure table projections**. The wizard always offers the **Documents** projection. Other projections are offered depending on the skills you select (such as **Key phrases**), or the enrichment granularity (**Pages**):

- **Documents**
- **Pages**
- **Key phrases**

The following screenshot shows the table projection selections in the wizard.

10. Continue to the next page.

Step 3: Configure the index

In this wizard step, configure an index for optional full-text search queries. You don't need a search index for a knowledge store, but the indexer requires one in order to run.

In this step, the wizard samples your data source to infer fields and data types. You only need to select the attributes for your desired behavior. For example, the **Retrievable** attribute allows the search service to return a field value, while the **Searchable** attribute enables full text search on the field.

1. For **Index name**, enter "hotel-reviews-idx".
2. For attributes, accept the default selections: **Retrievable** and **Searchable** for the new fields that the pipeline is creating.

Your index should look similar to the following image. Because the list is long, not all fields are visible in the image.

FIELD NAME	TYPE	RETRIEVABLE	FILTERABLE	SORTABLE	FACETABLE	SEARCHABLE	ANALYZER
keyphrases	Collection(E...)	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>	Standard - Luce...
translated_text	Collection(E...)	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input checked="" type="checkbox"/>	English - Lucene
sentiment	Collection(E...)	<input checked="" type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	

3. Continue to the next page.

Step 4: Configure and run the indexer

In this wizard step, configure an indexer that pulls together the data source, skillset, and the index you defined in the previous wizard steps.

1. For **Name**, enter "hotel-reviews-idxr".
2. For **Schedule**, keep the default **Once**.
3. Select **Submit** to run the indexer. Data extraction, indexing, application of cognitive skills all happen in this step.

Step 5: Check status

In the **Overview** page, open the **Indexers** tab in the middle of the page, and then select **hotels-reviews-idxr**. Within a minute or two, status should progress from "In progress" to "Success" with zero errors and warnings.

Check tables in Azure portal

1. In the Azure portal, [open the Storage account](#) used to create the knowledge store.

2. In the storage account's left pane, select **Storage browser** to view the new tables.

You should see three tables, one for each projection that was offered in the "Save enrichments" section of the "Add enrichments" page.

- "hotelReviewssDocuments" contains all of the first-level nodes of a document's enrichment tree that aren't collections.
- "hotelReviewssKeyPhrases" contains a long list of just the key phrases extracted from all reviews. Skills that output collections (arrays), such as key phrases and entities, send output to a standalone table.
- "hotelReviewssPages" contains enriched fields created over each page that was split from the document. In this skillset and data source, page-level enrichments consisting of sentiment labels and translated text. A pages table (or a sentences table if you specify that particular level of granularity) is created when you choose "pages" granularity in the skillset definition.

All of these tables contain ID columns to support table relationships in other tools and apps. When you open a table, scroll past these fields to view the content fields added by the pipeline.

In this quickstart, the table for "hotelReviewssPages" should look similar to the following screenshot:

The screenshot shows the Azure Storage browser (preview) interface. The left sidebar shows storage accounts (blobstorage2), favorites, recently viewed items (blobstorage2), blob containers, file shares, queues, and tables. The 'Tables' section is expanded, and 'hotelReviewsPages' is selected. The main area shows the 'hotelReviewsPages' table with 19 items. The table has columns: Pagesid, languageCode, sentimentScore, and translatedText. The rows show data corresponding to the table description in the text above.

Pagesid	languageCode	sentimentScore	translatedText
min walk al...	en	mixed	Pleasant 10 min walk al...
with very fri...	en	positive	Nice hotel , with very fri...
nin+ walk to...	en	positive	It was a 10 min+ walk to...

Clean up

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the **All resources** or **Resource groups** link in the left-navigation pane.

If you're using a free service, remember that you're limited to three indexes, indexers, and data sources. You can delete individual items in the Azure portal to stay under the limit.

Tip

If you want to repeat this exercise or try a different AI enrichment walkthrough, delete the **hotel-reviews-idxr** indexer and the related objects to recreate them. Deleting the indexer resets the free daily transaction counter to zero.

Next step

Now that you've been introduced to a knowledge store, take a closer look at each step by completing the REST API walkthrough. The walkthrough explains tasks that the wizard handled internally.

[Create a knowledge store using REST](#)

Last updated on 11/18/2025

Quickstart: Use Search explorer to run queries in the Azure portal

In this quickstart, you learn how to use **Search explorer**, a built-in query tool in the Azure portal for running queries against an Azure AI Search index. Use this tool to test a query or filter expression or to confirm whether content exists in the index.

This quickstart uses an existing index to demonstrate Search explorer.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An Azure AI Search service. [Create a service](#) or [find an existing service](#) in your current subscription. For this quickstart, you can use a free service.
- This quickstart uses the hotels-sample index. Follow the instructions in [this quickstart](#) to create the index.

Start Search explorer

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview**.
3. On the command bar, select **Search explorer**.

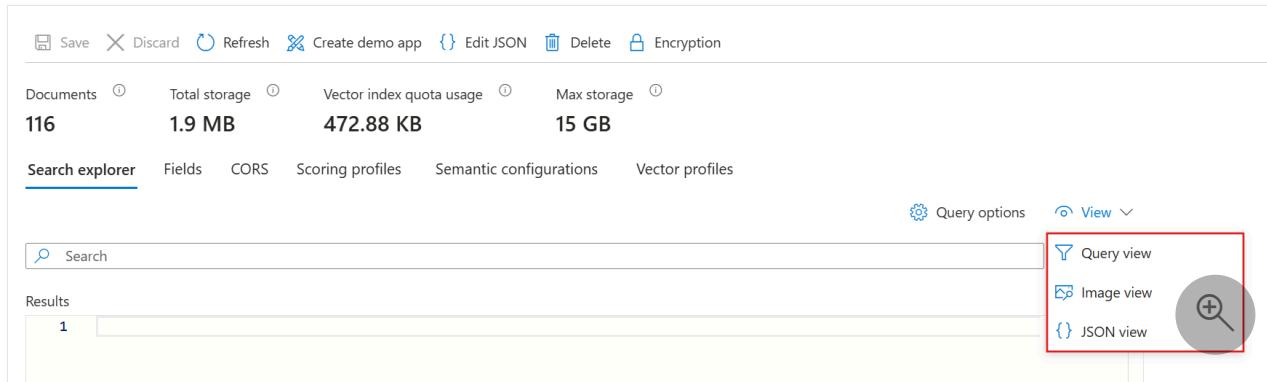

Alternatively, select the **Search explorer** tab on the index page.

Query three ways

There are three approaches to querying in Search explorer:

- Query view provides a default search bar. It accepts an empty query or free-text query with Booleans, such as `ocean view + parking`.
- Image view provides a window to browse or drag and drop PNG, JPG, or JPEG files. Unless your index has an [image vectorizer](#) and an equivalent skill, this view is unavailable.

- JSON view supports parameterized queries. Filters, orderby, select, count, searchFields, and all other parameters must be set in JSON view.

Example: Image query

Search explorer accepts images as query inputs through **Image view**, which requires that you use a supported vectorizer–skill pair. For more information, see [Configure a vectorizer in a search index](#).

The hotels-sample index isn't configured for image vectorization. If you want to run image queries, create an index as described in [Quickstart: Vector search in the Azure portal](#). The quickstart relies on text-based sample data, so you must use documents that contain images.

To run an image query, select or drag an image to the search area, and then select **Search**. Search explorer vectorizes the image and sends the vector to the search engine for query execution. The search engine returns documents that are sufficiently similar to the input image, up to the specified **k** number of results.

15        0.021560669.
```

Examples: JSON queries

The following are examples of JSON queries you can run using Search explorer. To follow these examples, switch to **JSON view**. You can paste each JSON example into the text area.

Tip

The JSON view supports intellisense for parameter name completion. Place your cursor inside the JSON view and enter a space character to see a list of all query parameters. You can also enter a letter, like `s`, to see only the query parameters that begin with that letter.

Intellisense doesn't exclude invalid parameters, so use your best judgment.

Run an unspecified query

In Search explorer, POST requests are formulated internally using [Documents - Search Post \(REST API\)](#), with responses returned as verbose JSON documents.

For a first look at content, execute an empty search by selecting **Search** with no terms provided. An empty search is useful as a first query because it returns entire documents so that you can review document composition. On an empty search, there's no search score, and

documents are returned in arbitrary order (`"@search.score": 1` for all documents). By default, 50 documents are returned per search request.

Add `"count": true` to get the number of matches found in an index. On an empty search, the count is the total number of documents in the index. On a qualified search, it's the number of documents matching the query input. Recall that the service returns the top-50 matches by default, so the count might indicate more matches in the index than what's returned in the results.

Equivalent syntax for an empty search is `*` or `"search": "*"`.

JSON

```
{  
  "search": "*",
  "count": true
}
```

Results

JSON query editor

```
1  {
2    "search": "*",
3    "count": true
4  }
```

Search

24           35.1087
25         ]
26       }
27     ]
28   }
29 }
```

Run a free-text query

Free-form search, with or without operators, is useful for simulating user-defined queries sent from a custom app to Azure AI Search. Only fields attributed as searchable in the index are

scanned for matches.

You don't need the JSON view for a free-text query, but we provide it in JSON for consistency with other examples in this article.

Notice that when you provide search criteria, such as query terms or expressions, search rank comes into play. The following example illustrates a free text search. The `@search.score` is a relevance score computed for the match using the [default scoring algorithm](#).

JSON

```
{  
  "search": "activities `outdoor pool` restaurant OR continental breakfast"  
}
```

Results

You can use Ctrl-F to search within results for specific terms of interest.

The screenshot shows a JSON query editor interface. At the top, there is a code editor window containing the following JSON:

```
1 {  
2   "search": "activities `outdoor pool` restaurant OR continental breakfast"  
3 }
```

Below the code editor is a results pane titled "Results". It displays a single JSON object with line numbers from 1 to 19. The line number 5 is highlighted with a red box, showing the field `"@search.score": 7.0059757,`. The results pane also contains a search bar with the text "outdoor pool", a status bar indicating "Aa ab .* 1 of 3", and a vertical scrollbar on the right.

Limit fields in search results

Add "[select](#)" to limit results to the explicitly named fields for more readable output in [Search explorer](#). Only fields attributed as retrievable in the index can show up in results.

20       "Description": "Plenty of great skiing, outdoor ice skating, sleigh rides, tubing and snow biking. Yoga, Pilates, and fitness classes available. Book now!",
21       "Tags": [
22     ]
23     }
24   ]
25 }
```

Return next batch of results

Azure AI Search returns the top-50 matches based on the search rank. The hotels-sample index only has 50 hotels, so we use a smaller number to illustrate paging. To get the next set of matching documents, append `"top": 20` and `"skip": 10` to increase the result set to 20 documents (default is 50, maximum is 1000), skipping the first 10 documents. You can check the document key (`HotelId`) to identify a document.

Recall that you need to provide search criteria, such as a query term or expression, to get ranked results. Search scores decrease the deeper you reach into search results.

JSON

```
{
  "search": "activities `outdoor pool` restaurant OR continental breakfast",
  "count": true,
  "select": "HotelId, HotelName, Tags, Description",
  "top": 20,

94        "dinner",  
95        "spa",  
96        "pool",  
97        "dinner",  
98        "spa",  
99        "pool",  
100       "dinner",  
101      ]  
102    }  
103  ]
```

Filter expressions (greater than, less than, equal to)

Use the `filter` parameter to specify inclusion or exclusion criteria. The field must be attributed as filterable in the index. This example searches for ratings greater than four:

JSON

```
{  
  "search": "activities `outdoor pool` restaurant OR continental breakfast",  
  "count": true,  
  "select": "HotelId, HotelName, Tags, Description, Rating",  
  "filter": "Rating gt 4"  
}
```

Results

JSON query editor

```

1  {
2    "search": "activities `outdoor pool` restaurant OR continental breakfast",
3    "count": true,
4    "select": "HotelId, HotelName, Tags, Description, Rating",
5    "filter": "Rating gt 4"
6  }

```

Search

Results

```

6  "@search.score": 6.787462,
7  "HotelId": "12",
8  "HotelName": "Winter Panorama Resort",
9  "Description": "Plenty of great skiing, outdoor ice skating, sleigh rides, tubing and snow biking. Yoga, i
10 "Tags": [
11   "restaurant",
12   "bar",
13   "pool"
14 ],
15 "Rating": 4.5
16 },
17 {
18   "@search.score": 5.4877596,
19   "HotelId": "18",
20   "HotelName": "Ocean Water Resort & Spa",
21   "Description": "New Luxury Hotel for the vacation of a lifetime. Bay views from every room, location near
22   "Tags": [
23     "view",
24     "pool",
25     "restaurant"
26 ],

```

Sort results

Add [orderby](#) to sort results by another field besides search score. The field must be attributed as sortable in the index. In situations where the filtered value is identical (for example, same price), the order is arbitrary, but you can add more criteria for deeper sorting. Here's an example expression you can use to test this out:

JSON

```
{
  "search": "activities `outdoor pool` restaurant OR continental breakfast",
  "count": true,
  "select": "HotelId, HotelName, Tags, Description, Rating, LastRenovationDate",
  "filter": "Rating gt 4",
  "orderby": "LastRenovationDate desc"
}
```

Results

JSON query editor

```

1   {

Takeaways

In this quickstart, you used **Search explorer** to query an index using the REST API.

- Results are returned as verbose JSON documents so that you can view the construction and content of each document in its entirety. The `select` parameter in a query expression limits which fields are returned.
- Search results are composed of all fields attributed as retrievable in the index. Select the **Fields** tab to review attributes.
- Keyword search, similar to what you might enter in a commercial web browser, is useful for testing an end-user experience. For example, assuming the hotels-sample index, you can enter `"activities 'outdoor pool' restaurant OR continental breakfast"`, and then you can use Ctrl-F to find terms within the search results.
- Query and filter expressions are articulated in a syntax implemented by Azure AI Search. The default is a [simple syntax](#), but you can optionally use [full Lucene](#) for more powerful queries. [Filter expressions](#) are articulated in an OData syntax.

Clean up resources

When you work in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money.

You can delete resources individually or delete the resource group to delete the entire set of resources.

In the Azure portal, you can find and manage resources by selecting **All resources** or **Resource groups** from the left pane.

Remember that a free search service is limited to three indexes, three indexers, and three data sources. To stay under the limit, you can delete these items individually in the Azure portal.

Next step

To learn more about query structures and syntax, use a REST client to create query expressions that use more parts of the REST API. [Documents - Search Post \(REST API\)](#) is especially helpful for learning and exploration.

[Quickstart: Full-text search](#)

Quickstart: Deploy Azure AI Search using an Azure Resource Manager template

Article • 03/04/2025

In this quickstart, you use an Azure Resource Manager (ARM) template to deploy an Azure AI Search service in the Azure portal.

An [Azure Resource Manager template](#) is a JavaScript Object Notation (JSON) file that defines the infrastructure and configuration for your project. The template uses declarative syntax. You describe your intended deployment without writing the sequence of programming commands to create the deployment.

Only those properties included in the template are used in the deployment. If more customization is required, such as [setting up network security](#), you can update the service as a post-deployment task. To customize an existing service with the fewest steps, use [Azure CLI](#) or [Azure PowerShell](#). If you're evaluating preview features, use the [Management REST API](#).

Assuming your environment meets the prerequisites and you're familiar with using ARM templates, select the **Deploy to Azure** button. The template will open in the Azure portal.

Deploy to Azure

Prerequisites

If you don't have an Azure subscription, create a [free account](#) before you begin.

Review the template

The template used in this quickstart is from [Azure Quickstart Templates](#).

JSON

```
{  
  "$schema": "https://schema.management.azure.com/schemas/2019-04-  
  01/deploymentTemplate.json#",

    "hostingMode": "[parameters('hostingMode')]"
  }
}
]
}

```

The Azure resource defined in this template:

- [Microsoft.Search/searchServices](#): create an Azure AI Search service

Deploy the template

Select the following image to sign in to Azure and open a template. The template creates an Azure AI Search resource.

The Azure portal displays a form that allows you to easily provide parameter values. Some parameters are prefilled with the default values from the template. Provide your subscription, resource group, location, and service name. If you want to use Azure AI services in an [AI enrichment](#) pipeline, for example to analyze binary image files for text, choose a location that offers both Azure AI Search and Azure AI services. Both services are required to be in the same region for AI enrichment workloads. After you complete the form, agree to the terms and conditions and then select the purchase button to complete your deployment.

TERMS AND CONDITIONS

[Template information](#) | [Azure Marketplace Terms](#) | [Azure Marketplace](#)

By clicking "Purchase," I (a) agree to the applicable legal terms associated with the offering; (b) authorize Microsoft to charge or bill my current payment method for the fees associated with the offering(s), including applicable taxes, with the same billing frequency as my Azure subscription, until I discontinue use of the offering(s); and (c) agree that, if the deployment involves 3rd party offerings, Microsoft may share my contact information and other details of such deployment with the publisher of that offering.

 I agree to the terms and conditions stated above[Purchase](#)

Review deployed resources

When your deployment is complete, you can access your new resource group and new search service in the Azure portal.

Clean up resources

Other Azure AI Search quickstarts and tutorials build upon this quickstart. If you plan to continue on to work with subsequent quickstarts and tutorials, you may wish to leave this resource in place. When no longer needed, you can delete the resource group, which deletes the Azure AI Search service and related resources.

Related content

In this quickstart, you created an Azure AI Search service using an ARM template and then validated the deployment. To learn more about Azure AI Search and Azure Resource Manager, see the following articles:

Quickstart: Deploy Azure AI Search using Bicep

Article • 03/04/2025

In this quickstart, you use a Bicep file to deploy an Azure AI Search service in the Azure portal.

Bicep is a domain-specific language (DSL) that uses declarative syntax to deploy Azure resources. It provides concise syntax, reliable type safety, and support for code reuse. Bicep offers the best authoring experience for your infrastructure-as-code solutions in Azure.

Only those properties included in the template are used in the deployment. If more customization is required, such as [setting up network security](#), you can update the service as a post-deployment task. To customize an existing service with the fewest steps, use [Azure CLI](#) or [Azure PowerShell](#). If you're evaluating preview features, use the [Management REST API](#).

💡 Tip

For an alternative Bicep template that deploys Azure AI Search with a pre-configured indexer to Cosmos DB for NoSQL, see [Bicep deployment of Azure AI Search](#). There's no bicep template support for Azure AI Search data plane operations like creating an index, but you can add a module that calls REST APIs. The sample includes a module that creates an index, data source connector, and an indexer that refreshes from Cosmos DB at 5-minute intervals.

Prerequisites

If you don't have an Azure subscription, create a [free account](#) before you begin.

Review the Bicep file

The Bicep file used in this quickstart is from [Azure Quickstart Templates](#).

Bicep

```
@description('Service name must only contain lowercase letters, digits or dashes, cannot use dash as the first two or last one characters, cannot contain consecutive dashes, and is limited between 2 and 60 characters in')
```

```
length.')
@minLength(2)
@maxLength(60)
param name string

@allowed([
    'free'
    'basic'
    'standard'
    'standard2'
    'standard3'
    'storage_optimized_l1'
    'storage_optimized_l2'
])
@description('The pricing tier of the search service you want to create (for example, basic or standard).')
param sku string = 'standard'

@description('Replicas distribute search workloads across the service. You need at least two replicas to support high availability of query workloads (not applicable to the free tier).')
@minValue(1)
@maxValue(12)
param replicaCount int = 1

@description('Partitions allow for scaling of document count as well as faster indexing by sharding your index over multiple search units.')
@allowed([
    1
    2
    3
    4
    6
    12
])
param partitionCount int = 1

@description('Applicable only for SKUs set to standard3. You can set this property to enable a single, high density partition that allows up to 1000 indexes, which is much higher than the maximum indexes allowed for any other SKU.')
@allowed([
    'default'
    'highDensity'
])
param hostingMode string = 'default'

@description('Location for all resources.')
param location string = resourceGroup().location

resource search 'Microsoft.Search/searchServices@2020-08-01' = {
    name: name
    location: location
    sku: {
        name: sku
    }
}
```

```
    }
  properties: {
    replicaCount: replicaCount
    partitionCount: partitionCount
    hostingMode: hostingMode
  }
}
```

The Azure resource defined in this Bicep file:

- [Microsoft.Search/searchServices](#): create an Azure AI Search service

Deploy the Bicep file

1. Save the Bicep file as **main.bicep** to your local computer.
2. Deploy the Bicep file using either Azure CLI or Azure PowerShell.

CLI

Azure CLI

```
az group create --name exampleRG --location eastus
az deployment group create --resource-group exampleRG --template-
file main.bicep --parameters serviceName=<service-name>
```

ⓘ Note

Replace **<service-name>** with the name of the Search service. The service name must only contain lowercase letters, digits, or dashes. You can't use a dash as the first two characters or the last character. The name has a minimum length of 2 characters and a maximum length of 60 characters.

When the deployment finishes, you should see a message indicating the deployment succeeded.

Review deployed resources

Use the Azure portal, Azure CLI, or Azure PowerShell to list the deployed resources in the resource group.

CLI

Azure CLI

```
az resource list --resource-group exampleRG
```

Clean up resources

Azure AI Search is a billable resource. If it's no longer needed, delete it from your subscription to avoid charges. You can use the Azure portal, Azure CLI, or Azure PowerShell to delete the resource group and its resources.

CLI

Azure CLI

```
az group delete --name exampleRG
```

Related content

Quickstart: Deploy Azure AI Search service using Terraform

05/29/2025

This article shows how to use Terraform to create an [Azure AI Search service](#) using [Terraform](#).

[Terraform](#)  enables the definition, preview, and deployment of cloud infrastructure. Using Terraform, you create configuration files using [HCL syntax](#)  . The HCL syntax allows you to specify the cloud provider - such as Azure - and the elements that make up your cloud infrastructure. After you create your configuration files, you create an *execution plan* that allows you to preview your infrastructure changes before they're deployed. Once you verify the changes, you apply the execution plan to deploy the infrastructure.

In this article, you learn how to:

- ✓ Create a random pet name for the Azure resource group name using [random_pet](#) 
- ✓ Create an Azure resource group using [azurerm_resource_group](#) 
- ✓ Create a random string using [random_string](#) 
- ✓ Create an Azure AI Search service using [azurerm_search_service](#) 

Prerequisites

- [Install and configure Terraform](#)

Implement the Terraform code

Note

See more [articles and sample code showing how to use Terraform to manage Azure resources](#)

1. Create a directory in which to test and run the sample Terraform code and make it the current directory.
2. Create a file named `main.tf` and insert the following code:

Terraform

```
resource "random_pet" "rg_name" {
    prefix = var.resource_group_name_prefix
}
```

```

resource "azurerm_resource_group" "rg" {
  name      = random_pet.rg_name.id
  location  = var.resource_group_location
}

resource "random_string" "azurerm_search_service_name" {
  length   = 25
  upper    = false
  numeric  = false
  special  = false
}

resource "azurerm_search_service" "search" {
  name          = random_string.azurerm_search_service_name.result
  resource_group_name = azurerm_resource_group.rg.name
  location      = azurerm_resource_group.rg.location
  sku           = var.sku
  replica_count = var.replica_count
  partition_count = var.partition_count
}

```

3. Create a file named `outputs.tf` and insert the following code:

```

Terraform

output "resource_group_name" {
  value = azurerm_resource_group.rg.name
}

output "azurerm_search_service_name" {
  value = azurerm_search_service.search.name
}

```

4. Create a file named `providers.tf` and insert the following code:

```

Terraform

terraform {
  required_version = ">=1.0"
  required_providers {
    azurerm = {
      source  = "hashicorp/azurerm"
      version = "~>3.0"
    }
    random = {
      source  = "hashicorp/random"
      version = "~>3.0"
    }
  }
}

```

```
provider "azurerm" {
  features {}
}
```

5. Create a file named `variables.tf` and insert the following code:

Terraform

```
variable "resource_group_location" {
  type     = string
  description = "Location for all resources."
  default    = "eastus"
}

variable "resource_group_name_prefix" {
  type     = string
  description = "Prefix of the resource group name that's combined with a
random ID so name is unique in your Azure subscription."
  default    = "rg"
}

variable "sku" {
  description = "The pricing tier of the search service you want to create
(for example, basic or standard)."
  default    = "standard"
  type       = string
  validation {
    condition    = contains(["free", "basic", "standard", "standard2",
"standard3", "storage_optimized_l1", "storage_optimized_l2"], var.sku)
    error_message = "The sku must be one of the following values: free,
basic, standard, standard2, standard3, storage_optimized_l1,
storage_optimized_l2."
  }
}

variable "replica_count" {
  type     = number
  description = "Replicas distribute search workloads across the service. You
need at least two replicas to support high availability of query workloads
(not applicable to the free tier)."
  default    = 1
  validation {
    condition    = var.replica_count >= 1 && var.replica_count <= 12
    error_message = "The replica_count must be between 1 and 12."
  }
}

variable "partition_count" {
  type     = number
  description = "Partitions allow for scaling of document count as well as
faster indexing by sharding your index over multiple search units."
  default    = 1
  validation {
```

```
    condition      = contains([1, 2, 3, 4, 6, 12], var.partition_count)
    error_message = "The partition_count must be one of the following values:
1, 2, 3, 4, 6, 12."
}
}
```

Initialize Terraform

Run [terraform init](#) to initialize the Terraform deployment. This command downloads the Azure provider required to manage your Azure resources.

Console

```
terraform init -upgrade
```

Key points:

- The `-upgrade` parameter upgrades the necessary provider plugins to the newest version that complies with the configuration's version constraints.

Create a Terraform execution plan

Run [terraform plan](#) to create an execution plan.

Console

```
terraform plan -out main.tfplan
```

Key points:

- The `terraform plan` command creates an execution plan, but doesn't execute it. Instead, it determines what actions are necessary to create the configuration specified in your configuration files. This pattern allows you to verify whether the execution plan matches your expectations before making any changes to actual resources.
- The optional `-out` parameter allows you to specify an output file for the plan. Using the `-out` parameter ensures that the plan you reviewed is exactly what is applied.

Apply a Terraform execution plan

Run [terraform apply](#) to apply the execution plan to your cloud infrastructure.

Console

```
terraform apply main.tfplan
```

Key points:

- The example `terraform apply` command assumes you previously ran `terraform plan -out main.tfplan`.
- If you specified a different filename for the `-out` parameter, use that same filename in the call to `terraform apply`.
- If you didn't use the `-out` parameter, call `terraform apply` without any parameters.

Verify the results

1. Get the Azure resource name in which the Azure AI Search service was created.

Console

```
resource_group_name=$(terraform output -raw resource_group_name)
```

2. Get the Azure AI Search service name.

Console

```
azurerm_search_service_name=$(terraform output -raw  
azurerm_search_service_name)
```

3. Run `az search service show` to show the Azure AI Search service you created in this article.

Azure CLI

```
az search service show --name $azurerm_search_service_name \  
--resource-group $resource_group_name
```

Clean up resources

When you no longer need the resources created via Terraform, do the following steps:

1. Run `terraform plan ↗` and specify the `destroy` flag.

Console

```
terraform plan -destroy -out main.destroy.tfplan
```

Key points:

- The `terraform plan` command creates an execution plan, but doesn't execute it. Instead, it determines what actions are necessary to create the configuration specified in your configuration files. This pattern allows you to verify whether the execution plan matches your expectations before making any changes to actual resources.
- The optional `-out` parameter allows you to specify an output file for the plan. Using the `-out` parameter ensures that the plan you reviewed is exactly what is applied.

2. Run [terraform apply](#) to apply the execution plan.

Console

```
terraform apply main.destroy.tfplan
```

Troubleshoot Terraform on Azure

[Troubleshoot common problems when using Terraform on Azure](#)

Next steps

[Create an Azure AI Search index using the Azure portal](#)

ⓘ **Note:** The author created this article with assistance from AI. [Learn more](#)

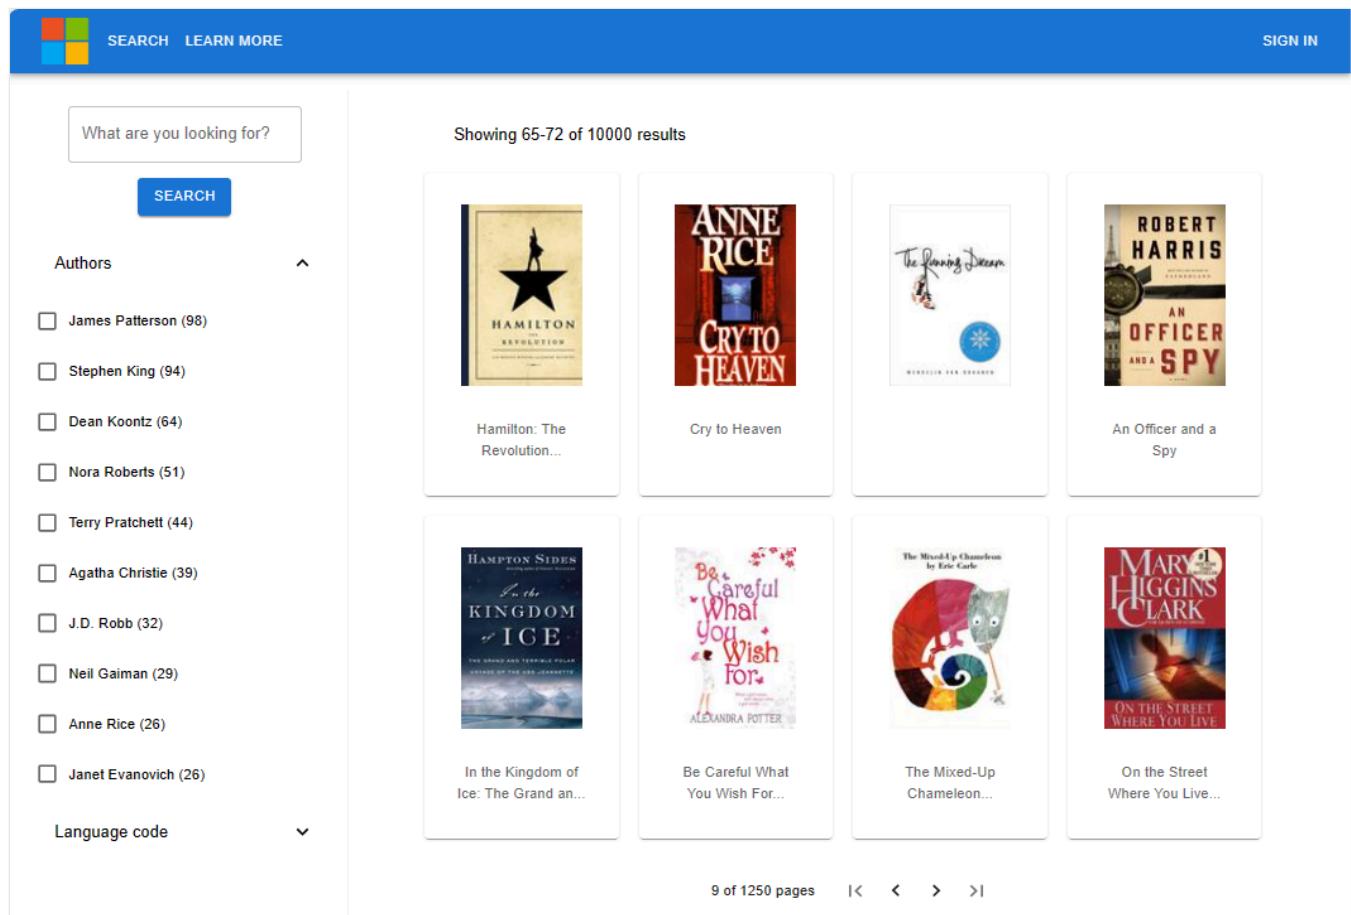

Step 1 - Overview of adding search to a static web app with .NET

09/23/2025

This tutorial builds a website that searches through a catalog of books and then deploys the website to an Azure Static Web App.

What does the sample do?

This sample website provides access to a catalog of 10,000 books. You can search the catalog by entering text in the search bar. While you enter text, the website uses the search index's suggestion feature to autocomplete the text. When the query finishes, the website displays the list of books with a portion of the details. You can select a book to see all the details, stored in the search index, of the book.

The screenshot shows a web application for searching a book catalog. At the top, there is a blue header bar with a Microsoft logo, a 'SEARCH' button, a 'LEARN MORE' link, and a 'SIGN IN' link. Below the header, a search bar contains the placeholder text 'What are you looking for?'. A blue 'SEARCH' button is positioned just below the search bar. To the left of the search results, there is a sidebar with a 'Authors' section containing a list of authors with their counts: James Patterson (98), Stephen King (94), Dean Koontz (64), Nora Roberts (51), Terry Pratchett (44), Agatha Christie (39), J.D. Robb (32), Neil Gaiman (29), Anne Rice (26), and Janet Evanovich (26). There is also a 'Language code' section with a dropdown arrow. The main content area displays a grid of book cards. The first row contains four cards: 'Hamilton: The Revolution...', 'Cry to Heaven', 'The Running Dream', and 'An Officer and a Spy'. The second row contains four cards: 'In the Kingdom of Ice: The Grand and Terrible Polar Voyage of the Jeannette', 'Be Careful What You Wish For...', 'The Mixed-Up Chameleon', and 'On the Street Where You Live...'. Each card includes the book title, author, and a small thumbnail image. At the bottom of the page, there is a footer with the text '9 of 1250 pages' and navigation icons for page navigation.

The search experience includes:

- **Search** – provides search functionality for the application.
- **Suggest** – provides suggestions as the user is typing in the search bar.
- **Facets and filters** - provides a faceted navigation structure that filters by author or language.

- [Paginated results](#) - provides paging controls for scrolling through results.
- [Document Lookup](#) – looks up a document by ID to retrieve all of its contents for the details page.

How is the sample organized?

The [sample code](#) includes the following components:

 Expand table

App	Purpose	GitHub Repository Location
client	React app (presentation layer) to display books, with search. It calls the Azure Function app.	/azure-search-static-web-app/client
api	Azure .NET Function app (business layer) - calls the Azure AI Search API using .NET SDK	/azure-search-static-web-app/api
bulk insert	.NET project to create the index and add documents to it.	/azure-search-static-web-app/bulk-insert

Set up your development environment

Create services and install the following software for your local development environment.

- [Azure AI Search](#), any region or tier
- [.NET 9](#) or latest version
- [Git](#)
- [Visual Studio Code](#)
- [C# Dev Tools extension for Visual Studio Code](#)
- [Azure Static Web App extension for Visual Studio Code](#)

This tutorial doesn't run the Azure Function API locally. If you want to run it locally, install [azure-functions-core-tools](#).

Fork and clone the search sample with git

To deploy the Static Web App, you need to fork the sample repository. The web apps use your GitHub fork location to decide the build actions and deployment content. Code execution in the Static Web App happens remotely, with Azure Static Web Apps reading the code from your forked sample.

1. On GitHub, fork the [azure-search-static-web-app repository](#).

Complete the [fork process](#) in your web browser with your GitHub account. This tutorial uses your fork as part of the deployment to an Azure Static Web App.

2. At a Bash terminal, download your forked sample application to your local computer.

Replace `YOUR-GITHUB-ALIAS` with your GitHub alias.

Bash

```
git clone https://github.com/YOUR-GITHUB-ALIAS/azure-search-static-web-app.git
```

3. At the same Bash terminal, go into your forked repository for this website search example:

Bash

```
cd azure-search-static-web-app
```

4. Use the Visual Studio Code command, `code .` to open your forked repository. You accomplish the remaining tasks from Visual Studio Code, unless specified.

Bash

```
code .
```

Next steps

- [Create an index and load it with documents](#)
- [Deploy your Static Web App](#)

Step 2 - Create and load the search index

Continue to build your search-enabled website by following these steps:

- Create a new index
- Load data

The program uses [Azure.Search.Documents](#) in the Azure SDK for .NET:

- NuGet package [Azure.Search.Documents](#)
- Reference Documentation

Before you start, make sure you have room on your search service for a new index. The free tier limit is three indexes. The Basic tier limit is 15.

Prepare the bulk import script for Search

1. In Visual Studio Code, open the `Program.cs` file in the subdirectory, `azure-search-static-web-app/bulk-insert`, replace the following variables with your own values to authenticate with the Azure Search SDK.

- YOUR-SEARCH-SERVICE-NAME (not the full URL)
- YOUR-SEARCH-ADMIN-API-KEY (see [Find API keys](#))

C#

```
using Azure;
using Azure.Search.Documents;
using Azure.Search.Documents.Indexes;
using Azure.Search.Documents.Indexes.Models;
using AzureSearch.BulkInsert;
using ServiceStack;

const string BOOKS_URL = "https://raw.githubusercontent.com/Azure-
Samples/azure-search-sample-data/main/good-books/books.csv";
const string SEARCH_ENDPOINT = "https://YOUR-SEARCH-RESOURCE-
NAME.search.windows.net";
const string SEARCH_KEY = "YOUR-SEARCH-ADMIN-KEY";
const string SEARCH_INDEX_NAME = "good-books";

Uri searchEndpointUri = new(SEARCH_ENDPOINT);

SearchClient client = new(
    searchEndpointUri,
    SEARCH_INDEX_NAME,
    new AzureKeyCredential(SEARCH_KEY));
```

```

SearchIndexClient clientIndex = new(
    searchEndpointUri,
    new AzureKeyCredential(SEARCH_KEY));

await CreateIndexAsync(clientIndex);
await BulkInsertAsync(client);

static async Task CreateIndexAsync(SearchIndexClient clientIndex)
{
    Console.WriteLine("Creating (or updating) search index");
    SearchIndex index = new BookSearchIndex(SEARCH_INDEX_NAME);
    var result = await clientIndex.CreateOrUpdateIndexAsync(index);

    Console.WriteLine(result);
}

static async Task BulkInsertAsync(SearchClient client)
{
    Console.WriteLine("Download data file");
    using HttpClient httpClient = new();

    var csv = await httpClient.GetStringAsync(BOOKS_URL);

    Console.WriteLine("Reading and parsing raw CSV data");
    var books =
        csv.ReplaceFirst("book_id", "id").FromCsv<List<BookModel>>();

    Console.WriteLine("Uploading bulk book data");
    _ = await client.UploadDocumentsAsync(books);

    Console.WriteLine("Finished bulk inserting book data");
}

```

2. Open an integrated terminal in Visual Studio Code for the project directory's subdirectory, `azure-search-static-web-app/bulk-insert`.

3. Run the following command to install the dependencies.

Bash

```
dotnet restore
```

Run the bulk import script for Search

1. Still in the same subdirectory (`azure-search-static-web-app/bulk-insert`), run the program:

Bash

```
dotnet run
```

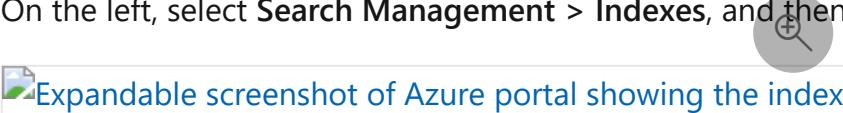

- As the code runs, the console displays progress. You should see the following output.

Bash

```
Creating (or updating) search index
Status: 201, Value: Azure.Search.Documents.Indexes.Models.SearchIndex
Download data file
Reading and parsing raw CSV data
Uploading bulk book data
Finished bulk inserting book data
```

Review the new search index

Once the upload completes, the search index is ready to use. Review your new index in Azure portal.

- In Azure portal, [find your search service ↗](#).
- On the left, select **Search Management > Indexes**, and then select the good-books index.

- By default, the index opens in the **Search Explorer** tab. Select **Search** to return documents from the index.

Rollback bulk import file changes

Use the following git command in the Visual Studio Code integrated terminal at the `bulk-insert` directory to roll back the changes to the `Program.cs` file. They aren't needed to continue the tutorial and you shouldn't save or push your API keys or search service name to your repo.

```
git
```

```
git checkout .
```

Next steps

[Deploy your Static Web App](#)

Last updated on 11/21/2025

Step 3 - Deploy the search-enabled .NET website

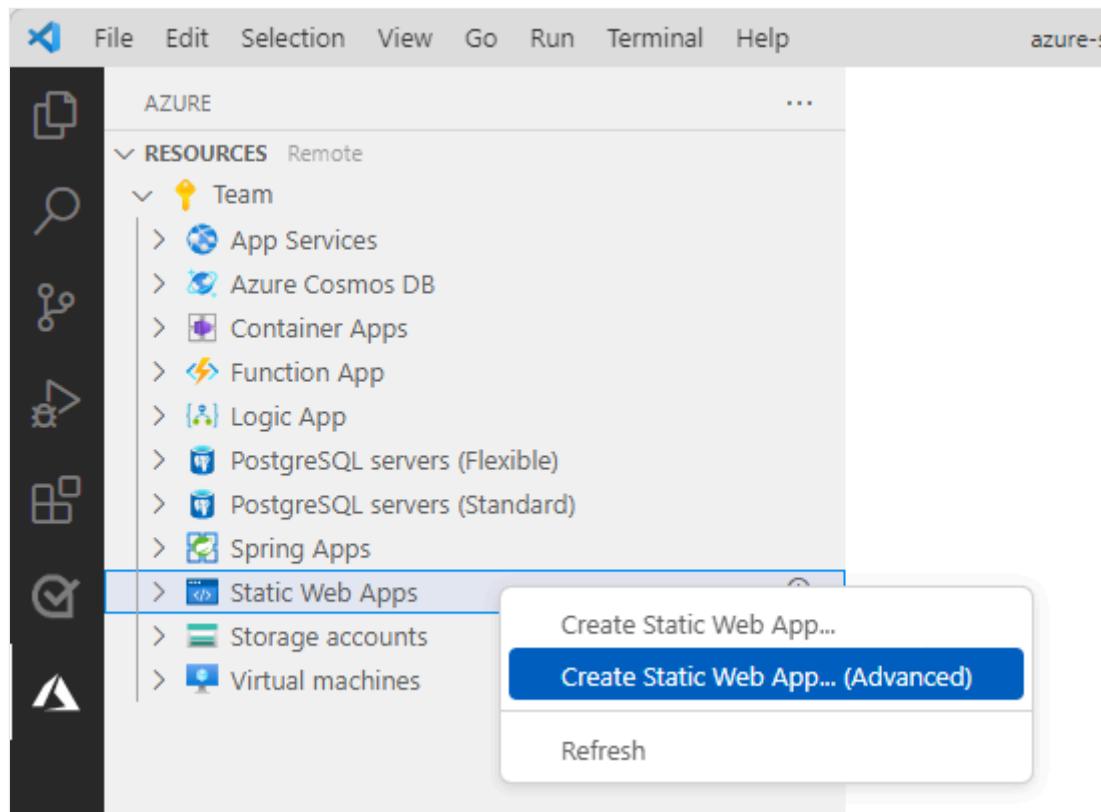

09/23/2025

Deploy the search-enabled website as an Azure Static Web Apps site. This deployment includes both the React app for the web pages, and the Function app for search operations.

The static web app pulls the information and files for deployment from GitHub using your fork of the `azure-search-static-web-app` repository.

Create a Static Web App in Visual Studio Code

1. In Visual Studio Code, make sure you're at the repository root, and not the bulk-insert folder (for example, `azure-search-static-web-app`).
2. Select **Azure** from the Activity Bar, then open **Resources** from the side bar.
3. Right-click **Static Web Apps** and then select **Create Static Web App (Advanced)**. If you don't see this option, verify that you have the Azure Functions extension for Visual Studio Code.

4. If you see a pop-up window asking you to commit your changes, don't do this. The secrets from the bulk import step shouldn't be committed to the repository.

To roll back the changes, in Visual Studio Code select the Source Control icon in the Activity bar, then select each changed file in the Changes list and select the **Discard changes** icon.

5. Follow the prompts to create the static web app:

 Expand table

Prompt	Enter
Select a resource group for new resources.	Create a new resource group for the static app.
Enter the name for the new Static Web App.	Give your static app a name, such as <code>my-demo-static-web-app</code> .
Select a SKU	Select the free SKU for this tutorial.
Select a location for new resources.	Choose a region near you.
Choose build preset to configure default project structure.	Select Custom .
Select the location of your client application code	<code>client</code> This is the path, from the root of the repository, to your static web app.
Enter the path of your build output...	<code>build</code> This is the path, from your static web app, to your generated files.

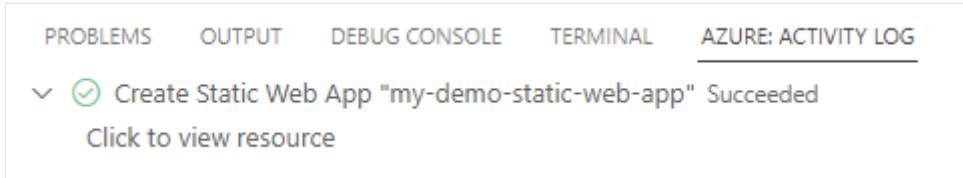

If you get an error about an incorrect region, make sure the resource group and static web app resource are in one of the supported regions listed in the error response.

6. When the static web app is created, a GitHub workflow YML file is also created locally and on GitHub in your fork. This workflow executes in your fork, building and deploying the static web app and functions.

Check the status of static web app deployment using any of these approaches:

- Select **Open Actions in GitHub** from the Notifications. This opens a browser window pointed to your forked repo.
- Select the **Actions** tab in your forked repository. You should see a list of all workflows on your fork.

- Select the **Azure: Activity Log** in Visual Code. You should see a message similar to the following screenshot.

The screenshot shows the Visual Studio Code interface with the "AZURE: ACTIVITY LOG" tab selected in the top navigation bar. Below the tab, there is a single log entry: "Create Static Web App "my-demo-static-web-app"" followed by the status "Succeeded". A link "Click to view resource" is provided below the log entry.

Get the Azure AI Search query key in Visual Studio Code

While you might be tempted to reuse your search admin key for query purposes that isn't following the principle of least privilege. The Azure Function should use the query key to conform to least privilege.

1. In Visual Studio Code, open a new terminal window.
2. Get the query API key with this Azure CLI command:

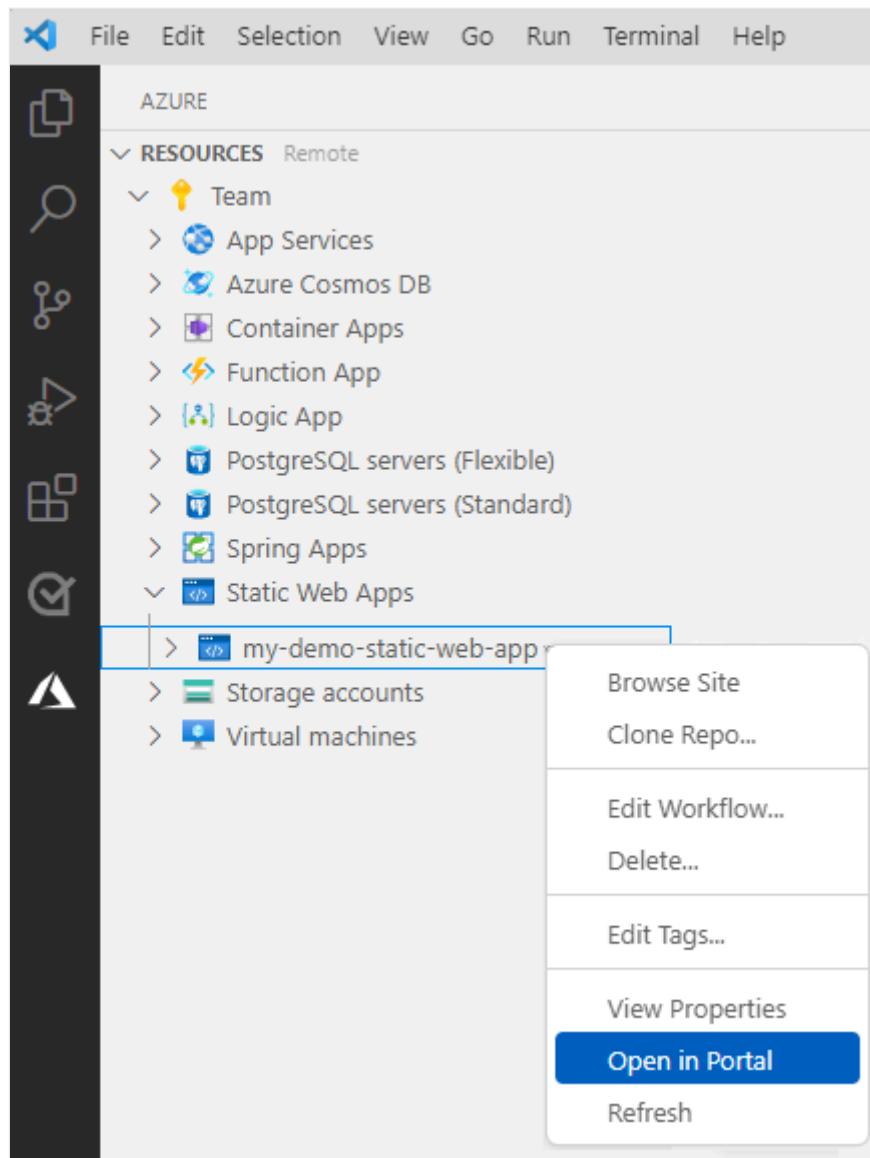

```
Azure CLI  
  
az search query-key list --resource-group YOUR-SEARCH-SERVICE-RESOURCE-GROUP  
--service-name YOUR-SEARCH-SERVICE-NAME
```

3. Keep this query key to use in the next section. The query key authorizes read access to a search index.

Add environment variables in Azure portal

The Azure Function app won't return search data until the search secrets are in settings.

1. Select **Azure** from the Activity Bar.
2. Right-click on your Static Web Apps resource then select **Open in Portal**.

3. Select **Environment variables** then select + Add application setting.

A screenshot of the Azure portal showing the configuration for the 'my-demo-static-web-app'. The left sidebar has links for Home, my-demo-static-web-app, Overview, Access control (IAM), Tags, Diagnose and solve problems, Resource visualizer, Settings, Configuration, Environment variables (which is selected and highlighted in grey), Application Insights, and Custom domains. The main content area shows the 'my-demo-static-web-app | Environment variables' page. It includes sections for Overview, Environment variables, and Application settings. The 'Add application setting' button is highlighted with a red box. A table lists environment variables: Name (SearchApiKey) and Value (Hidden value. Click to show value).

4. Add each of the following settings:

Expand table

Setting	Your Search resource value
SearchApiKey	Your search query key
SearchServiceName	Your search resource name
SearchIndexName	good-books
SearchFacets	authors*,language_code

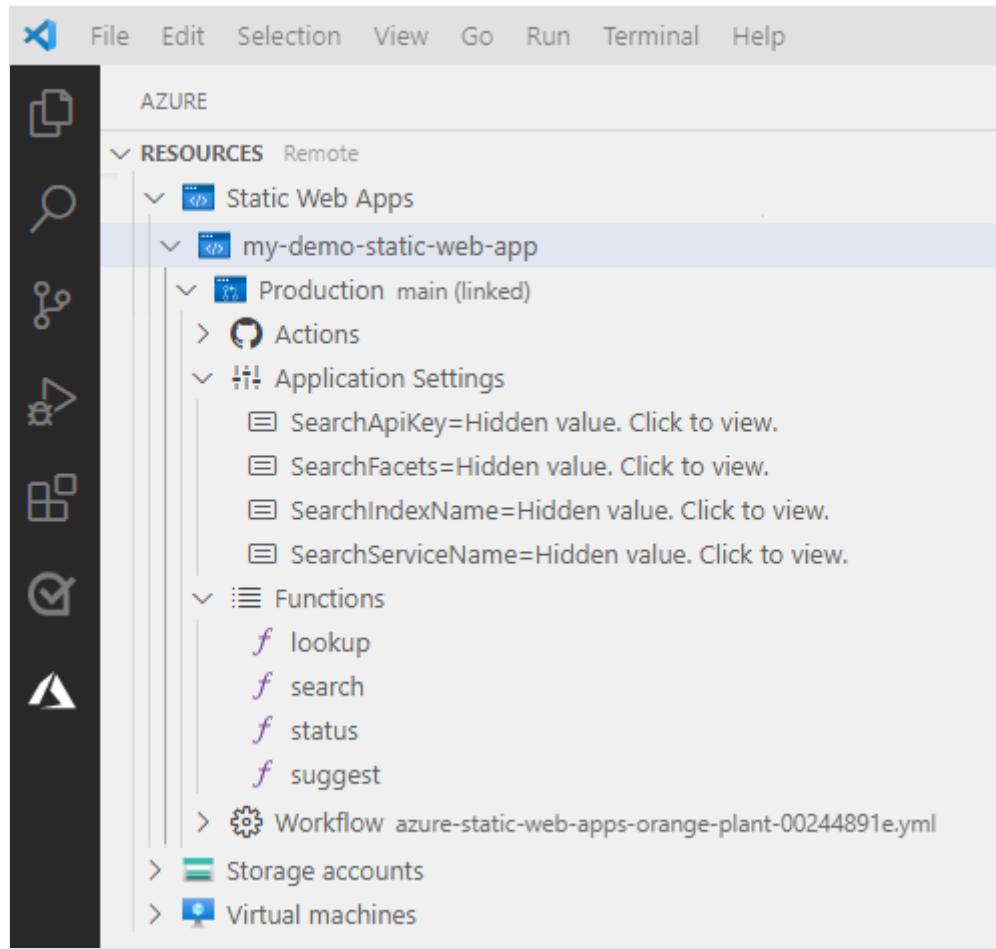

Azure AI Search requires different syntax for filtering collections than it does for strings. Add a `*` after a field name to denote that the field is of type `Collection(Edm.String)`. This allows the Azure Function to add filters correctly to queries.

5. Check your settings to make sure they look like the following screenshot.

Name	Value	Delete
SearchApiKey	Hidden value. Click to show value	
SearchFacets	Hidden value. Click to show value	
SearchIndexName	Hidden value. Click to show value	
SearchServiceName	Hidden value. Click to show value	

6. Return to Visual Studio Code.

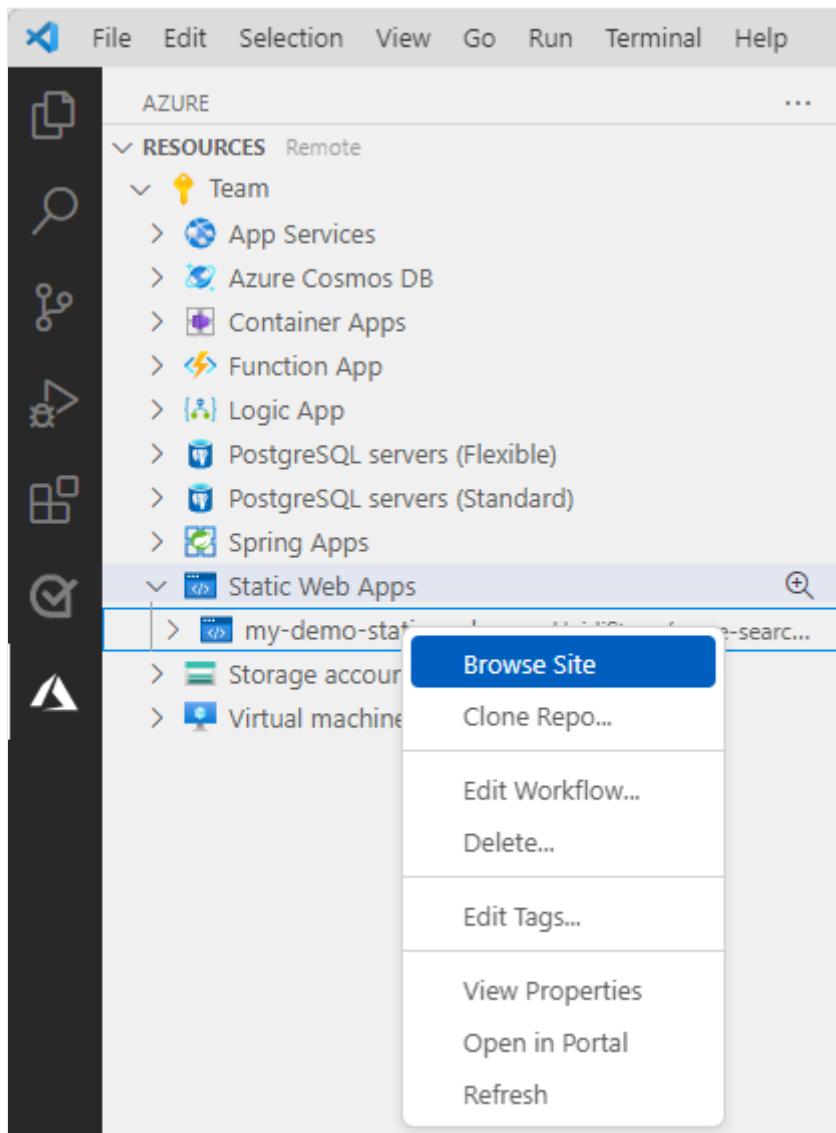

7. Refresh your static web app to see the application settings and functions.

If you don't see the application settings, revisit the steps for updating and relaunching the GitHub workflow.

Use search in your static web app

1. In Visual Studio Code, open the [Activity bar](#), and select the Azure icon.
2. In the Side bar, **right-click on your Azure subscription** under the `Static Web Apps` area and find the static web app you created for this tutorial.
3. Right-click the static web app name and select **Browse site**.

4. Select **Open** in the pop-up dialog.
5. In the website search bar, enter a search query such as `code`, so the suggest feature suggests book titles. Select a suggestion or continue entering your own query. Press enter when you've completed your search query.
6. Review the results then select one of the books to see more details.

Troubleshooting

If the web app didn't deploy or work, use the following list to determine and fix the issue:

- **Did the deployment succeed?**

In order to determine if your deployment succeeded, you need to go to *your* fork of the sample repo and review the success or failure of the GitHub action. There should be only one action and it should have static web app settings for the `app_location`, `api_location`,

and `output_location`. If the action didn't deploy successfully, dive into the action logs and look for the last failure.

- **Does the client (front-end) application work?**

You should be able to get to your web app and it should successfully display. If the deployment succeeded but the website doesn't display, this might be an issue with how the static web app is configured for rebuilding the app, once it is on Azure.

- **Does the API (serverless back-end) application work?**

You should be able to interact with the client app, searching for books and filtering. If the form doesn't return any values, open the browser's developer tools, and determine if the HTTP calls to the API were successful. If the calls weren't successful, the most likely reason if the static web app configurations for the API endpoint name and search query key are incorrect.

If the path to the Azure function code (`api_location`) isn't correct in the YML file, the application loads but won't call any of the functions that provide integration with Azure AI Search. Revisit the deployment section to make sure paths are correct.

Clean up resources

To clean up the resources created in this tutorial, delete the resource group or individual resources.

1. In Visual Studio Code, open the [Activity bar](#), and select the Azure icon.
2. In the Side bar, **right-click on your Azure subscription** under the `Static Web Apps` area and find the app you created for this tutorial.
3. Right-click the app name then select **Delete**.
4. If you no longer want the GitHub fork of the sample, remember to delete that on GitHub. Go to your fork's **Settings** then delete the repository.
5. To delete Azure AI Search, [find your search service](#) and select **Delete** at the top of the page.

Next steps

- [Understand Search integration for the search-enabled website](#)

Step 4 - Explore the .NET search code

09/23/2025

In the previous lessons, you added search to a static web app. This lesson highlights the essential steps that establish integration. If you're looking for a cheat sheet on how to integrate search into your web app, this article explains what you need to know.

Azure SDK Azure.Search.Documents

The Function app uses the Azure SDK for Azure AI Search:

- NuGet: [Azure.Search.Documents](#)
- Reference Documentation: [Client Library](#)

The function app authenticates through the SDK to the cloud-based Azure AI Search API using your resource name, resource key, and index name. The secrets are stored in the static web app settings and pulled in to the function as environment variables.

Configure secrets in a local.settings.json file

```
JSON

{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "",
    "FUNCTIONS_WORKER_RUNTIME": "dotnet-isolated",
    "SearchApiKey": "",
    "SearchServiceName": "",
    "SearchIndexName": "good-books"
  },
  "Host": {
    "CORS": "*"
  }
}
```

Azure Function: Search the catalog

The [Search API](#) takes a search term and searches across the documents in the search index, returning a list of matches. Through the Suggest API, partial strings are sent to the search engine as the user types, suggesting search terms such as book titles and authors across the documents in the search index, and returning a small list of matches.

The Azure function pulls in the search configuration information, and fulfills the query.

The search suggester, `sg`, is defined in the [schema file](#) used during bulk upload.

C#

```
using Azure;
using Azure.Core.Serialization;
using Azure.Search.Documents;
using Azure.Search.Documents.Models;
using Microsoft.Azure.Functions.Worker;
using Microsoft.Azure.Functions.Worker.Http;
using Microsoft.Extensions.Logging;
using System.Net;
using System.Text.Json;
using System.Text.Json.Serialization;
using WebSearch.Models;
using SearchFilter = WebSearch.Models.SearchFilter;

namespace WebSearch.Function
{
    public class Search
    {
        private static string searchApiKey =
Environment.GetEnvironmentVariable("SearchApiKey",
EnvironmentVariableTarget.Process);
        private static string searchServiceName =
Environment.GetEnvironmentVariable("SearchServiceName",
EnvironmentVariableTarget.Process);
        private static string searchIndexName =
Environment.GetEnvironmentVariable("SearchIndexName",
EnvironmentVariableTarget.Process) ?? "good-books";

        private readonly ILogger<Lookup> _logger;

        public Search	ILogger<Lookup> logger)
        {
            _logger = logger;
        }

        [Function("search")]
        public async Task<HttpResponseData> RunAsync(
            [HttpTrigger(AuthorizationLevel.Anonymous, "post")] HttpRequestData
req,
            FunctionContext executionContext)
        {
            string requestBody = await new
StreamReader(req.Body).ReadToEndAsync();
            var data = JsonSerializer.Deserialize<RequestBodySearch>(requestBody);

            // Azure AI Search
            Uri serviceEndpoint =
new($"https://{{searchServiceName}}.search.windows.net/");
            ...
        }
    }
}
```

```

        SearchClient searchClient = new(
            serviceEndpoint,
            searchIndexName,
            new AzureKeyCredential(searchApiKey)
        );

        SearchOptions options = new()

        {
            Size = data.Size,
            Skip = data.Skip,
            IncludeTotalCount = true,
            Filter = CreateFilterExpression(data.Filters)
        };
        options.Facets.Add("authors");
        options.Facets.Add("language_code");

        SearchResults<SearchDocument> searchResults =
searchClient.Search<SearchDocument>(data.SearchText, options);

        var facetOutput = new Dictionary<string, IList<FacetValue>>();
        foreach (var facetResult in searchResults.Facets)
        {
            facetOutput[facetResult.Key] = facetResult.Value
                .Select(x => new FacetValue { value =
x.Value.ToString(), count = x.Count })

                .ToList();
        }

        // Data to return
        var output = new SearchOutput
        {
            Count = searchResults.TotalCount,
            Results = searchResults.GetResults().ToList(),
            Facets = facetOutput
        };

        var response = req.CreateResponse(HttpStatusCode.Found);

        // Serialize data
        var serializer = new JsonObjectSerializer(
            new JsonSerializerOptions(JsonSerializerDefaults.Web));
        await response.WriteAsJsonAsync(output, serializer);

        return response;
    }

    public static string CreateFilterExpression(List<SearchFilter> filters)
    {
        if (filters is null or { Count: <= 0 })
        {
            return null;
        }
    }
}

```

```

        List<string> filterExpressions = new();

        List<SearchFilter> authorFilters = filters.Where(f => f.field == "authors").ToList();
        List<SearchFilter> languageFilters = filters.Where(f => f.field == "language_code").ToList();

        List<string> authorFilterValues = authorFilters.Select(f => f.value).ToList();

        if (authorFilterValues.Count > 0)
        {
            string filterStr = string.Join(", ", authorFilterValues);
            filterExpressions.Add($"\"authors\"/any(t: search.in(t, '{filterStr}', ','))");
        }

        List<string> languageFilterValues = languageFilters.Select(f => f.value).ToList();
        foreach (var value in languageFilterValues)
        {
            filterExpressions.Add($"language_code eq '{value}'");
        }

        return string.Join(" and ", filterExpressions);
    }
}
}

```

Client: Search from the catalog

Call the Azure Function in the React client at `\client\src\pages\Search\Search.jsx` with the following code to search for books.

```

C#

import React, { useEffect, useState, Suspense } from 'react';
import fetchInstance from '..../url-fetch';
import CircularProgress from '@mui/material/CircularProgress';
import { useLocation, useNavigate } from "react-router-dom";

import Results from '..../components/Results/Results';
import Pager from '..../components/Pager/Pager';
import Facets from '..../components/Facets/Facets';
import SearchBar from '..../components/SearchBar/SearchBar';

import './Search.css';

export default function Search() {

```

```
let location = useLocation();
const navigate = useNavigate();

const [results, setResults] = useState([]);
const [resultCount, setResultCount] = useState(0);
const [currentPage, setCurrentPage] = useState(1);
const [q, setQ] = useState(new URLSearchParams(location.search).get('q') ?? "*");
const [top] = useState(new URLSearchParams(location.search).get('top') ?? 8);
const [skip, setSkip] = useState(new URLSearchParams(location.search).get('skip') ?? 0);
const [filters, setFilters] = useState([]);
const [facets, setFacets] = useState({});
const [isLoading, setIsLoading] = useState(true);

let resultsPerPage = top;

// Handle page changes in a controlled manner
function handlePageChange(newPage) {
  setCurrentPage(newPage);
}

// Calculate skip value and fetch results when relevant parameters change
useEffect(() => {
  // Calculate skip based on current page
  const calculatedSkip = (currentPage - 1) * top;

  // Only update if skip has actually changed
  if (calculatedSkip !== skip) {
    setSkip(calculatedSkip);
    return; // Skip the fetch since skip will change and trigger another
  }
  useEffect(() => {
    // Proceed with fetch
    setIsLoading(true);

    const body = {
      q,
      top,
      skip,
      filters
    };

    fetchInstance('/api/search', { body, method: 'POST' })
      .then(response => {
        setResults(response.results);
        setFacets(response.facets);
        setResultCount(response.count);
        setIsLoading(false);
      })
      .catch(error => {
        console.log(error);
        setIsLoading(false);
      })
  }, [skip]);
}

handlePageChange(2);
```

```

        });
    }, [q, top, skip, filters, currentPage]);

    // pushing the new search term to history when q is updated
    // allows the back button to work as expected when coming back from the details
page
    useEffect(() => {
        navigate('/search?q=' + q);
        setCurrentPage(1);
        setFilters([]);
        // eslint-disable-next-line react-hooks/exhaustive-deps
    }, [q]);

let postSearchHandler = (searchTerm) => {
    setQ(searchTerm);
}

// filters should be applied across entire result set,
// not just within the current page
const updateFilterHandler = (newFilters) => {

    // Reset paging
    setSkip(0);
    setCurrentPage(1);

    // Set filters
    setFilters(newFilters);
};

return (
    <main className="main main--search container-fluid">
        <div className="row">
            <div className="search-bar-column col-md-3">
                <div className="search-bar-column-container">
                    <SearchBar postSearchHandler={postSearchHandler} query={q} width={false}></SearchBar>
                </div>
                <Facets facets={facets} filters={filters} setFilters={updateFilterHandler}></Facets>
            </div>
            <div className="search-bar-results">
                {isLoading ? (
                    <div className="col-md-9">
                        <CircularProgress />
                    </div>
                ) : (
                    <div className="search-results-container">
                        <Results documents={results} top={top} skip={skip} count={resultCount} query={q}></Results>
                        <Pager className="pager-style" currentPage={currentPage} resultCount={resultCount} resultsPerPage={resultsPerPage} onPageChange={handlePageChange}></Pager>
                    </div>
                )}
            </div>
        </div>
    </main>
)

```

```
        )}
      </div>
    </div>
  </main>
);
}
```

Client: Suggestions from the catalog

The Suggest function API is called in the React app at

`\client\src\components\SearchBar\SearchBar.jsx` as part of the [Material UI's Autocomplete component](#). This component uses the input text to search for authors and books that match the input text then displays those possible matches at selectable items in the drop-down list.

C#

```
import React, { useState, useEffect } from 'react';
import { TextField, Autocomplete, Button, Box } from '@mui/material';
import fetchInstance from '../.../url-fetch';
import './SearchBar.css';

export default function SearchBar({ postSearchHandler, query, width }) {
  const [q, setQ] = useState(() => query || '');
  const [suggestions, setSuggestions] = useState([]);

  const search = (value) => {
    postSearchHandler(value);
  };

  useEffect(() => {
    if (q) {

      const body = { q, top: 5, suggester: 'sg' };

      fetchInstance('/api/suggest', { body, method: 'POST' })
        .then(response => {
          setSuggestions(response.suggestions.map(s => s.text));
        })
        .catch(error => {
          console.log(error);
          setSuggestions([]);
        });
    }
  }, [q]);

  const onInputChangeHandler = (event, value) => {
    setQ(value);
  };
}
```

```
const onChangeHandler = (event, value) => {
  setQ(value);
  search(value);
};

const onEnterButton = (event) => {
  // if enter key is pressed
  if (event.key === 'Enter') {
    search(q);
  }
};

return (
  <div
    className={width ? "search-bar search-bar-wide" : "search-bar search-bar-narrow"}>
    <Box className="search-bar-box">
      <Autocomplete
        className="autocomplete"
        freeSolo
        value={q}
        options={suggestions}
        onInputChange={onInputChangeHandler}
        onChange={onChangeHandler}
        disableClearable
        renderInput={(params) => (
          <TextField
            {...params}
            id="search-box"
            className="form-control rounded-0"
            placeholder="What are you looking for?"
            onBlur={() => setSuggestions([])}
            onClick={() => setSuggestions([])}
          />
        )}
      />
      <div className="search-button" >
        <Button variant="contained" color="primary" onClick={() => {
          search(q)
        }}>
          Search
        </Button>
      </div>
    </Box>
  </div>
);
}
```

Azure Function: Get specific document

The [Document Lookup API](#) takes an ID and returns the document object from the Search Index.

C#

```
using Azure;
using Azure.Core.Serialization;
using Azure.Search.Documents;
using Azure.Search.Documents.Models;
using Microsoft.Azure.Functions.Worker;
using Microsoft.Azure.Functions.Worker.Http;
using Microsoft.Extensions.Logging;
using System.Net;
using System.Text.Json;
using WebSearch.Models;

namespace WebSearch.Function
{
    public class Lookup
    {
        private static string searchApiKey =
Environment.GetEnvironmentVariable("SearchApiKey",
EnvironmentVariableTarget.Process);
        private static string searchServiceName =
Environment.GetEnvironmentVariable("SearchServiceName",
EnvironmentVariableTarget.Process);
        private static string searchIndexName =
Environment.GetEnvironmentVariable("SearchIndexName",
EnvironmentVariableTarget.Process) ?? "good-books";

        private readonly ILogger<Lookup> _logger;

        public Lookup(ILogger<Lookup> logger)
        {
            _logger = logger;
        }

        [Function("lookup")]
        public async Task<HttpResponseData> RunAsync(
            [HttpTrigger(AuthorizationLevel.Anonymous, "get", "post")]
HttpRequestData req,
            FunctionContext executionContext)
        {

            // Get Document Id
            var query = System.Web.HttpUtility.ParseQueryString(req.Url.Query);
            string documentId = query[ "id" ].ToString();

            // Azure AI Search
            Uri serviceEndpoint =

        searchIndexName,
        new AzureKeyCredential(searchApiKey)
    );

    var getDocumentResponse = await
searchClient.GetDocumentAsync<SearchDocument>(documentId);

    // Data to return
    var output = new LookupOutput
    {
        Document = getDocumentResponse.Value
    };

    var response = req.CreateResponse(HttpStatusCode.Found);

    // Serialize data
    var serializer = new JsonObjectSerializer(
        new JsonSerializerOptions(JsonSerializerDefaults.Web));
    await response.WriteAsJsonAsync(output, serializer);

    return response;
}
}
}
}

```

Client: Get specific document

This function API is called in the React app at `\client\src\pages\Details\Details.jsx` as part of component initialization:

```

C#

import React, { useState, useEffect } from "react";
import { useParams } from 'react-router-dom';
import Rating from '@mui/material/Rating';
import CircularProgress from '@mui/material/CircularProgress';
import Tabs from '@mui/material/Tabs';
import Tab from '@mui/material/Tab';
import Box from '@mui/material/Box';

import fetchInstance from '.../url-fetch';

import "./Details.css";

function CustomTabPanel(props) {

```

```
const { children, value, index, ...other } = props;

return (
  <div
    className="tab-panel"
    role="tabpanel"
    hidden={value !== index}
    id={`simple-tabpanel-${index}`}
    aria-labelledby={`simple-tab-${index}`}
    {...other}
    // Ensure it takes full width
  >
  {value === index && <Box className="tab-panel-value">{children}</Box>}
</div>
);
}

export default function BasicTabs() {
  const { id } = useParams();
  const [document, setDocument] = useState({});
  const [value, setValue] = React.useState(0);
  const [isLoading, setIsLoading] = useState(true);

  useEffect(() => {
    setIsLoading(true);
    fetchInstance('/api/lookup', { query: { id } })
      .then(response => {
        console.log(JSON.stringify(response))
        const doc = response.document;
        setDocument(doc);
        setIsLoading(false);
      })
      .catch(error => {
        console.log(error);
        setIsLoading(false);
      });
  }, [id]);

  const handleChange = (event, newValue) => {
    setValue(newValue);
  };

  if (isLoading || !id || Object.keys(document).length === 0) {
    return (
      <div className="loading-container">

C# models to support function app

The following models are used to support the functions in this app.

```

C#

using Azure.Search.Documents.Models;
using System.Text.Json.Serialization;

namespace WebSearch.Models
{
  public class RequestBodyLookUp
  {
    [JsonPropertyName("id")]
    public string Id { get; set; }
  }

  public class RequestBodySuggest
  {
    [JsonPropertyName("q")]
    public string SearchText { get; set; }
  }
}

```

```
[JsonPropertyName("top")]
public int Size { get; set; }

[JsonPropertyName("suggester")]
public string SuggesterName { get; set; }
}

public class RequestBodySearch
{
    [JsonPropertyName("q")]
    public string SearchText { get; set; }

    [JsonPropertyName("skip")]
    public int Skip { get; set; }

    [JsonPropertyName("top")]
    public int Size { get; set; }

    [JsonPropertyName("filters")]
    public List<SearchFilter> Filters { get; set; }
}

public class SearchFilter
{
    public string field { get; set; }
    public string value { get; set; }

Next steps

To continue learning more about Azure AI Search development, try this next tutorial about indexing:

- [Index Azure SQL data](#)

Tutorial: Optimize indexing using the push API

Azure AI Search supports two basic methods for [importing data](#) into a search index: *pushing* your data into the index programmatically or *pulling* your data by pointing an [indexer](#) to a supported data source.

This tutorial explains how to efficiently index data using the [push model](#) by batching requests and using an exponential backoff retry strategy. You can download and run the [sample application](#). This tutorial also explains the key aspects of the application and what factors to consider when indexing data.

In this tutorial, you use C# and the [Azure.Search.Documents library](#) from the Azure SDK for .NET to:

- ✓ Create an index
- ✓ Test various batch sizes to determine the most efficient size
- ✓ Index batches asynchronously
- ✓ Use multiple threads to increase indexing speeds
- ✓ Use an exponential backoff retry strategy to retry failed documents

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Visual Studio](#).

Download files

Source code for this tutorial is in the [optimize-data-indexing/v11](#) folder in the [Azure-Samples/azure-search-dotnet-scale](#) GitHub repository.

Key considerations

The following factors affect indexing speeds. For more information, see [Index large data sets](#).

- **Pricing tier and number of partitions(replicas)**: Adding partitions or upgrading your tier increases indexing speeds.
- **Index schema complexity**: Adding fields and field properties lowers indexing speeds. Smaller indexes are faster to index.
- **Batch size**: The optimal batch size varies based on your index schema and dataset.

- **Number of threads/workers:** A single thread doesn't take full advantage of indexing speeds.
- **Retry strategy:** An exponential backoff retry strategy is a best practice for optimum indexing.
- **Network data transfer speeds:** Data transfer speeds can be a limiting factor. Index data from within your Azure environment to increase data transfer speeds.

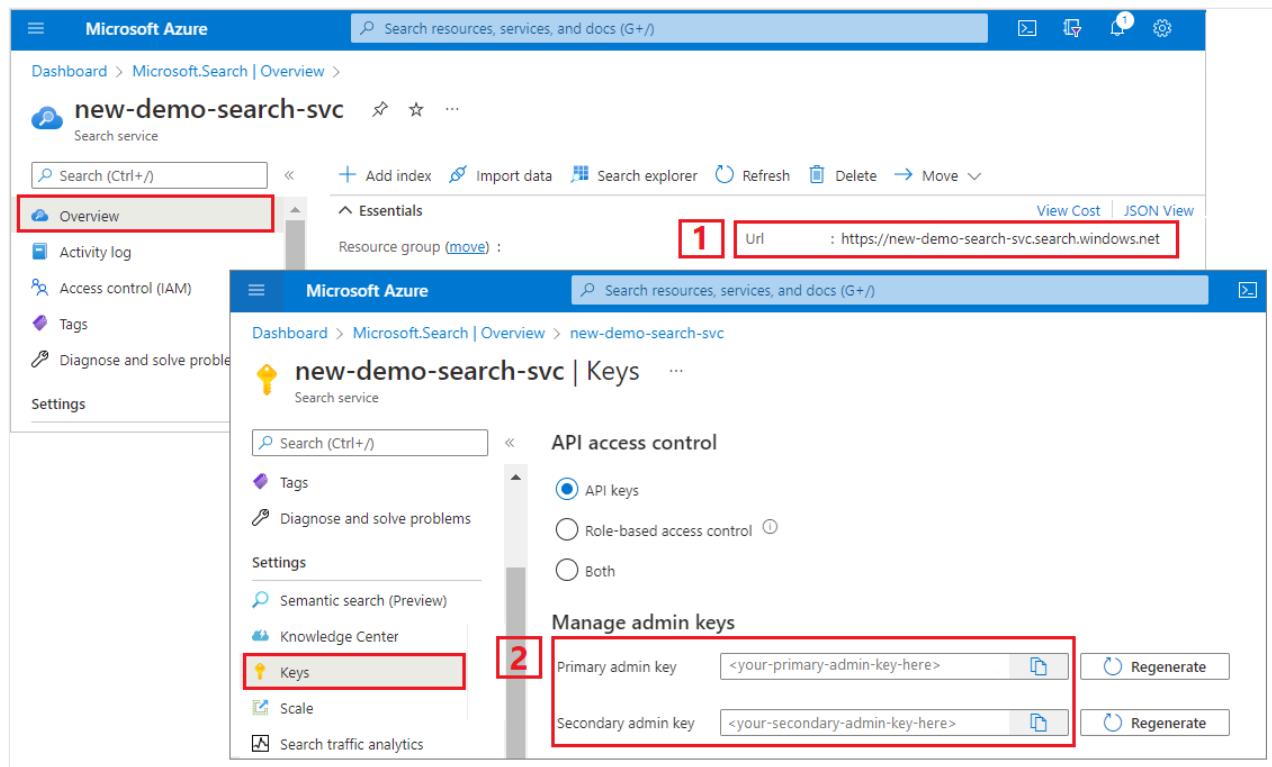

Create a search service

This tutorial requires an Azure AI Search service, which you can [create in the Azure portal](#). You can also [find an existing service](#) in your current subscription. To accurately test and optimize indexing speeds, we recommend using the same pricing tier you plan to use in production.

Get an admin key and URL for Azure AI Search

This tutorial uses key-based authentication. Copy an admin API key to paste into the `appsettings.json` file.

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview** and copy the endpoint. It should be in this format:
`https://my-service.search.windows.net`
3. From the left pane, select **Settings > Keys** and copy an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests to add, modify, or delete objects.

Set up your environment

1. Open the `OptimizeDataIndexing.sln` file in Visual Studio.
2. In Solution Explorer, edit the `appsettings.json` file with the connection information you collected in the previous step.

```
JSON
{
  "SearchServiceUri": "https://{{service-name}}.search.windows.net",
  "SearchServiceAdminApiKey": "",
  "SearchIndexName": "optimize-indexing"
}
```

Explore the code

After you update `appsettings.json`, the sample program in `OptimizeDataIndexing.sln` should be ready to build and run.

This code is derived from the C# section of [Quickstart: Full-text search](#), which provides detailed information about the basics of working with the .NET SDK.

This simple C#/NET console app performs the following tasks:

- Creates a new index based on the data structure of the C# `Hotel` class (which also references the `Address` class)
- Tests various batch sizes to determine the most efficient size
- Indexes data asynchronously
 - Using multiple threads to increase indexing speeds
 - Using an exponential backoff retry strategy to retry failed items

Before you run the program, take a minute to study the code and the index definitions for this sample. The relevant code is in several files:

- `Hotel.cs` and `Address.cs` contain the schema that defines the index
- `DataGenerator.cs` contains a simple class to make it easy to create large amounts of hotel data
- `ExponentialBackoff.cs` contains code to optimize the indexing process as described in this article
- `Program.cs` contains functions that create and delete the Azure AI Search index, indexes batches of data, and tests different batch sizes

Create the index

This sample program uses the Azure SDK for .NET to define and create an Azure AI Search index. It takes advantage of the `FieldBuilder` class to generate an index structure from a C# data model class.

The data model is defined by the `Hotel` class, which also contains references to the `Address` class. `FieldBuilder` drills down through multiple class definitions to generate a complex data structure for the index. Metadata tags are used to define the attributes of each field, such as whether it's searchable or sortable.

The following snippets from the `Hotel.cs` file specify a single field and a reference to another data model class.

```
C#
...
[SearchableField(IsSortable = true)]
public string HotelName { get; set; }
...
public Address Address { get; set; }
...
```

In the `Program.cs` file, the index is defined with a name and a field collection generated by the `FieldBuilder.Build(typeof(Hotel))` method, and then created as follows:

C#

```
private static async Task CreateIndexAsync(string indexName, SearchIndexClient indexClient)
{
    // Create a new search index structure that matches the properties of the Hotel
    // class.
    // The Address class is referenced from the Hotel class. The FieldBuilder
    // will enumerate these to create a complex data structure for the index.
    FieldBuilder builder = new FieldBuilder();
    var definition = new SearchIndex(indexName, builder.Build(typeof(Hotel)));

    await indexClient.CreateIndexAsync(definition);
}
```

Generate data

A simple class is implemented in the `DataGenerator.cs` file to generate data for testing. The purpose of this class is to make it easy to generate a large number of documents with a unique ID for indexing.

To get a list of 100,000 hotels with unique IDs, run the following code:

C#

```
long numDocuments = 100000;
DataGenerator dg = new DataGenerator();
List<Hotel> hotels = dg.GetHotels(numDocuments, "large");
```

There are two sizes of hotels available for testing in this sample: *small* and *large*.

The schema of your index affects indexing speeds. After you complete this tutorial, consider converting this class to generate data that best matches your intended index schema.

Test batch sizes

To load single or multiple documents into an index, Azure AI Search supports the following APIs:

- [Documents - Index \(REST API\)](#)
- [IndexDocumentsAction class](#)
- [IndexDocumentsBatch class](#)

Indexing documents in batches significantly improves indexing performance. These batches can be up to 1,000 documents or up to about 16 MB per batch.

Determining the optimal batch size for your data is a key component of optimizing indexing speeds. The two primary factors influencing the optimal batch size are:

- The schema of your index
- The size of your data

Because the optimal batch size depends on your index and your data, the best approach is to test different batch sizes to determine what results in the fastest indexing speeds for your scenario.

The following function demonstrates a simple approach to testing batch sizes.

C#

```
public static async Task TestBatchSizesAsync(SearchClient searchClient, int min = 100, int max = 1000, int step = 100, int numTries = 3)
{
    DataGenerator dg = new DataGenerator();

    Console.WriteLine("Batch Size \t Size in MB \t MB / Doc \t Time (ms) \t MB / Second");
    for (int numDocs = min; numDocs <= max; numDocs += step)
    {
        List<TimeSpan> durations = new List<TimeSpan>();
        double sizeInMb = 0.0;
        for (int x = 0; x < numTries; x++)
        {
            List<Hotel> hotels = dg.GetHotels(numDocs, "large");

            DateTime startTime = DateTime.Now;
            await UploadDocumentsAsync(searchClient, hotels).ConfigureAwait(false);
            DateTime endTime = DateTime.Now;
            durations.Add(endTime - startTime);

            sizeInMb = EstimateObjectSize(hotels);
        }

        var avgDuration = durations.Average(TimeSpan => TimeSpan.TotalMilliseconds);
        var avgDurationInSeconds = avgDuration / 1000;
        var mbPerSecond = sizeInMb / avgDurationInSeconds;

        Console.WriteLine("{0} \t\t {1} \t\t {2} \t\t {3} \t\t {4}", numDocs,
Math.Round(sizeInMb, 3), Math.Round(sizeInMb / numDocs, 3), Math.Round(avgDuration, 3), Math.Round(mbPerSecond, 3));

        // Pausing 2 seconds to let the search service catch its breath
        Thread.Sleep(2000);
    }

    Console.WriteLine();
}
```

Because not all documents are the same size (although they are in this sample), we estimate the size of the data we're sending to the search service. You can do this by using the following function that first converts the object to JSON and then determines its size in bytes. This technique allows us to determine which batch sizes are most efficient in terms of MB/s indexing speeds.

C#

```
// Returns size of object in MB
public static double EstimateObjectSize(object data)
{
    // converting object to byte[] to determine the size of the data
    BinaryFormatter bf = new BinaryFormatter();
    MemoryStream ms = new MemoryStream();
    byte[] Array;

    // converting data to json for more accurate sizing
    var json = JsonSerializer.Serialize(data);
    bf.Serialize(ms, json);
    Array = ms.ToArray();

    // converting from bytes to megabytes
    double sizeInMb = (double)Array.Length / 1000000;

    return sizeInMb;
}
```

The function requires a `SearchClient` plus the number of tries you'd like to test for each batch size. Because there might be variability in indexing times for each batch, try each batch three times by default to make the results more statistically significant.

C#

```
await TestBatchSizesAsync(searchClient, numTries: 3);
```

When you run the function, you should see an output in your console similar to the following example:

```

Deleting index...

Creating index...

Finding optimal batch size...

Batch Size      Size in MB      MB / Doc      Time (ms)      MB / Second
100            0.29            0.003          241.517        1.202
200            0.58            0.003          279.182        2.079
300            0.871           0.003          434.859        2.003
400            1.161           0.003          506.927        2.291
500            1.452           0.003          593.79         2.445
600            1.742           0.003          752.854        2.314
700            2.032           0.003          862.523        2.356
800            2.323           0.003          929.534        2.499
900            2.614           0.003          1082.359       2.415
1000           2.904          0.003          1255.456       2.313

Complete. Press any key to end application...

```

Identify which batch size is most efficient and use that batch size in the next step of this tutorial. You might see a plateau in MB/s across different batch sizes.

Index the data

Now that you identified the batch size you intend to use, the next step is to begin to index the data. To index data efficiently, this sample:

- Uses multiple threads/workers
- Implements an exponential backoff retry strategy

Uncomment lines 41 through 49, and then rerun the program. On this run, the sample generates and sends batches of documents, up to 100,000 if you run the code without changing the parameters.

Use multiple threads/workers

To take advantage of Azure AI Search's indexing speeds, use multiple threads to send batch indexing requests concurrently to the service.

Several of the [key considerations](#) can affect the optimal number of threads. You can modify this sample and test with different thread counts to determine the optimal thread count for your scenario. However, as long as you have several threads running concurrently, you should be able to take advantage of most of the efficiency gains.

As you ramp up the requests hitting the search service, you might encounter [HTTP status codes](#) indicating the request didn't fully succeed. During indexing, two common HTTP status codes are:

- **503 Service Unavailable:** This error means that the system is under heavy load and your request can't be processed at this time.
- **207 Multi-Status:** This error means that some documents succeeded, but at least one failed.

Implement an exponential backoff retry strategy

If a failure happens, you should retry requests using an [exponential backoff retry strategy](#).

Azure AI Search's .NET SDK automatically retries 503s and other failed requests, but you should implement your own logic to retry 207s. Open-source tools like [Polly](#) can be useful in a retry strategy.

In this sample, we implement our own exponential backoff retry strategy. We start by defining some variables, including the `maxRetryAttempts` and the initial `delay` for a failed request.

```
C#  
  
// Create batch of documents for indexing  
var batch = IndexDocumentsBatch.Upload(hotels);  
  
// Create an object to hold the result  
IndexDocumentsResult result = null;  
  
// Define parameters for exponential backoff  
int attempts = 0;  
TimeSpan delay = delay = TimeSpan.FromSeconds(2);  
int maxRetryAttempts = 5;
```

The results of the indexing operation are stored in the variable `IndexDocumentResult result`. This variable allows you to check if documents in the batch failed, as shown in the following example. If there's a partial failure, a new batch is created based on the failed documents' ID.

`RequestFailedException` exceptions should also be caught, as they indicate the request failed completely, and retried.

```
C#  
  
// Implement exponential backoff  
do  
{  
    try
```

```

{
    attempts++;
    result = await
searchClient.IndexDocumentsAsync(batch).ConfigureAwait(false);

    var failedDocuments = result.Results.Where(r => r.Succeeded != true).ToList();

    // handle partial failure
    if (failedDocuments.Count > 0)
    {
        if (attempts == maxRetryAttempts)
        {
            Console.WriteLine("[MAX RETRIES HIT] - Giving up on the batch
starting at {0}", id);
            break;
        }
        else
        {
            Console.WriteLine("[Batch starting at doc {0} had partial failure]", id);
            Console.WriteLine("[Retrying {0} failed documents] \n", failedDocuments.Count);

            // creating a batch of failed documents to retry
            var failedDocumentKeys = failedDocuments.Select(doc =>
doc.Key).ToList();
            hotels = hotels.Where(h =>
failedDocumentKeys.Contains(h.HotelId)).ToList();
            batch = IndexDocumentsBatch.Upload(hotels);

            Task.Delay(delay).Wait();
            delay = delay * 2;
            continue;
        }
    }

    return result;
}
catch (RequestFailedException ex)
{
    Console.WriteLine("[Batch starting at doc {0} failed]", id);
    Console.WriteLine("[Retrying entire batch] \n");

    if (attempts == maxRetryAttempts)
    {
        Console.WriteLine("[MAX RETRIES HIT] - Giving up on the batch starting
at {0}", id);
        break;
    }

    Task.Delay(delay).Wait();
    delay = delay * 2;
}
} while (true);

```

From here, wrap the exponential backoff code into a function so it can be easily called.

Another function is then created to manage the active threads. For simplicity, that function isn't included here but can be found in *ExponentialBackoff.cs*. You can call the function using the following command, where `hotels` is the data we want to upload, `1000` is the batch size, and `8` is the number of concurrent threads.

C#

```
await ExponentialBackoff.IndexData(indexClient, hotels, 1000, 8);
```

When you run the function, you should see an output similar to the following example:

When a batch of documents fails, an error is printed indicating the failure and that the batch is being retried.

```
[Batch starting at doc 6000 had partial failure]  
[Retrying 560 failed documents]
```

After the function finishes running, you can verify that all of the documents were added to the index.

Explore the index

After the program finishes running, you can explore the populated search index either programmatically or using the [Search explorer](#) in the Azure portal.

Programmatically

There are two main options for checking the number of documents in an index: the [Count Documents API](#) and the [Get Index Statistics API](#). Both paths require time to process, so don't be alarmed if the number of documents returned is initially lower than you expect.

Count Documents

The Count Documents operation retrieves a count of the number of documents in a search index.

C#

```
long indexDocCount = await searchClient.GetDocumentCountAsync();
```

Get Index Statistics

The Get Index Statistics operation returns a document count for the current index, plus storage usage. Index statistics take longer to update than document count.

C#

```
var indexStats = await indexClient.GetIndexStatisticsAsync(indexName);
```

Azure portal

In the Azure portal, from the left pane, find the **optimize-indexing** index in the **Indexes** list.

The **Document Count** and **Storage Size** are based on the [Get Index Statistics API](#) and can take several minutes to update.

Reset and rerun

In the early experimental stages of development, the most practical approach for design iteration is to delete the objects from Azure AI Search and allow your code to rebuild them. Resource names are unique. Deleting an object lets you recreate it using the same name.

The sample code for this tutorial checks for existing indexes and deletes them so that you can rerun your code.

You can also use the Azure portal to delete indexes.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the **All resources** or **Resource groups** link in the left-navigation pane.

Next step

To learn more about indexing large amounts data, try the following tutorial:

[Tutorial: Index large data from Apache Spark using SynapseML and Azure AI Search](#)

Last updated on 11/21/2025

Tutorial: Index large data from Apache Spark using SynapseML and Azure AI Search

In this Azure AI Search tutorial, you learn how to index and query large data loaded from a Spark cluster. You set up a Jupyter Notebook to:

- ✓ Load various forms (invoices) into a data frame in an Apache Spark session
- ✓ Analyze the forms to determine their features
- ✓ Assemble the resulting output into a tabular data structure
- ✓ Write the output to a search index hosted in Azure AI Search
- ✓ Explore and query over the content you created

This tutorial takes a dependency on [SynapseML](#)¹, an open-source library that supports massively parallel machine learning over big data. In SynapseML, search indexing and machine learning are exposed through *transformers* that perform specialized tasks. Transformers tap into a wide range of AI capabilities. In this exercise, you use the **AzureSearchWriter** APIs for analysis and AI enrichment.

Although Azure AI Search has native [AI enrichment](#), this tutorial shows you how to access AI capabilities outside of Azure AI Search. By using SynapseML instead of indexers or skills, you're not subject to data limits or other constraints associated with those objects.

💡 Tip

Watch a [short video of this demo](#)². The video expands on this tutorial with more steps and visuals.

Prerequisites

You need the `synapseml` library and several Azure resources. If possible, use the same subscription and region for your Azure resources and put everything into one resource group for simple cleanup later. The following links are for portal installs. The sample data is imported from a public site.

- [SynapseML package](#)¹
- [Azure AI Search](#) (any tier)²
- [Microsoft Foundry resource](#) (any tier) with an **API Kind** of `AI Services`³
- [Azure Databricks](#) (any tier) with Apache Spark 3.3.0 runtime⁴

¹ This link resolves to a tutorial for loading the package.

² You can use the Free tier to index the sample data, but [choose a higher tier](#) if your data volumes are large. For billable tiers, provide the [search API key](#) in the [Set up dependencies](#) step further on.

³ This tutorial uses Document Intelligence and Translator from Foundry Tools. In the instructions that follow, provide a [Foundry resource](#) key and the region. The same key works for both services. **For this tutorial, it's important that you use a Foundry resource with an API kind of AIServices.** You can check the API kind in the Azure portal on the [Overview](#) page of your Foundry resource. For more information about API kind, see [Attach a Foundry resource in Azure AI Search](#).

⁴ In this tutorial, Azure Databricks provides the Spark computing platform. We used the [portal instructions](#) to set up the cluster and workspace.

 **Note**

The preceding Azure resources support security features in the Microsoft Identity platform. For simplicity, this tutorial assumes key-based authentication, using endpoints and keys copied from the Azure portal pages of each service. If you implement this workflow in a production environment or share the solution with others, remember to replace hard-coded keys with integrated security or encrypted keys.

Create a Spark cluster and notebook

In this section, you create a cluster, install the `synapseml` library, and create a notebook to run the code.

1. In the Azure portal, find your Azure Databricks workspace and select **Launch workspace**.
2. On the left menu, select **Compute**.
3. Select **Create compute**.
4. Accept the default configuration. It takes several minutes to create the cluster.
5. Verify the cluster is operational and running. A green dot by the cluster name confirms its status.

The screenshot shows the Databricks interface. On the left, there's a sidebar with 'New', 'Workspace', and 'Recents'. The main area is titled 'Compute' and shows a search bar 'Search Demo Cluster' with a red box around it. Below the search bar are tabs for 'Configuration' (which is underlined), 'Notebooks (0)', 'Libraries', 'Event log', and 'Spark UI'.

6. After the cluster is created, install the `synapseml` library:

a. Select **Libraries** from the tabs at the top of the cluster's page.

b. Select **Install new**.

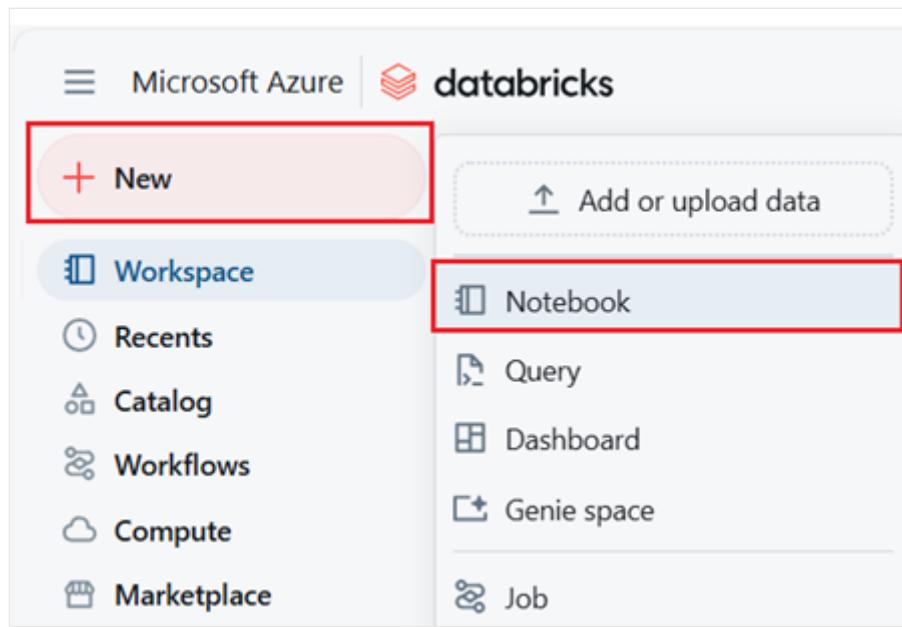

c. Select **Maven**.

d. In **Coordinates**, search for `com.microsoft.azure:synapseml_2.12:1.0.9`.

e. Select **Install**.

7. On the left menu, select **Create > Notebook**.

8. Give the notebook a name, select Python as the default language, and select the cluster that has the `synapseml` library.
9. Create seven consecutive cells. In the following sections, you paste code in these cells.

Set up dependencies

Paste the following code into the first cell of your notebook.

Replace the placeholders with endpoints and access keys for each resource. Provide a name for a new search index to be created for you. No other modifications are required, so run the code when you're ready.

This code imports multiple packages and sets up access to the Azure resources used in this tutorial.

Python

```
import os
from pyspark.sql.functions import udf, trim, split, explode, col,
monotonically_increasing_id, lit
from pyspark.sql.types import StringType
from synapse.ml.core.spark import FluentAPI

cognitive_services_key = "placeholder-azure-ai-foundry-key"
cognitive_services_region = "placeholder-azure-ai-foundry-region"

search_service = "placeholder-search-service-name"
search_key = "placeholder-search-service-admin-api-key"
search_index = "placeholder-for-new-search-index-name"
```

Load data into Spark

Paste the following code into the second cell. No modifications are required, so run the code when you're ready.

This code loads a few external files from an Azure storage account. The files are various invoices that are read into a data frame.

Python

```
def blob_to_url(blob):
    [prefix, postfix] = blob.split("@")
    container = prefix.split("/")[-1]
    split_postfix = postfix.split("/")
    account = split_postfix[0]
    filepath = "/".join(split_postfix[1:])
    return "https://{}//{}//{}//{}".format(account, container, filepath)

df2 = (spark.read.format("binaryFile")
       .load("wasbs://publicwasb@mmlspark.blob.core.windows.net/form_subset/*")
       .select("path")
       .limit(10)
       .select(udf(blob_to_url, StringType())("path").alias("url"))
       .cache())

display(df2)
```

Add document intelligence

Paste the following code into the third cell. No modifications are required, so run the code when you're ready.

This code loads the [AnalyzeInvoices transformer](#) and passes a reference to the data frame containing the invoices. It calls the prebuilt [invoice model](#) of Azure Document Intelligence in Foundry Tools to extract information from the invoices.

Python

```
from synapse.ml.services import AnalyzeInvoices

analyzed_df = (AnalyzeInvoices()
               .setSubscriptionKey(cognitive_services_key)
               .setLocation(cognitive_services_region)
               .setImageUrlCol("url")
               .setOutputCol("invoices")
               .setErrorCol("errors")
               .setConcurrency(5))
```

```

    .transform(df2)
    .cache()

display(analyzed_df)

```

The output should look similar to the following screenshot. Notice how the forms analysis is packed into a densely structured column, which is difficult to work with. The next transformation resolves this issue by parsing the column into rows and columns.

Table	Data Profile	
url	errors	invoices
https://mmlsparkdemo.blob.core.windows.net/analyzed/invoices.pdf	null	<pre> object status: "succeeded" createdDateTime: "2022-08-23T19:58:16Z" lastUpdatedDateTime: "2022-08-23T19:58:20Z" analyzeResult: version: "2.1.0" readResults: [{"page": 1, "language": null, "angle": 0, "width": 8.5, "height": 11, "unit": "inch", "lines": null}] pageResults: [{"page": 1, "keyValuePairs": null, "tables": [{"rows": 4, "columns": 8, "cells": [{"rowIndex": 0, "columnIndex": 0, "text": "Item", "boundingBox": [1.1026, 4.8201, 1.4418, 4.8201, 1.4418, 5.0852, 1.1026, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 1, "text": "Qty", "boundingBox": [1.4418, 4.8201, 1.9115, 4.8201, 1.9115, 5.0852, 1.4418, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 2, "text": "Description", "boundingBox": [1.9115, 4.8201, 4.2928, 4.8201, 4.2993, 5.0852, 1.9115, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 3, "text": "Price", "boundingBox": [4.2928, 4.8201, 4.9322, 4.8201, 4.9322, 5.0852, 4.2993, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 4, "text": "Discount", "boundingBox": [4.9322, 4.8201, 5.6433, 4.8201, 5.6498, 5.0852, 4.9322, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 5, "text": "(Pct)", "boundingBox": [5.6433, 4.8201, 6.1261, 4.8201, 6.1326, 5.0852, 5.6498, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 6, "text": "Tax", "boundingBox": [6.1261, 4.8201, 6.7263, 4.8201, 6.7263, 5.0852, 6.1326, 5.0852], "isHeader": true, "elements": null}, {"rowIndex": 0, "columnIndex": 7, "text": "LineTotal", "boundingBox": [6.7263, 4.8201, 7.4201, 4.8201, 7.4201, 5.0852, 6.7263, 5.0852], "isHeader": true, "elements": null}], "isHeader": true, "elements": null}, {"rowIndex": 1, "columnIndex": 0, "text": "1", "boundingBox": [1.1026, 4.8201, 1.4418, 4.8201, 1.4418, 5.0852, 1.1026, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 1, "text": "1", "boundingBox": [1.4418, 4.8201, 1.9115, 4.8201, 1.9115, 5.0852, 1.4418, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 2, "text": "Laptop", "boundingBox": [1.9115, 4.8201, 4.2928, 4.8201, 4.2993, 5.0852, 1.9115, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 3, "text": "100", "boundingBox": [4.2928, 4.8201, 4.9322, 4.8201, 4.9322, 5.0852, 4.2993, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 4, "text": "0", "boundingBox": [4.9322, 4.8201, 5.6433, 4.8201, 5.6498, 5.0852, 4.9322, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 5, "text": "0", "boundingBox": [5.6433, 4.8201, 6.1261, 4.8201, 6.1326, 5.0852, 5.6498, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 6, "text": "0", "boundingBox": [6.1261, 4.8201, 6.7263, 4.8201, 6.7263, 5.0852, 6.1326, 5.0852], "isHeader": false, "elements": null}, {"rowIndex": 1, "columnIndex": 7, "text": "100", "boundingBox": [6.7263, 4.8201, 7.4201, 4.8201, 7.4201, 5.0852, 6.7263, 5.0852], "isHeader": false, "elements": null}], "isHeader": false, "elements": null} </pre>

Restructure document intelligence output

Paste the following code into the fourth cell and run it. No modifications are required.

This code loads [FormOntologyLearner](#), a transformer that analyzes the output of Azure Document Intelligence transformers and infers a tabular data structure. The output of AnalyzeInvoices is dynamic and varies based on the features detected in your content. Furthermore, the transformer consolidates the output into a single column. Because the output is dynamic and consolidated, it's difficult to use in downstream transformations that require more structure.

FormOntologyLearner extends the utility of the AnalyzeInvoices transformer by looking for patterns that can be used to create a tabular data structure. Organizing the output into multiple columns and rows makes the content consumable in other transformers, like AzureSearchWriter.

Python

```

from synapse.ml.cognitive import FormOntologyLearner

itemized_df = (FormOntologyLearner()
    .setInputCol("invoices")
    .setOutputCol("extracted"))

```

```

    .fit(analyzed_df)
    .transform(analyzed_df)
    .select("url", "extracted.*").select("*", explode(col("Items")).alias("Item"))
    .drop("Items").select("Item.*", "*").drop("Item"))

display(itemized_df)

```

Notice how this transformation recasts the nested fields into a table, which enables the next two transformations. This screenshot is trimmed for brevity. If you're following along in your own notebook, you have 19 columns and 26 rows.

Table Data Profile							
	ProductCode	Tax	Quantity	UnitPrice	Description	Amount	url
1	61	3.78	1	54	One sat on shoe gnome	57.78	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117876.pdf
2	23	17.22	2	123	White Door	263.22	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117876.pdf
3	42	5.67	1	90	Metal Shelving	86.67	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117876.pdf
4	35	4.2	2	30	Wood Pack	64.2	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117874.pdf
5	45	30.45	3	145	Wooden Saw	465.45	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117874.pdf
6	23	25.83	3	123	White Door	394.83	https://mmlsparkdemo.blob.core.windows.net/ignite2021/form_subset/Invoice117874.pdf
7							

Showing all 26 rows.

Add translations

Paste the following code into the fifth cell. No modifications are required, so run the code when you're ready.

This code loads [Translate](#), a transformer that calls Azure Translator in Foundry Tools. The original text, which is in English in the "Description" column, is machine-translated into various languages. All of the output is consolidated into the "output.translations" array.

Python

```

from synapse.ml.cognitive import Translate

translated_df = (Translate()
    .setSubscriptionKey(cognitive_services_key)
    .setLocation(cognitive_services_region)
    .setTextCol("Description")
    .setErrorCol("TranslationError")
    .setOutputCol("output")
    .setToLanguage(["zh-Hans", "fr", "ru", "cy"])
    .setConcurrency(5)
    .transform(itemized_df)
    .withColumn("Translations", col("output.translations")[0])
    .drop("output", "TranslationError")
    .cache())

display(translated_df)

```

💡 Tip

To check for translated strings, scroll to the end of the rows.

Add a search index with AzureSearchWriter

Paste the following code in the sixth cell and run it. No modifications are required.

This code loads [AzureSearchWriter](#). It consumes a tabular dataset and infers a search index schema that defines one field for each column. Because the translations structure is an array, it's articulated in the index as a complex collection with subfields for each language translation. The generated index has a document key and uses the default values for fields created using the [Create Index REST API](#).

Python

```
from synapse.ml.cognitive import *

(translated_df.withColumn("DocID", monotonically_increasing_id().cast("string"))
 .withColumn("SearchAction", lit("upload"))
 .writeToAzureSearch(
     subscriptionKey=search_key,
     actionCol="SearchAction",
     serviceName=search_service,
     indexName=search_index,
     keyCol="DocID",
 ))
```

To explore the index definition created by AzureSearchWriter, check the search service pages in the Azure portal.

⚠ Note

If you can't use the default search index, you can provide an external custom definition in JSON, passing its URL as a string in the "indexJson" property. Generate the default index first so that you know which fields to specify, and then follow with customized properties if you need specific analyzers, for example.

Query the index

Paste the following code into the seventh cell and run it. No modifications are required, except that you might want to vary the syntax or try more examples to further explore your content:

- [Query syntax](#)
- [Query examples](#)

There's no transformer or module that issues queries. This cell is a simple call to the [Search Documents REST API](#).

This particular example is searching for the word "door" (`"search": "door"`). It also returns a "count" of the number of matching documents and selects just the contents of the "Description" and "Translations" fields for the results. If you want to see the full list of fields, remove the "select" parameter.

Python

```
import requests

url = "https://{}.search.windows.net/indexes/{}/docs/search?api-version=2025-09-01".format(search_service, search_index)
requests.post(url, json={"search": "door", "count": "true", "select": "Description, Translations"}, headers={"api-key": search_key}).json()
```

The following screenshot shows the cell output for sample script.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the [All resources](#) or [Resource groups](#) link in the left-navigation pane.

Next steps

In this tutorial, you learned about the [AzureSearchWriter](#) transformer in SynapseML, which is a new way of creating and loading search indexes in Azure AI Search. The transformer takes structured JSON as an input. FormOntologyLearner can provide the necessary structure for output produced by the Azure Document Intelligence transformers in SynapseML.

As a next step, review the other SynapseML tutorials that produce transformed content you might want to explore through Azure AI Search:

Tutorial: Text Analytics with Foundry Tools

Tutorial: Index Azure SQL data using the .NET SDK

Article • 04/09/2025

Learn how to configure an [indexer](#) to extract searchable data from Azure SQL Database and send it to a search index in Azure AI Search.

In this tutorial, you use C# and the [Azure SDK for .NET](#) to:

- ✓ Create a data source that connects to Azure SQL Database
- ✓ Create an indexer
- ✓ Run an indexer to load data into an index
- ✓ Query an index as a verification step

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Azure SQL Database](#) using SQL Server authentication.
- [Azure AI Search](#). [Create a service](#) or [find an existing service](#) in your current subscription.
- [Visual Studio](#).

ⓘ Note

You can use a free search service for this tutorial. The Free tier limits you to three indexes, three indexers, and three data sources. This tutorial creates one of each. Before you start, make sure you have room on your service to accept the new resources.

Download files

Source code for this tutorial is in the [DotNetHowToIndexer](#) folder in the [Azure-Samples/search-dotnet-getting-started](#) GitHub repository.

Create services

This tutorial uses Azure AI Search for indexing and queries and Azure SQL Database as an external data source. If possible, create both services in the same region and resource group for proximity and manageability. In practice, Azure SQL Database can be in any region.

Start with Azure SQL Database

This tutorial provides the *hotels.sql* file in the sample download to populate the database. Azure AI Search consumes flattened rowsets, such as one generated from a view or query. The SQL file in the sample solution creates and populates a single table.

If you have an existing Azure SQL Database resource, you can add the hotels table to it starting at the **Open query** step.

1. Create an Azure SQL database.

Server configuration for the database is important:

- Choose the SQL Server authentication option that prompts you to specify a username and password. You need this for the ADO.NET connection string used by the indexer.
- Choose a public connection, which makes this tutorial easier to complete. Public isn't recommended for production, and we recommend [deleting this resource](#) at the end of the tutorial.

The screenshot shows the 'Create SQL Database' wizard in the Azure portal. The 'Networking' tab is selected. In the 'Connectivity method' section, the 'Public endpoint' option is selected and highlighted with a red box. In the 'Firewall rules' section, the 'Allow Azure services and resources to access this server' option is set to 'Yes' and highlighted with a red box. The 'Add current client IP address' option is also set to 'Yes'.

2. In the Azure portal, go to the new resource.

3. Add a firewall rule that allows access from your client. You can run `ipconfig` from a command prompt to get your IP address.

4. Use the Query editor to load the sample data. On the navigation pane, select **Query editor (preview)** and enter the username and password of the server admin.

If you get an access denied error, copy the client IP address from the error message, open the network security page for the server, and add an inbound rule that allows access from your client.

5. In Query editor, select **Open query** and navigate to the location of *hotels.sql* file on your local computer.

6. Select the file and select **Open**. The script should look similar to the following screenshot:

```
Query 1 × Query 2 ×

Run Cancel query Save query Export data as .json ...

1 ALTER DATABASE CURRENT
2 SET CHANGE_TRACKING = ON
3 (CHANGE_RETENTION = 2 DAYS, AUTO_CLEANUP = ON)
4
5 CREATE TABLE Hotels (
6     [HotelId] nvarchar(450) NOT NULL PRIMARY KEY,
7     [BaseRate] float NULL,
8     [Category] nvarchar(max) NULL,
9     [Description] nvarchar(max) NULL,
10    [Description_fr] nvarchar(max) NULL,
11    [HotelName] nvarchar(max) NULL,
12    [Tags] nvarchar(max) NULL,
13    [IsDeleted] bit NOT NULL,
14    [LastRenovationDate] DateTime NULL,
)

Results Messages

Query succeeded: Affected rows: 0Affected rows: 3
```

7. Select **Run** to execute the query. In the **Results** pane, you should see a query succeeded message for three rows.

8. To return a rowset from this table, you can execute the following query as a verification step:

```
SQL

SELECT * FROM Hotels
```

9. Copy the ADO.NET connection string for the database. Under **Settings > Connection Strings**, copy the ADO.NET connection string, which should be similar to the following example:

SQL

```
Server=tcp:<YOUR-DATABASE-NAME>.database.windows.net,1433;Initial Catalog=hotels-db;Persist Security Info=False;User ID=<YOUR-USER-NAME>;Password=<YOUR-PASSWORD>;MultipleActiveResultSets=False;Encrypt=True;TrustServerCertificate=False;Connection Timeout=30;
```

You'll need this connection string to set up your environment in the next step.

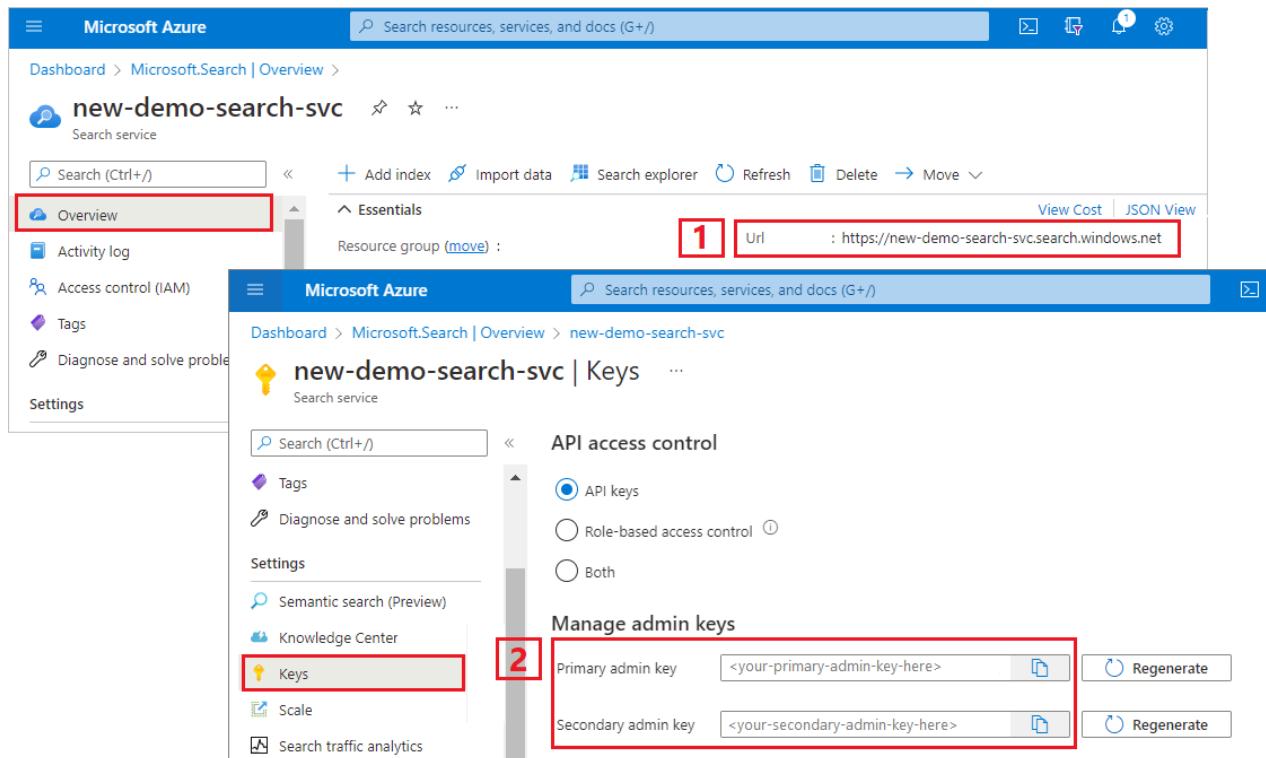

Azure AI Search

The next component is Azure AI Search, which you can [create in the Azure portal](#). You can use the Free tier to complete this tutorial.

Get an admin key and URL for Azure AI Search

API calls require the service URL and an access key. A search service is created with both, so if you added Azure AI Search to your subscription, follow these steps to get the necessary information:

1. Sign in to the [Azure portal](#). On your service **Overview** page, copy the endpoint URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. On **Settings > Keys**, get an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either the primary or secondary key on requests for adding, modifying, and deleting objects.

Set up your environment

1. Start Visual Studio and open `DotNetHowToIndexers.sln`.
2. In Solution Explorer, open `appsettings.json` to provide connection information.
3. For `SearchServiceEndPoint`, if the full URL on your service **Overview** page is `https://my-demo-service.search.windows.net`, provide the entire URL.
4. For `AzureSqlConnectionString`, the string format is similar to `"Server=tcp:<your-database-name>.database.windows.net,1433;Initial Catalog=hotels-db;Persist Security Info=False;User ID=<your-user-name>;Password=<your-password>;MultipleActiveResultSets=False;Encrypt=True;TrustServerCertificate=False;Connection Timeout=30;"`.

```
JSON

{
  "SearchServiceEndPoint": "<placeholder-search-full-url>",
  "SearchServiceAdminApiKey": "<placeholder-admin-key-for-search-service>",
  "AzureSqlConnectionString": "<placeholder-ADO.NET-connection-string>",
}
```

5. Replace the user password in the SQL connection string with a valid password. While the database and usernames will copy over, you must enter the password manually.

Create the pipeline

Indexers require a data source object and an index. The relevant code is in two files:

- *hotel.cs* contains a schema that defines the index
- *Program.cs* contains functions for creating and managing structures in your service

In hotel.cs

The index schema defines the fields collection, including attributes specifying allowed operations, such as whether a field is full-text searchable, filterable, or sortable, as shown in the following field definition for `HotelName`. A [SearchableField](#) is, by definition, full-text searchable. Other attributes are explicitly assigned.

```
C#  
.  
.  
[SearchableField(IsFilterable = true, IsSortable = true)]  
[JsonPropertyName("hotelName")]  
public string HotelName { get; set; }  
.  
.
```

A schema can also include other elements, such as scoring profiles for boosting a search score and custom analyzers. However, for this tutorial, the schema is sparsely defined, consisting only of fields found in the sample datasets.

In Program.cs

The main program includes logic for creating [an indexer client](#), an index, a data source, and an indexer. The code checks for and deletes existing resources of the same name, assuming that you might run this program multiple times.

The data source object is configured with settings that are specific to Azure SQL Database resources, including [partial or incremental indexing](#) for using the built-in [change detection features](#) of Azure SQL. The source demo hotels database in Azure SQL has a "soft delete" column named `IsDeleted`. When this column is set to true in the database, the indexer removes the corresponding document from the Azure AI Search index.

```
C#  
  
Console.WriteLine("Creating data source...");  
  
var dataSource =  
    new SearchIndexerDataSourceConnection(  
        . . . );
```

```

    "hotels-sql-ds",
    SearchIndexerDataSourceType.AzureSql,
    configuration[ "AzureSQLConnectionString" ],
    new SearchIndexerDataContainer( "hotels" ));

indexerClient.CreateOrUpdateDataSourceConnection(dataSource);

```

An indexer object is platform agnostic, where configuration, scheduling, and invocation are the same regardless of the source. This example indexer includes a schedule and a reset option that clears the indexer history. It also calls a method to create and run the indexer immediately. To create or update an indexer, use [CreateOrUpdateIndexerAsync](#).

C#

```

Console.WriteLine("Creating Azure SQL indexer...");

var schedule = new IndexingSchedule(TimeSpan.FromDays(1))
{
    StartTime = DateTimeOffset.Now
};

var parameters = new IndexingParameters()
{
    BatchSize = 100,
    MaxFailedItems = 0,
    MaxFailedItemsPerBatch = 0
};

// Indexer declarations require a data source and search index.
// Common optional properties include a schedule, parameters, and field mappings
// The field mappings below are redundant due to how the Hotel class is defined,
// but
// we included them anyway to show the syntax
var indexer = new SearchIndexer("hotels-sql-idxr", dataSource.Name,
searchIndex.Name)
{
    Description = "Data indexer",
    Schedule = schedule,
    Parameters = parameters,
    FieldMappings =
    {
        new FieldMapping("_id") {TargetFieldName = "HotelId"},
        new FieldMapping("Amenities") {TargetFieldName = "Tags"}
    }
};

await indexerClient.CreateOrUpdateIndexerAsync(indexer);

```

Indexer runs are usually scheduled, but during development, you might want to run the indexer immediately using [RunIndexerAsync](#).

C#

```
Console.WriteLine("Running Azure SQL indexer...");

try
{
    await indexerClient.RunIndexerAsync(indexer.Name);
}
catch (RequestFailedException ex) when (ex.Status == 429)
{
    Console.WriteLine("Failed to run indexer: {0}", ex.Message);
}
```

Build the solution

Select F5 to build and run the solution. The program executes in debug mode. A console window reports the status of each operation.

```
Creating index...
Creating data source...
Creating Azure SQL indexer...
Running Azure SQL indexer...
Press any key to continue...
```

Your code runs locally in Visual Studio, connecting to your search service on Azure, which in turn connects to Azure SQL Database and retrieves the dataset. With this many operations, there are several potential points of failure. If you get an error, check the following conditions first:

- Search service connection information that you provide is the full URL. If you only entered the service name, operations stop at index creation, with a failure to connect error.
- Database connection information in *appsettings.json*. It should be the ADO.NET connection string obtained from the Azure portal, modified to include a username and password that are valid for your database. The user account must have permission to retrieve data. Your local client IP address must be allowed inbound access through the firewall.
- Resource limits. Recall that the Free tier has limits of three indexes, indexers, and data sources. A service at the maximum limit can't create new objects.

Search

Use the Azure portal to verify object creation, and then use **Search explorer** to query the index.

1. Sign in to the [Azure portal](#) and go to your search service. From the left pane, open each page to verify the objects are created. **Indexes**, **Indexers**, and **Data Sources** should have **hotels-sql-idx**, **hotels-sql-indexer**, and **hotels-sql-ds**, respectively.
2. On the **Indexes** tab, select the **hotels-sql-idx** index. On the hotels page, **Search explorer** is the first tab.
3. Select **Search** to issue an empty query.

The three entries in your index are returned as JSON documents. Search explorer returns documents in JSON so that you can view the entire structure.

The screenshot shows the Azure Search Explorer interface for the 'hotels-sql-idx' index. The top navigation bar includes 'Dashboard > Indexes > hotels-sql-idx'. Below the navigation is a toolbar with 'Save', 'Discard', 'Refresh', 'Create Demo App', 'Edit JSON', and 'Delete' buttons. The main area displays document statistics: 'Documents' (3) and 'Storage' (19.77 KB). A navigation bar below the stats includes tabs for 'Search explorer' (which is selected and highlighted with a red box), 'Fields', 'CORS', 'Scoring profiles', 'Semantic configurations', and 'Vector profiles'. To the right of the tabs are 'Query options' and 'View' dropdowns. A search bar with a magnifying glass icon and a 'Search' button are located at the bottom of the main area. The 'Results' section contains a table with 35 rows of JSON document data. The first few rows are:

Line Number	Document Content
18	{
19	"@search.score": 1,
20	"hotelID": "2",
21	"baseRate": 79.99,
22	"description": "Cheapest hotel in town",
23	"description_fr": "Hôtel le moins cher en ville",
24	"hotelName": "Roach Motel",
25	"category": "Budget",
26	"tags": [
27	"motel",
28	"budget"
29],
30	"parkingIncluded": true,
31	"smokingAllowed": true,
32	"lastRenovationDate": "1982-04-28T00:00:00Z",
33	"rating": 1
34	},
35	{

4. Switch to **JSON view** so that you can enter query parameters.

The screenshot shows the Azure Search Explorer interface with the 'JSON' tab selected. The JSON input field contains the following search query:

```
{
  "search": "river",
  "count": true
}
```

This query invokes full text search on the term `river`. The result includes a count of the matching documents. Returning the count of matching documents is helpful in testing scenarios where you have a large index with thousands or millions of documents. In this case, only one document matches the query.

5. Enter parameters that limit search results to fields of interest.

JSON

```
{  
  "search": "river",  
  "select": "hotelId, hotelName, baseRate, description",  
  "count": true  
}
```

The query response is reduced to selected fields, resulting in more concise output.

Reset and rerun

In the early experimental stages of development, the most practical approach for design iteration is to delete the objects from Azure AI Search and allow your code to rebuild them. Resource names are unique. Deleting an object lets you recreate it using the same name.

The sample code for this tutorial checks for existing objects and deletes them so that you can rerun your code.

You can also use the Azure portal to delete indexes, indexers, and data sources.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the All resources or Resource groups link in the left-navigation pane.

Next steps

Now that you're familiar with the basics of SQL Database indexing, take a closer look at indexer configuration:

Configure a SQL Database indexer

Tutorial: Index nested JSON blobs from Azure Storage using REST

Azure AI Search can index JSON documents and arrays in Azure Blob Storage using an [indexer](#) that knows how to read semi-structured data. Semi-structured data contains tags or markings that separate content within the data. It splits the difference between unstructured data, which must be fully indexed, and formally structured data that adheres to a data model, such as a relational database schema that can be indexed on a per-field basis.

This tutorial shows you how to index nested JSON arrays, using a REST client and the [Search REST APIs](#) to:

- ✓ Set up sample data and configure an `azureblob` data source
- ✓ Create an Azure AI Search index to contain searchable content
- ✓ Create and run an indexer to read the container and extract searchable content
- ✓ Search the index you just created

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Azure Storage](#).
- [Azure AI Search](#). [Create a service](#) or [find an existing service](#) in your current subscription.
- [Visual Studio Code](#) with a [REST client](#).

Note

You can use a free search service for this tutorial. The Free tier limits you to three indexes, three indexers, and three data sources. This tutorial creates one of each. Before you start, make sure you have room on your service to accept the new resources.

Download files

Download a zip file of the sample data repository and extract the contents. [Learn how](#).

- [ny-philharmonic-free](#)

The sample data is a single JSON file that contains a JSON array and 1,521 nested JSON elements. The data originates from the [NY Philharmonic Performance History](#) on Kaggle. We

chose one JSON file to stay under the storage limits of the Free tier.

Here's the first nested JSON in the file. The remainder of the file includes 1,520 other instances of concert performances.

JSON

```
{  
  "id": "7358870b-65c8-43d5-ab56-514bde52db88-0.1",  
  "programID": "11640",  
  "orchestra": "New York Philharmonic",  
  "season": "2011-12",  
  "concerts": [  
    {  
      "eventType": "Non-Subscription",  
      "Location": "Manhattan, NY",  
      "Venue": "Avery Fisher Hall",  
      "Date": "2011-09-07T04:00:00Z",  
      "Time": "7:30PM"  
    },  
    {  
      "eventType": "Non-Subscription",  
      "Location": "Manhattan, NY",  
      "Venue": "Avery Fisher Hall",  
      "Date": "2011-09-08T04:00:00Z",  
      "Time": "7:30PM"  
    }  
,  
  ],  
  "works": [  
    {  
      "ID": "5733*",  
      "composerName": "Bernstein, Leonard",  
      "workTitle": "WEST SIDE STORY (WITH FILM)",  
      "conductorName": "Newman, David",  
      "soloists": []  
    },  
    {  
      "ID": "0*",  
      "interval": "Intermission",  
      "soloists": []  
    }  
  ]  
}
```

Upload sample data to Azure Storage

1. In Azure Storage, create a new container named **ny-philharmonic-free**.
2. [Upload the sample data files](#).

3. Get a storage connection string so that you can formulate a connection in Azure AI Search.

a. On the left, select **Access keys**.

b. Copy the connection string for either key one or key two. The connection string is similar to the following example:

HTTP

```
DefaultEndpointsProtocol=https;AccountName=<your account name>;AccountKey=<your account key>;EndpointSuffix=core.windows.net
```

Copy a search service URL and API key

For this tutorial, connections to Azure AI Search require an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Managed identities](#).

1. Sign in to the [Azure portal](#) and select your search service.

2. From the left pane, select **Overview** and copy the endpoint. It should be in this format:

```
https://my-service.search.windows.net
```

3. From the left pane, select **Settings > Keys** and copy an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests to add, modify, or delete objects.

The screenshot displays two separate windows of the Microsoft Azure portal. The top window is titled 'new-demo-search-svc' and shows the 'Overview' tab selected. A red box highlights the 'Overview' tab, and another red box highlights the URL 'https://new-demo-search-svc.search.windows.net'. The bottom window is also titled 'new-demo-search-svc' and shows the 'Keys' tab selected. A red box highlights the 'Keys' tab, and another red box highlights the 'Primary admin key' and 'Secondary admin key' fields, which both contain placeholder text '<your-primary-admin-key-here>' and '<your-secondary-admin-key-here>'. Both of these fields have 'Regenerate' buttons to their right.

Set up your REST file

1. Start Visual Studio Code and create a new file.
2. Provide values for variables used in the request.

```
HTTP

@baseUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE
@apiKey = PUT-YOUR-ADMIN-API-KEY-HERE
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE
@blobContainer = PUT-YOUR-CONTAINER-NAME-HERE
```

3. Save the file using a `.rest` or `.http` file extension.

For help with the REST client, see [Quickstart: Full-text search using REST](#).

Create a data source

[Create Data Source \(REST\)](#) creates a data source connection that specifies what data to index.

```
HTTP

### Create a data source
POST {{baseUrl}}/datasources?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}
```

```
{
    "name" : "ny-philharmonic-ds",
    "description": null,
    "type": "azureblob",
    "subtype": null,
    "credentials": {
        "connectionString": "{{storageConnection}}"
    },
    "container": {
        "name": "{{blobContainer}}",
        "query": null
    },
    "dataChangeDetectionPolicy": null,
    "dataDeletionDetectionPolicy": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
ETag: "0x8DC43A5FDB8448F"
Location: https://<YOUR-SEARCH-SERVICE-NAME>.search.windows.net:443/datasources('ny-philharmonic-ds')?api-version=2025-09-01
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 7ca53f73-1054-4959-bc1f-616148a9c74a
elapsed-time: 111
Date: Wed, 13 Mar 2024 21:38:58 GMT
Connection: close

{
    "@odata.context": "https://<YOUR-SEARCH-SERVICE-NAME>.search.windows.net/$metadata#datasources/$entity",
    "@odata.etag": "\"0x8DC43A5FDB8448F\"",
    "name": "ny-philharmonic-ds",
    "description": null,
    "type": "azureblob",
    "subtype": null,
    "credentials": {
        "connectionString": null
    },
    "container": {
        "name": "ny-philharmonic-free",
        "query": null
    },
    "dataChangeDetectionPolicy": null,
    "dataDeletionDetectionPolicy": null,
```

```
        "encryptionKey": null  
    }
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the parameters and their attributes.

For nested JSON, the index fields must be identical to the source fields. Currently, Azure AI Search doesn't support field mappings to nested JSON, so field names and data types must match completely. The following index aligns to the JSON elements in the raw content.

HTTP

```
### Create an index  
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1  
Content-Type: application/json  
api-key: {{apiKey}}  
  
{  
    "name": "ny-philharmonic-index",  
    "fields": [  
        {"name": "programID", "type": "Edm.String", "key": true, "searchable": true,  
        "retrievable": true, "filterable": true, "facetable": true, "sortable": true},  
        {"name": "orchestra", "type": "Edm.String", "searchable": true,  
        "retrievable": true, "filterable": true, "facetable": true, "sortable": true},  
        {"name": "season", "type": "Edm.String", "searchable": true, "retrievable":  
        true, "filterable": true, "facetable": true, "sortable": true},  
        {"name": "concerts", "type": "Collection(Edm.ComplexType)",  
        "fields": [  
            { "name": "eventType", "type": "Edm.String", "searchable": true,  
            "retrievable": true, "filterable": false, "sortable": false, "facetable": false},  
            { "name": "Location", "type": "Edm.String", "searchable": true,  
            "retrievable": true, "filterable": true, "sortable": false, "facetable": true },  
            { "name": "Venue", "type": "Edm.String", "searchable": true,  
            "retrievable": true, "filterable": true, "sortable": false, "facetable": true },  
            { "name": "Date", "type": "Edm.String", "searchable": false,  
            "retrievable": true, "filterable": true, "sortable": false, "facetable": true },  
            { "name": "Time", "type": "Edm.String", "searchable": false,  
            "retrievable": true, "filterable": true, "sortable": false, "facetable": true }  
        ]  
    ],  
    { "name": "works", "type": "Collection(Edm.ComplexType)",  
    "fields": [  
        { "name": "ID", "type": "Edm.String", "searchable": true, "retrievable":  
        true, "filterable": false, "sortable": false, "facetable": false},  
        { "name": "composerName", "type": "Edm.String", "searchable": true,  
        "retrievable": true, "filterable": true, "sortable": false, "facetable": true },  
        { "name": "workTitle", "type": "Edm.String", "searchable": true,  
        "retrievable": true, "filterable": true, "sortable": false, "facetable": true },  
        { "name": "conductorName", "type": "Edm.String", "searchable": true,
```

```

    "retrievable": true, "filterable": true, "sortable": false, "facetable": true },
        { "name": "soloists", "type": "Collection(Edm.String)", "searchable": true,
        "retrievable": true, "filterable": true, "sortable": false, "facetable": true }
    }
]
}
}

```

Key points:

- You can't use [field mappings](#) to reconcile differences in field names or data types. This index schema is designed to mirror the raw content.
- Nested JSON is modeled as `Collection(Edm.ComplexType)`. In the raw content, there are multiple concerts for each season, and multiple works for each concert. To accommodate this structure, use collections for complex types.
- In the raw content, `Date` and `Time` are strings, so the corresponding data types in the index are also strings.

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads and indexes data, and optionally provides a schedule to automate the data refresh.

The indexer configuration includes the `jsonArray` parsing mode and a `documentRoot`.

HTTP

```

### Create and run an indexer
POST {{baseUrl}}/indexers?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "name" : "ny-philharmonic-indexer",
    "dataSourceName" : "ny-philharmonic-ds",
    "targetIndexName" : "ny-philharmonic-index",
    "parameters" : {
        "configuration" : {
            "parsingMode" : "jsonArray", "documentRoot": "/programs"
        },
        "fieldMappings" : [
        ]
    }
}

```

Key points:

- The raw content file contains a JSON array ("programs") with 1,526 nested JSON structures. Set `parsingMode` to `jsonArray` to tell the indexer that each blob contains a JSON array. Because the nested JSON starts one level down, set `documentRoot` to `/programs`.
- The indexer runs for several minutes. Wait for indexer execution to complete before running any queries.

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```
### Query the index
POST {{baseUrl}}/indexes/ny-philharmonic-index/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "search": "*",
  "count": true
}
```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
HTTP/1.1 200 OK
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Content-Encoding: gzip
Vary: Accept-Encoding
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: a95c4021-f7b4-450b-ba55-596e59ecb6ec
elapsed-time: 106
Date: Wed, 13 Mar 2024 22:09:59 GMT
Connection: close
```

```
{  
    "@odata.context": "https://<YOUR-SEARCH-SERVICE-  
NAME>.search.windows.net/indexes('ny-philharmonic-index')/$metadata#docs(*)",  
    "@odata.count": 1521,  
    "@search.nextPageParameters": {  
        "search": "*",  
        "count": true,  
        "skip": 50  
    },  
    "value": [  
    ],  
    "@odata.nextLink": "https://<YOUR-SEARCH-SERVICE-  
NAME>.search.windows.net/indexes/ny-philharmonic-index/docs/search?api-version=2025-  
09-01"  
}
```

Add a `search` parameter to search on a string, a `select` parameter to limit the results to fewer fields, and a `filter` to further narrow the search.

HTTP

```
### Query the index  
POST {{baseUrl}}/indexes/ny-philharmonic-index/docs/search?api-version=2025-09-01  
HTTP/1.1  
Content-Type: application/json  
api-key: {{apiKey}}  
  
{  
    "search": "puccini",  
    "count": true,  
    "select": "season, concerts/Date, works/composerName, works/workTitle",  
    "filter": "season gt '2015-16'"  
}
```

Two documents are returned in the response.

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case -sensitive. For more information and examples, see [Create a query](#).

ⓘ Note

The `$filter` parameter only works on fields that were marked filterable during index creation.

Reset and rerun

Indexers can be reset to clear execution history, which allows a full rerun. The following POST requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{baseUrl}}/indexers/ny-philharmonic-indexer/reset?api-version=2025-09-01
HTTP/1.1
    api-key: {{apiKey}}
```

HTTP

```
### Run the indexer
POST {{baseUrl}}/indexers/ny-philharmonic-indexer/run?api-version=2025-09-01
HTTP/1.1
    api-key: {{apiKey}}
```

HTTP

```
### Check indexer status
GET {{baseUrl}}/indexers/ny-philharmonic-indexer/status?api-version=2025-09-01
HTTP/1.1
    api-key: {{apiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

Next steps

Now that you're familiar with the basics of Azure Blob indexing, take a closer look at indexer configuration for JSON blobs in Azure Storage:

[Configure JSON blob indexing](#)

Tutorial: Index nested Markdown blobs from Azure Storage using REST

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

Azure AI Search can index Markdown documents and arrays in Azure Blob Storage using an [indexer](#) that knows how to read Markdown data.

This tutorial shows you how to index Markdown files indexed using the `oneToMany` Markdown parsing mode and the [Search Service REST APIs](#).

In this tutorial, you:

- ✓ Set up sample data and configure an `azureblob` data source
- ✓ Create an Azure AI Search index to contain searchable content
- ✓ Create and run an indexer to read the container and extract searchable content
- ✓ Search the index you just created

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure Storage account](#).
- An [Azure AI Search service](#).
- [Visual Studio Code](#) with the [REST Client Extension](#).

! Note

You can use a free search service for this tutorial. The Free tier limits you to three indexes, three indexers, and three data sources. This tutorial creates one of each. Before you start, make sure your service has room to accept the new resources.

Prepare sample data

Create a Markdown file

Copy and paste the following Markdown into a file named `sample_markdown.md`. The sample data is a single Markdown file containing various Markdown elements. We chose one Markdown file to stay under the storage limits of the Free tier.

Markdown

Project Documentation

Introduction

This document provides a complete overview of the **Markdown Features** used within this project. The following sections demonstrate the richness of Markdown formatting, with examples of lists, tables, links, images, blockquotes, inline styles, and more.

Table of Contents

1. [Headers](#headers)
2. [Introduction](#introduction)
3. [Basic Text Formatting](#basic-text-formatting)
4. [Lists](#lists)
5. [Blockquotes](#blockquotes)
6. [Images](#images)
7. [Links](#links)
8. [Tables](#tables)
9. [Code Blocks and Inline Code](#code-blocks-and-inline-code)
10. [Horizontal Rules](#horizontal-rules)
11. [Inline Elements](#inline-elements)
12. [Escaping Characters](#escaping-characters)
13. [HTML Elements](#html-elements)
14. [Emojis](#emojis)
15. [Footnotes](#footnotes)
16. [Task Lists](#task-lists)
17. [Conclusion](#conclusion)

Headers

Markdown supports six levels of headers. Use `#` to create headers:

"# Project Documentation" at the top of the document is an example of an h1 header.

"## Headers" above is an example of an h2 header.

h3 example

h4 example

h5 example

h6 example

This is an example of content underneath a header.

Basic Text Formatting

You can apply various styles to your text:

- **Bold**: Use double asterisks or underscores: `**bold**` or `__bold__`.
- *Italic*: Use single asterisks or underscores: `*italic*` or `_italic_`.

- ~~Strikethrough~~: Use double tildes: `~~strikethrough~~`.

Lists

Ordered List

1. First item
2. Second item
3. Third item

Unordered List

- Item A
- Item B
- Item C

Nested List

1. Parent item
 - Child item
 - Child item

Blockquotes

> This is a blockquote.
> Blockquotes are great for emphasizing important information.
>> Nested blockquotes are also possible!

Images

![Markdown Logo](<https://markdown-here.com/img/icon256.png>)

Links

[Visit Markdown Guide](<https://www.markdownguide.org>)

Tables

Syntax	Description	Example
Header	Title	Header Cell
Paragraph	Text block	Row Content

Code Blocks and Inline Code

Inline Code

Use backticks to create `inline code`.

Code Block

```
```javascript
// JavaScript example
function greet(name) {
 console.log(`Hello, ${name}!`);
}
greet('World');
```
```

Horizontal Rules

Use three or more dashes or underscores to create a horizontal rule.

Inline Elements

Sometimes, it's useful to include `inline code` to highlight code-like content.

You can also emphasize text like *this* or make it **bold**.

Escaping Characters

To render special Markdown characters, use backslashes:

- *Asterisks*
- \#Hashes\#
- \[Brackets\]

HTML Elements

You can mix HTML tags with Markdown:

```
<table>
  <tr>
    <th>HTML Table</th>
    <th>With Markdown</th>
  </tr>
  <tr>
    <td>Row 1</td>
    <td>Data 1</td>
  </tr>
</table>
```

Emojis

Markdown supports some basic emojis:

- :smile: 😊
- :rocket: 🚀
- :checkered_flag: 🇩🇪

Footnotes

This is an example of a footnote^[^1]. Footnotes allow you to add notes without cluttering the main text.

[^1]: This is the content of the footnote.

Task Lists

- [x] Complete the introduction
- [] Add more examples
- [] Review the document

Conclusion

Markdown is a lightweight yet powerful tool for writing documentation. It supports a variety of formatting options while maintaining simplicity and readability.

Thank you for reviewing this example!

Upload the file and get a connection string

Follow these instructions to upload the `sample_markdown.md` file to a container in your Azure Storage account. You must also get the storage account connection string. Make a note of the connection string and the container name for later use.

Copy a search service URL and API key

For this tutorial, connections to Azure AI Search require an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Managed identities](#).

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview**.
3. Make a note of the URL, which should look like `https://my-service.search.windows.net`.
4. From the left pane, select **Settings > Keys**.
5. Make a note of an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests for adding, modifying, and deleting objects.

Screenshot of the URL and API keys in the Azure portal.

Set up your REST file

1. Create a file in Visual Studio Code.
2. Provide values for variables used in the request.

HTTP

```
@baseUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE  
apiKey = PUT-YOUR-ADMIN-API-KEY-HERE  
@storageConnectionString = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE  
@blobContainer = PUT-YOUR-CONTAINER-NAME-HERE
```

3. Save the file using a `.rest` or `.http` file extension.

For help with the REST client, see [Quickstart: Full-text search using REST](#).

Create a data source

[Create Data Source \(REST\)](#) creates a data source connection that specifies what data to index.

HTTP

```
### Create a data source
POST {{baseUrl}}/datasources?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "name" : "sample-markdown-ds",
    "description": null,
    "type": "azureblob",
    "subtype": null,
    "credentials": {
        "connectionString": "{{storageConnectionString}}"
    },
    "container": {
        "name": "{{blobContainer}}",
        "query": null
    },
    "dataChangeDetectionPolicy": null,
    "dataDeletionDetectionPolicy": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
ETag: "0x8DCF52E926A3C76"

}
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the fields and their attributes.

In one-to-many parsing, the search document defines the 'many' side of the relationship. The fields you specify in the index determine the structure of the search document.

You only need fields for the Markdown elements that the parser supports. These fields are:

- `content`: A string that contains the raw Markdown found in a specific location, based on the header metadata at that point in the document.
- `sections`: An object that contains subfields for the header metadata up to the desired header level. For example, when `markdownHeaderDepth` is set to `h3`, contains string fields `h1`, `h2`, and `h3`. These fields are indexed by mirroring this structure in the index, or through field mappings in the format `/sections/h1`, `sections/h2`, etc. For in-context examples, see the index and indexer configurations in the following samples. The subfields contained are:
 - `h1` - A string containing the `h1` header value. Empty string if not set at this point in the document.
 - (Optional) `h2` - A string containing the `h2` header value. Empty string if not set at this point in the document.
 - (Optional) `h3` - A string containing the `h3` header value. Empty string if not set at this point in the document.
 - (Optional) `h4` - A string containing the `h4` header value. Empty string if not set at this point in the document.
 - (Optional) `h5` - A string containing the `h5` header value. Empty string if not set at this point in the document.
 - (Optional) `h6` - A string containing the `h6` header value. Empty string if not set at this point in the document.

- `ordinal_position`: An integer value that indicates the position of the section within the document hierarchy. This field is used for ordering the sections in their original sequence as they appear in the document, beginning with an ordinal position of 1 and incrementing sequentially for each content block.

This implementation uses [field mappings](#) in the indexer to map from the enriched content to the index. For more information about the parsed one-to-many document structure, see [Index Markdown blobs](#).

This example provides samples of how to index data both with and without field mappings. In this case, we know that `h1` contains the title of the document, so we can map it to a field named `title`. We'll also be mapping the `h2` and `h3` fields to `h2_subheader` and `h3_subheader`, respectively. The `content` and `ordinal_position` fields require no mapping because they're extracted from the Markdown directly into fields using those names. For an example of a full index schema that doesn't require field mappings, see the end of this section.

HTTP

```
### Create an index
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "name": "sample-markdown-index",
  "fields": [
    {"name": "id", "type": "Edm.String", "key": true, "searchable": true,
    "retrievable": true, "filterable": true, "facetable": true, "sortable": true},
    {"name": "content", "type": "Edm.String", "key": false, "searchable": true,
    "retrievable": true, "filterable": true, "facetable": true, "sortable": true},
    {"name": "title", "type": "Edm.String", "searchable": true, "retrievable": true,
    "filterable": true, "facetable": true, "sortable": true},
    {"name": "h2_subheader", "type": "Edm.String", "searchable": true,
    "retrievable": true, "filterable": true, "facetable": true, "sortable": true},
    {"name": "h3_subheader", "type": "Edm.String", "searchable": true,
    "retrievable": true, "filterable": true, "facetable": true, "sortable": true},
    {"name": "ordinal_position", "type": "Edm.Int32", "searchable": false,
    "retrievable": true, "filterable": true, "facetable": true, "sortable": true}
  ]
}
```

Index schema in a configuration with no field mappings

Field mappings allow you to manipulate and filter enriched content to fit into your desired index shape. However, you might just want to take the enriched content directly. In that case, the schema would look like:

HTTP

```
{  
  "name": "sample-markdown-index",  
  "fields": [  
    {"name": "id", "type": "Edm.String", "key": true, "searchable": true,  
     "retrievable": true, "filterable": true, "facetable": true, "sortable": true},  
    {"name": "content", "type": "Edm.String", "key": false, "searchable": true,  
     "retrievable": true, "filterable": true, "facetable": true, "sortable": true},  
    {"name": "sections",  
      "type": "Edm.ComplexType",  
      "fields": [  
        {"name": "h1", "type": "Edm.String", "searchable": true, "retrievable":  
         true, "filterable": true, "facetable": true, "sortable": true},  
        {"name": "h2", "type": "Edm.String", "searchable": true, "retrievable":  
         true, "filterable": true, "facetable": true, "sortable": true},  
        {"name": "h3", "type": "Edm.String", "searchable": true, "retrievable":  
         true, "filterable": true, "facetable": true, "sortable": true}  
      ]  
    },  
    {"name": "ordinal_position", "type": "Edm.Int32", "searchable": false,  
     "retrievable": true, "filterable": true, "facetable": true, "sortable": true}  
  ]  
}
```

To reiterate, we have subfields up to `h3` in the sections object because `markdownHeaderDepth` is set to `h3`.

If you use this schema, be sure to adjust later requests accordingly. This will require removing the field mappings from the indexer configuration and updating search queries to use the corresponding field names.

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads and indexes data, and optionally provides a schedule to automate the data refresh.

HTTP

```
### Create and run an indexer  
POST {{baseUrl}}/indexers?api-version=2025-09-01 HTTP/1.1  
Content-Type: application/json  
api-key: {{apiKey}}  
  
{  
  "name": "sample-markdown-indexer",  
  "dataSourceName": "sample-markdown-ds",  
  "targetIndexName": "sample-markdown-index",
```

```

"parameters" : {
  "configuration": {
    "parsingMode": "markdown",
    "markdownParsingSubmode": "oneToMany",
    "markdownHeaderDepth": "h3"
  }
},
"fieldMappings" : [
  {
    "sourceFieldName": "/sections/h1",
    "targetFieldName": "title",
    "mappingFunction": null
  }
]
}

```

Key points:

- The indexer will only parse headers up to `h3`. Any lower-level headers (`h4, h5, h6`) are treated as plain text and show up in the `content` field. This is why the index and field mappings only exist up to a depth of `h3`.
- The `content` and `ordinal_position` fields require no field mapping because they exist with those names in the enriched content.

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```

### Query the index
POST {{baseUrl}}/indexes/sample-markdown-index/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "search": "*",
  "count": true
}

```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
HTTP/1.1 200 OK
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Content-Encoding: gzip
Vary: Accept-Encoding
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 6b94e605-55e8-47a5-ae15-834f926ddd14
elapsed-time: 77
Date: Fri, 25 Oct 2024 20:22:58 GMT
Connection: close

{
    "@odata.context": "https://<YOUR-SEARCH-SERVICE-NAME>.search.windows.net/indexes('sample-markdown-index')/$metadata#docs(*)",
    "@odata.count": 22,
    "value": [
        <22 search documents here>
    ]
}
```

Add a `search` parameter to search on a string.

HTTP

```
### Query the index
POST {{baseUrl}}/indexes/sample-markdown-index/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "search": "h4",
    "count": true
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 200 OK
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Content-Encoding: gzip
Vary: Accept-Encoding
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
```

```

Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: ec5d03f1-e3e7-472f-9396-7ff8e3782105
elapsed-time: 52
Date: Fri, 25 Oct 2024 20:26:29 GMT
Connection: close

{
  "@odata.context": "https://<YOUR-SEARCH-SERVICE-NAME>.search.windows.net/indexes('sample-markdown-index')/$metadata#docs(*)",
  "@odata.count": 1,
  "value": [
    {
      "@search.score": 0.8744742,
      "section_id": "aHR0cHM6Ly9hcmpmZ2Fubmpma2ZpbGVzLmJsb2IuY29yZS53aW5kb3dzLm5ldC9tYXJrZG93bi10dXRvcmlhbC9zYW1wbGVfbWFya2Rvd24ubWQ7NA2",
      "content": "#### h4 example\r\n##### h5 example\r\n##### h6 example\r\nThis is an example of content underneath a header.\r\n",
      "title": "Project Documentation",
      "h2_subheader": "Headers",
      "h3_subheader": "h3 example",
      "ordinal_position": 4
    }
  ]
}

```

Key points:

- Because the `markdownHeaderDepth` is set to `h3`, the `h4`, `h5`, and `h6` headers are treated as plaintext, so they appear in the `content` field.
- Ordinal position here is `4`. This content appears fourth out of the 22 total content sections.

Add a `select` parameter to limit the results to fewer fields. Add a `filter` to further narrow the search.

HTTP

```

### Query the index
POST {{baseUrl}}/indexes/sample-markdown-index/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "search": "Markdown",
  "count": true,
  "select": "title, content, h2_subheader",
}

```

```
        "filter": "h2_subheader eq 'Conclusion'"  
    }
```

JSON

```
HTTP/1.1 200 OK  
Transfer-Encoding: chunked  
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;  
charset=utf-8  
Content-Encoding: gzip  
Vary: Accept-Encoding  
Server: Microsoft-IIS/10.0  
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains  
Preference-Applied: odata.include-annotations="*"  
OData-Version: 4.0  
request-id: a6f9bd46-a064-4e28-818f-ea077618014b  
elapsed-time: 35  
Date: Fri, 25 Oct 2024 20:36:10 GMT  
Connection: close  
  
{  
    "@odata.context": "https://<YOUR-SEARCH-SERVICE-  
NAME>.search.windows.net/indexes('sample-markdown-index')/$metadata#docs(*)",  
    "@odata.count": 1,  
    "value": [  
        {  
            "@search.score": 1.1029507,  
            "content": "Markdown is a lightweight yet powerful tool for writing  
documentation. It supports a variety of formatting options while maintaining  
simplicity and readability.\r\n\r\nThank you for reviewing this example!",  
            "title": "Project Documentation",  
            "h2_subheader": "Conclusion"  
        }  
    ]  
}
```

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case sensitive. For more information and examples, see [Create a query](#).

ⓘ Note

The `$filter` parameter only works on fields that were marked filterable at the creation of your index.

Reset and rerun

Indexers can be reset to clear execution history, which allows a full rerun. The following GET requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{baseUrl}}/indexers/sample-markdown-indexer/reset?api-version=2025-09-01
HTTP/1.1
api-key: {{apiKey}}

### Run the indexer
POST {{baseUrl}}/indexers/sample-markdown-indexer/run?api-version=2025-09-01
HTTP/1.1
api-key: {{apiKey}}

### Check indexer status
GET {{baseUrl}}/indexers/sample-markdown-indexer/status?api-version=2025-09-01
HTTP/1.1
api-key: {{apiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

Next steps

Now that you're familiar with the basics of Azure Blob indexing, take a closer look at indexer configuration for Markdown blobs in Azure Storage:

[Configure Markdown blob indexing](#)

Last updated on 11/21/2025

Tutorial: Index from multiple data sources using the .NET SDK

Azure AI Search supports importing, analyzing, and indexing data from multiple data sources into a single consolidated search index.

This C# tutorial uses the [Azure.Search.Documents](#) client library in the Azure SDK for .NET to index sample hotel data from an Azure Cosmos DB instance. You then merge the data with hotel room details drawn from Azure Blob Storage documents. The result is a combined hotel search index containing hotel documents, with rooms as complex data types.

In this tutorial, you:

- ✓ Upload sample data to data sources
- ✓ Identify the document key
- ✓ Define and create the index
- ✓ Index hotel data from Azure Cosmos DB
- ✓ Merge hotel room data from Blob Storage

Overview

This tutorial uses [Azure.Search.Documents](#) to create and run multiple indexers. You upload sample data to two Azure data sources and configure an indexer that pulls from both sources to populate a single search index. The two data sets must have a value in common to support the merge. In this tutorial, that field is an ID. As long as there's a field in common to support the mapping, an indexer can merge data from disparate resources: structured data from Azure SQL, unstructured data from Blob Storage, or any combination of [supported data sources](#) on Azure.

A finished version of the code in this tutorial can be found in the following project:

- [multiple-data-sources/v11 \(GitHub\)](#) ↗

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#) ↗ .
- An [Azure Cosmos DB for NoSQL account](#).
- An [Azure Storage account](#).
- An [Azure AI Search service](#).
- [Visual Studio](#) ↗ .

Note

You can use a free search service for this tutorial. The free tier limits you to three indexes, three indexers, and three data sources. This tutorial creates one of each. Before you start, make sure you have room on your service to accept the new resources.

Prepare services

This tutorial uses Azure AI Search for indexing and queries, Azure Cosmos DB for the first data set, and Azure Blob Storage for the second data set.

If possible, create all services in the same region and resource group for proximity and manageability. In practice, your services can be in any region.

This sample uses two small sets of data describing seven fictional hotels. One set describes the hotels themselves and will be loaded into an Azure Cosmos DB database. The other set contains hotel room details and is provided as seven separate JSON files to be uploaded into Azure Blob Storage.

Start with Azure Cosmos DB

1. Sign in to the [Azure portal](#) and select your Azure Cosmos DB account.
2. From the left pane, select **Data Explorer**.
3. Select **New Container > New Database**.

4. Enter **hotel-rooms-db** for the name. Accept the default values for the remaining settings.

5. Create a container that targets the database you previously created. Enter **hotels** for the container name and **/HotelId** for the partition key.

New Container

* Database id ⓘ

Create new Use existing

hotel-rooms-db

* Container id ⓘ

hotels

* Partition key ⓘ

/HotelId

+ Add unique key

Analytical store ⓘ

On Off

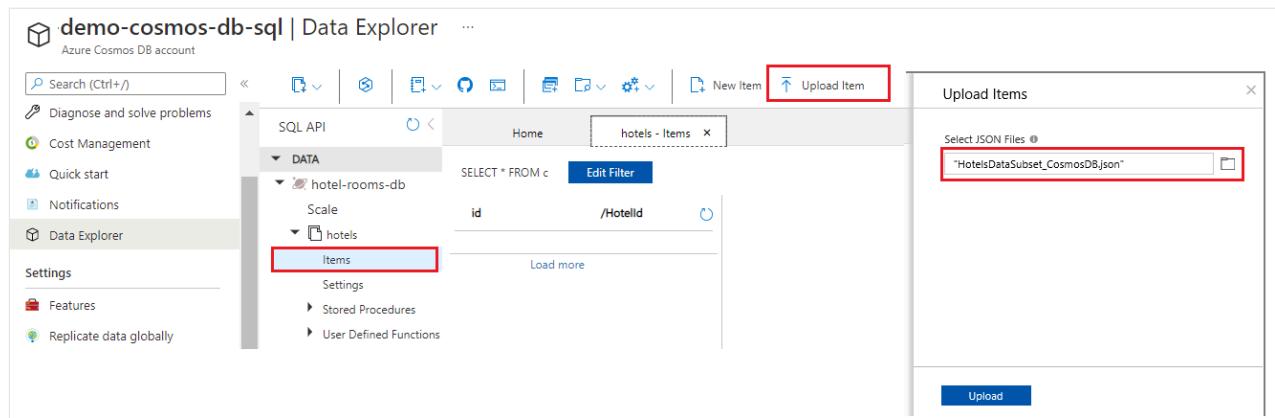

Azure Synapse Link is required for creating an analytical store container. Enable Synapse Link for this Cosmos DB account. [Learn more](#)

Enable

> Advanced

OK

6. Select **hotels** > **Items**, and then select **Upload Item** on the command bar.
7. Upload the JSON file from the `cosmosdb` folder in [multiple-data-sources/v11](#).

8. Use the refresh button to refresh your view of the items in the hotels collection. You should see seven new database documents listed.
9. From the left pane, select **Settings > Keys**.
10. Make a note of a connection string. You need this value for `appsettings.json` in a later step. If you didn't use the suggested **hotel-rooms-db** database name, copy the database name as well.

Azure Blob Storage

1. Sign in to the [Azure portal](#) and select your Azure Storage account.
2. From the left pane, select **Data storage > Containers**.
3. [Create a blob container](#) named **hotel-rooms** to store the sample hotel room JSON files. You can set the access level to any valid value.

4. Open the container, and then select **Upload** on the command bar.
5. Upload the seven JSON files from the `blob` folder in [multiple-data-sources/v11](#).

6. From the left pane, select **Security + networking > Access keys**.
7. Make a note of the account name and a connection string. You need both values for `appsettings.json` in a later step.

Azure AI Search

The third component is Azure AI Search, which you can [create in the Azure portal](#) or [find an existing search service](#) in your Azure resources.

Copy an admin key and URL for Azure AI Search

To authenticate to your search service, you need the service URL and an access key. Having a valid key establishes trust on a per-request basis between the application sending the request and the service handling it.

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Overview**.
3. Make a note of the URL, which should look like `https://my-service.search.windows.net`.
4. From the left pane, select **Settings > Keys**.
5. Make a note of an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests for adding, modifying, and deleting objects.

Set up your environment

1. Open the `AzureSearchMultipleDataSources.sln` file from [multiple-data-sources/v11](#) in Visual Studio.
2. In Solution Explorer, right-click the project and select **Manage NuGet Packages for Solution....**
3. On the **Browse** tab, find and install the following packages:
 - **Azure.Search.Documents** (version 11.0 or later)
 - **Microsoft.Extensions.Configuration**
 - **Microsoft.Extensions.Configuration.Json**
4. In Solution Explorer, edit the `appsettings.json` file with the connection information you collected in the previous steps.

JSON

```
{  
  "SearchServiceUri": "<YourSearchServiceURL>",  
  "SearchServiceAdminApiKey": "<YourSearchServiceAdminApiKey>",  
  "BlobStorageAccountName": "<YourBlobStorageAccountName>",  
  "BlobStorageConnectionString": "<YourBlobStorageConnectionString>",  
  "CosmosDBConnectionString": "<YourCosmosDBConnectionString>"}
```

```
        "CosmosDBDatabaseName": "hotel-rooms-db"  
    }
```

Map key fields

Merging content requires that both data streams are targeting the same documents in the search index.

In Azure AI Search, the key field uniquely identifies each document. Every search index must have exactly one key field of type `Edm.String`. That key field must be present for each document in a data source that is added to the index. (In fact, it's the only required field.)

When indexing data from multiple data sources, make sure each incoming row or document contains a common document key. This allows you to merge data from two physically distinct source documents into a new search document in the combined index.

It often requires some up-front planning to identify a meaningful document key for your index and to make sure it exists in both data sources. In this demo, the `HotelId` key for each hotel in Azure Cosmos DB is also present in the rooms JSON blobs in Blob Storage.

Azure AI Search indexers can use field mappings to rename and even reformat data fields during the indexing process, so that source data can be directed to the correct index field. For example, in Azure Cosmos DB, the hotel identifier is called `HotelId`, but in the JSON blob files for the hotel rooms, the hotel identifier is named `Id`. The program handles this discrepancy by mapping the `Id` field from the blobs to the `HotelId` key field in the indexer.

(!) Note

In most cases, autogenerated document keys, such as those created by default by some indexers, don't make good document keys for combined indexes. In general, use a meaningful, unique key value that already exists in your data sources or can be easily added.

Explore the code

When the data and configuration settings are in place, the sample program in `AzureSearchMultipleDataSources.sln` should be ready to build and run.

This simple C#/.NET console app performs the following tasks:

- Creates a new index based on the data structure of the C# Hotel class, which also references the Address and Room classes.
- Creates a new data source and an indexer that maps Azure Cosmos DB data to index fields. These are both objects in Azure AI Search.
- Runs the indexer to load hotel data from Azure Cosmos DB.
- Creates a second data source and an indexer that maps JSON blob data to index fields.
- Runs the second indexer to load hotel room data from Blob Storage.

Before you run the program, take a minute to study the code, index definition, and indexer definition. The relevant code is in two files:

- `Hotel.cs` contains the schema that defines the index.
- `Program.cs` contains functions that create the Azure AI Search index, data sources, and indexers, and load the combined results into the index.

Create an index

This sample program uses `CreateIndexAsync` to define and create an Azure AI Search index. It takes advantage of the `FieldBuilder` class to generate an index structure from a C# data model class.

The data model is defined by the Hotel class, which also contains references to the Address and Room classes. The FieldBuilder drills down through multiple class definitions to generate a complex data structure for the index. Metadata tags are used to define the attributes of each field, such as whether it's searchable or sortable.

The program deletes any existing index of the same name before creating the new one, in case you want to run this example more than once.

The following snippets from the `Hotel.cs` file show single fields, followed by a reference to another data model class, `Room[]`, which in turn is defined in `Room.cs` file (not shown).

C#

```
...
[SimpleField(IsFilterable = true, IsKey = true)]
public string HotelId { get; set; }

[SearchableField(IsFilterable = true, IsSortable = true)]
public string HotelName { get; set; }
...
public Room[] Rooms { get; set; }
...
```

In the `Program.cs` file, a `SearchIndex` is defined with a name and a field collection generated by the `FieldBuilder.Build` method, and then created as follows:

C#

```
private static async Task CreateIndexAsync(string indexName, SearchIndexClient indexClient)
{
    // Create a new search index structure that matches the properties of the Hotel
    // class.
    // The Address and Room classes are referenced from the Hotel class. The
    FieldBuilder
    // will enumerate these to create a complex data structure for the index.
    FieldBuilder builder = new FieldBuilder();
    var definition = new SearchIndex(indexName, builder.Build(typeof(Hotel)));

    await indexClient.CreateIndexAsync(definition);
}
```

Create Azure Cosmos DB data source and indexer

The main program includes logic to create the Azure Cosmos DB data source for the hotels data.

First, it concatenates the Azure Cosmos DB database name to the connection string. It then defines a `SearchIndexerDataSourceConnection` object.

C#

```
private static async Task CreateAndRunCosmosDbIndexerAsync(string indexName,
SearchIndexerClient indexerClient)
{
    // Append the database name to the connection string
    string cosmosConnectionString =
        configuration["CosmosDBConnectionString"]
        + ";Database="
        + configuration["CosmosDBDatabaseName"];

    SearchIndexerDataSourceConnection cosmosDbDataSource = new
    SearchIndexerDataSourceConnection(
        name: configuration["CosmosDBDatabaseName"],
        type: SearchIndexerDataSourceType.CosmosDb,
        connectionString: cosmosConnectionString,
        container: new SearchIndexerDataContainer("hotels"));

    // The Azure Cosmos DB data source does not need to be deleted if it already
    exists,
    // but the connection string might need to be updated if it has changed.
    await indexerClient.CreateOrUpdateDataSourceConnectionAsync(cosmosDbDataSource);
```

After the data source is created, the program sets up an Azure Cosmos DB indexer named `hotel-rooms-cosmos-indexer`.

The program updates any existing indexers with the same name, overwriting the existing indexer with the content of the previous code. It also includes reset and run actions, in case you want to run this example more than once.

The following example defines a schedule for the indexer, so that it runs once per day. You can remove the `schedule` property from this call if you don't want the indexer to automatically run again in the future.

C#

```
SearchIndexer cosmosDbIndexer = new SearchIndexer(
    name: "hotel-rooms-cosmos-indexer",
    dataSourceName: cosmosDbDataSource.Name,
    targetIndexName: indexName)
{
    Schedule = new IndexingSchedule(TimeSpan.FromDays(1))
};

// Indexers keep metadata about how much they have already indexed.
// If we already ran the indexer, it "remembers" and does not run again.
// To avoid this, reset the indexer if it exists.
try
{
    await indexerClient.GetIndexerAsync(cosmosDbIndexer.Name);
    // Reset the indexer if it exists.
    await indexerClient.ResetIndexerAsync(cosmosDbIndexer.Name);
}
catch (RequestFailedException ex) when (ex.Status == 404)
{
    // If the indexer does not exist, 404 will be thrown.
}

await indexerClient.CreateOrUpdateIndexerAsync(cosmosDbIndexer);

Console.WriteLine("Running Azure Cosmos DB indexer...\n");

try
{
    // Run the indexer.
    await indexerClient.RunIndexerAsync(cosmosDbIndexer.Name);
}
catch (RequestFailedException ex) when (ex.Status == 429)
{
    Console.WriteLine("Failed to run indexer: {0}", ex.Message);
}
```

This example includes a simple try-catch block to report any errors that might occur during execution.

After the Azure Cosmos DB indexer runs, the search index contains a full set of sample hotel documents. However, the rooms field for each hotel is an empty array, since the Azure Cosmos DB data source omits room details. Next, the program pulls from Blob Storage to load and merge the room data.

Create Blob Storage data source and indexer

To get the room details, the program first sets up a Blob Storage data source to reference a set of individual JSON blob files.

C#

```
private static async Task CreateAndRunBlobIndexerAsync(string indexName,
SearchIndexerClient indexerClient)
{
    SearchIndexerDataSourceConnection blobDataSource = new
    SearchIndexerDataSourceConnection(
        name: configuration["BlobStorageAccountName"],
        type: SearchIndexerDataSourceType.AzureBlob,
        connectionString: configuration["BlobStorageConnectionString"],
        container: new SearchIndexerDataContainer("hotel-rooms"));

    // The blob data source does not need to be deleted if it already exists,
    // but the connection string might need to be updated if it has changed.
    await indexerClient.CreateOrUpdateDataSourceConnectionAsync(blobDataSource);
```

After the data source is created, the program sets up a blob indexer named `hotel-rooms-blob-indexer`, as shown below.

The JSON blobs contain a key field named `Id` instead of `HotelId`. The code uses the `FieldMapping` class to tell the indexer to direct the `Id` field value to the `HotelId` document key in the index.

Blob Storage indexers can use `IndexingParameters` to specify a parsing mode. You should set different parsing modes depending on whether blobs represent a single document or multiple documents within the same blob. In this example, each blob represents a single JSON document, so the code uses the `json` parsing mode. For more information about indexer parsing parameters for JSON blobs, see [Index JSON blobs](#).

This example defines a schedule for the indexer, so that it runs once per day. You can remove the `schedule` property from this call if you don't want the indexer to automatically run again in the future.

C#

```

IndexingParameters parameters = new IndexingParameters();
parameters.Configuration.Add("parsingMode", "json");

SearchIndexer blobIndexer = new SearchIndexer(
    name: "hotel-rooms-blob-indexer",
    dataSourceName: blobDataSource.Name,
    targetIndexName: indexName)
{
    Parameters = parameters,
    Schedule = new IndexingSchedule(TimeSpan.FromDays(1))
};

// Map the Id field in the Room documents to the HotelId key field in the index
blobIndexer.FieldMappings.Add(new FieldMapping("Id") { TargetFieldName = "HotelId" });

// Reset the indexer if it already exists
try
{
    await indexerClient.GetIndexerAsync(blobIndexer.Name);
    await indexerClient.ResetIndexerAsync(blobIndexer.Name);
}
catch (RequestFailedException ex) when (ex.Status == 404) { }

await indexerClient.CreateOrUpdateIndexerAsync(blobIndexer);

try
{
    // Run the indexer.
    await searchService.Indexers.RunAsync(blobIndexer.Name);
}
catch (CloudException e) when (e.Response.StatusCode == (HttpStatusCode)429)
{
    Console.WriteLine("Failed to run indexer: {0}", e.Response.Content);
}

```

Because the index is already populated with hotel data from the Azure Cosmos DB database, the blob indexer updates the existing documents in the index and adds the room details.

Note

If you have the same non-key fields in both of your data sources, and the data in those fields doesn't match, the index contains the values from whichever indexer ran most recently. In our example, both data sources contain a `HotelName` field. If for some reason the data in this field is different, for documents with the same key value, the `HotelName` data from the most recently indexed data source is the value stored in the index.

Search

After you run the program, you can explore the populated search index using [Search explorer](#) in the Azure portal.

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Search management > Indexes**.
3. Select **hotel-rooms-sample** from the list of indexes.
4. On the **Search explorer** tab, enter a query for a term like `Luxury`.

You should see at least one document in the results. This document should contain a list of room objects in its `Rooms` array.

Reset and rerun

In the early experimental stages of development, the most practical approach for design iteration is to delete the objects from Azure AI Search and allow your code to rebuild them. Resource names are unique. Deleting an object lets you recreate it using the same name.

The sample code checks for existing objects and deletes or updates them so that you can rerun the program. You can also use the Azure portal to delete indexes, indexers, and data sources.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal using the All resources or Resource groups link in the left pane.

Next step

Now that you're familiar with ingesting data from multiple sources, take a closer look at indexer configuration, starting with Azure Cosmos DB:

[Configure an Azure Cosmos DB for NoSQL indexer](#)

Tutorial: Create a custom analyzer for phone numbers

In search solutions, strings that have complex patterns or special characters can be challenging to work with because the [default analyzer](#) strips out or misinterprets meaningful parts of a pattern. This results in a poor search experience where users can't find the information they expect. Phone numbers are a classic example of strings that are difficult to analyze. They come in various formats and include special characters that the default analyzer ignores.

With phone numbers as its subject, this tutorial uses the [Search Service REST APIs](#) to solve patterned data problems using a [custom analyzer](#). This approach can be used as is for phone numbers or adapted for fields with the same characteristics (patterned with special characters), such as URLs, emails, postal codes, and dates.

In this tutorial, you:

- ✓ Understand the problem
- ✓ Develop an initial custom analyzer for handling phone numbers
- ✓ Test the custom analyzer
- ✓ Iterate on custom analyzer design to further improve results

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#).
- [Visual Studio Code](#) with the [REST Client extension](#).

Download files

Source code for this tutorial is in the [custom-analyzer.rest](#) file in the [Azure-Samples/azure-search-rest-samples](#) GitHub repository.

Copy an admin key and URL

The REST calls in this tutorial require a search service endpoint and an admin API key. You can get these values from the Azure portal.

1. Sign in to the [Azure portal](#) and select your search service.

2. From the left pane, select **Overview** and copy the endpoint. It should be in this format:

```
https://my-service.search.windows.net
```

3. From the left pane, select **Settings > Keys** and copy an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests to add, modify, or delete objects.

The screenshot shows two side-by-side Azure search service pages. The top page is the 'Overview' section of a service named 'new-demo-search-svc'. The URL 'https://new-demo-search-svc.search.windows.net' is displayed in the top right. The bottom page is the 'Keys' section of the same service, showing two admin keys: 'Primary admin key' and 'Secondary admin key', both of which are highlighted with red boxes. Red numbers 1 and 2 are overlaid on the respective sections to indicate the steps described in the text above.

Create an initial index

1. Open a new text file in Visual Studio Code.

2. Set variables to the search endpoint and the API key you collected in the previous section.

```
HTTP
@baseUrl = PUT-YOUR-SEARCH-SERVICE-URL-HERE
@apiKey = PUT-YOUR-ADMIN-API-KEY-HERE
```

3. Save the file with a `.rest` file extension.

4. Paste the following example to create a small index called `phone-numbers-index` with two fields: `id` and `phone_number`.

```
HTTP
```

```

### Create a new index
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "name": "phone-numbers-index",
  "fields": [
    {
      "name": "id",
      "type": "Edm.String",
      "key": true,
      "searchable": true,
      "filterable": false,
      "facetable": false,
      "sortable": true
    },
    {
      "name": "phone_number",
      "type": "Edm.String",
      "sortable": false,
      "searchable": true,
      "filterable": false,
      "facetable": false
    }
  ]
}

```

You haven't defined an analyzer yet, so the `standard.lucene` analyzer is used by default.

5. Select **Send request**. You should have an `HTTP/1.1 201 Created` response, and the response body should include the JSON representation of the index schema.

6. Load data into the index using documents that contain various phone number formats. This is your test data.

HTTP

```

### Load documents
POST {{baseUrl}}/indexes/phone-numbers-index/docs/index?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "value": [
    {
      "@search.action": "upload",
      "id": "1",
      "phone_number": "425-555-0100"
    },
    {

```

```

        "@search.action": "upload",
        "id": "2",
        "phone_number": "(321) 555-0199"
    },
    {
        "@search.action": "upload",
        "id": "3",
        "phone_number": "+1 425-555-0100"
    },
    {
        "@search.action": "upload",
        "id": "4",
        "phone_number": "+1 (321) 555-0199"
    },
    {
        "@search.action": "upload",
        "id": "5",
        "phone_number": "4255550100"
    },
    {
        "@search.action": "upload",
        "id": "6",
        "phone_number": "13215550199"
    },
    {
        "@search.action": "upload",
        "id": "7",
        "phone_number": "425 555 0100"
    },
    {
        "@search.action": "upload",
        "id": "8",
        "phone_number": "321.555.0199"
    }
]
}

```

7. Try queries similar to what a user might type. For example, a user might search for (425) 555-0100 in any number of formats and still expect results to be returned. Start by searching (425) 555-0100.

HTTP

```

### Search for a phone number
POST {{baseUrl}}/indexes/phone-numbers-index/docs/search?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "search": "(425) 555-0100"
}

```

The query returns three out of four expected results but also returns two unexpected results.

JSON

```
{  
  "value": [  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "+1 425-555-0100"  
    },  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "425 555 0100"  
    },  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "425-555-0100"  
    },  
    {  
      "@search.score": 0.020766128,  
      "phone_number": "(321) 555-0199"  
    },  
    {  
      "@search.score": 0.020766128,  
      "phone_number": "+1 (321) 555-0199"  
    }  
  ]  
}
```

8. Try again without any formatting: 4255550100.

HTTP

```
### Search for a phone number  
POST {{baseUrl}}/indexes/phone-numbers-index/docs/search?api-version=2025-09-01  
HTTP/1.1  
Content-Type: application/json  
api-key: {{apiKey}}  
  
{  
  "search": "4255550100"  
}
```

This query does even worse, returning only one of four correct matches.

JSON

```
{  
  "value": [  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "+1 425-555-0100"  
    },  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "425 555 0100"  
    },  
    {  
      "@search.score": 0.05634898,  
      "phone_number": "425-555-0100"  
    },  
    {  
      "@search.score": 0.020766128,  
      "phone_number": "(321) 555-0199"  
    },  
    {  
      "@search.score": 0.020766128,  
      "phone_number": "+1 (321) 555-0199"  
    }  
  ]  
}
```

```

        "@search.score": 0.6015292,
        "phone_number": "4255550100"
    }
]
}

```

If you find these results confusing, you're not alone. The next section explains why you're getting these results.

Review how analyzers work

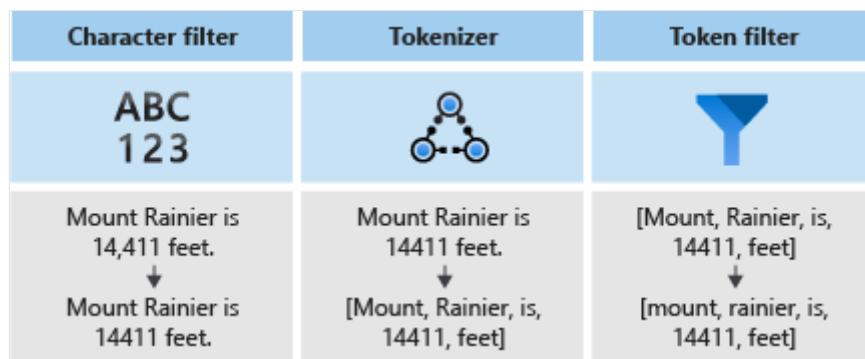

To understand these search results, you must understand what the analyzer is doing. From there, you can test the default analyzer using the [Analyze API](#), providing a foundation for designing an analyzer that better meets your needs.

An [analyzer](#) is a component of the [full-text search engine](#) responsible for processing text in query strings and indexed documents. Different analyzers manipulate text in different ways depending on the scenario. For this scenario, we need to build an analyzer tailored to phone numbers.

Analyzers consist of three components:

- [Character filters](#) that remove or replace individual characters from the input text.
- A [tokenizer](#) that breaks the input text into tokens, which become keys in the search index.
- [Token filters](#) that manipulate the tokens produced by the tokenizer.

The following diagram shows how these three components work together to tokenize a sentence.

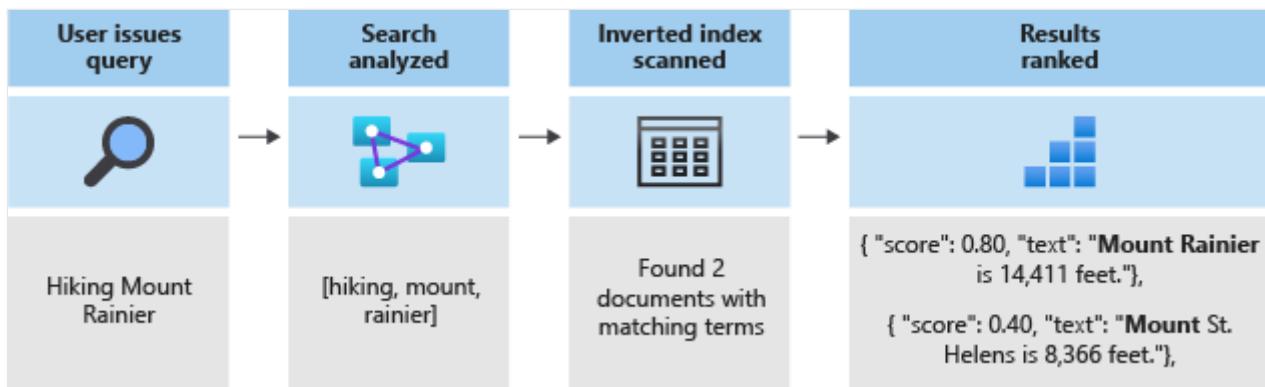

These tokens are then stored in an inverted index, which allows for fast, full-text searches. An inverted index enables full-text search by mapping all unique terms extracted during lexical analysis to the documents in which they occur. You can see an example in the following diagram:

All of search comes down to searching for the terms stored in the inverted index. When a user issues a query:

1. The query is parsed and the query terms are analyzed.
2. The inverted index is scanned for documents with matching terms.
3. The [scoring algorithm](#) ranks the retrieved documents.

If the query terms don't match the terms in your inverted index, results aren't returned. To learn more about how queries work, see [Full-text search in Azure AI Search](#).

Note

Partial term queries are an important exception to this rule. Unlike regular term queries, these queries (prefix query, wildcard query, and regex query) bypass the lexical analysis process. Partial terms are only lowercased before being matched against terms in the index. If an analyzer isn't configured to support these types of queries, you often receive unexpected results because matching terms don't exist in the index.

Test analyzers using the Analyze API

Azure AI Search provides an [Analyze API](#) that allows you to test analyzers to understand how they process text.

Call the Analyze API using the following request:

HTTP

```
### Test analyzer
POST {{baseUrl}}/indexes/phone-numbers-index/analyze?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
    "text": "(425) 555-0100",
```

```
        "analyzer": "standard.lucene"  
    }
```

The API returns the tokens extracted from the text, using the analyzer you specified. The standard Lucene analyzer splits the phone number into three separate tokens.

JSON

```
{  
    "tokens": [  
        {  
            "token": "425",  
            "startOffset": 1,  
            "endOffset": 4,  
            "position": 0  
        },  
        {  
            "token": "555",  
            "startOffset": 6,  
            "endOffset": 9,  
            "position": 1  
        },  
        {  
            "token": "0100",  
            "startOffset": 10,  
            "endOffset": 14,  
            "position": 2  
        }  
    ]  
}
```

Conversely, the phone number `4255550100` formatted without any punctuation is tokenized into a single token.

JSON

```
{  
    "text": "4255550100",  
    "analyzer": "standard.lucene"  
}
```

Response:

JSON

```
{  
    "tokens": [  
        {  
            "token": "4255550100",  
            "startOffset": 0,  
            "endOffset": 10,  
            "position": 0  
        }  
    ]  
}
```

```
        "endOffset": 10,  
        "position": 0  
    }  
]  
}
```

Keep in mind that both query terms and the indexed documents undergo analysis. Thinking back to the search results from the previous step, you can start to see why those results are returned.

In the first query, unexpected phone numbers are returned because one of their tokens, 555, matched one of the terms you searched. In the second query, only the one number is returned because it's the only record that has a token matching 4255550100.

Build a custom analyzer

Now that you understand the results you're seeing, build a custom analyzer to improve the tokenization logic.

The goal is to provide intuitive search against phone numbers no matter what format the query or indexed string is in. To achieve this outcome, specify a [character filter](#), a [tokenizer](#), and a [token filter](#).

Character filters

Character filters process text before it's fed into the tokenizer. Common uses of character filters are filtering out HTML elements and replacing special characters.

For phone numbers, you want to remove whitespace and special characters because not all phone number formats contain the same special characters and spaces.

JSON

```
"charFilters": [  
    {  
        "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",  
        "name": "phone_char_mapping",  
        "mappings": [  
            "-=>",  
            "(=>",  
            ")=>",  
            "+=>",  
            ".=>",  
            "\u0020=>"  
        ]  
    }]
```

```
    }  
]
```

The filter removes `-` `(` `)` `+` `.` and spaces from the input.

[Expand table](#)

Input	Output
<code>(321) 555-0199</code>	<code>3215550199</code>
<code>321.555.0199</code>	<code>3215550199</code>

Tokenizers

Tokenizers split text into tokens and discard some characters, such as punctuation, along the way. In many cases, the goal of tokenization is to split a sentence into individual words.

For this scenario, use a keyword tokenizer, `keyword_v2`, to capture the phone number as a single term. This isn't the only way to solve this problem, as explained in the [Alternate approaches](#) section.

Keyword tokenizers always output the same text they're given as a single term.

[Expand table](#)

Input	Output
<code>The dog swims.</code>	<code>[The dog swims.]</code>
<code>3215550199</code>	<code>[3215550199]</code>

Token filters

Token filters modify or filter out the tokens generated by the tokenizer. One common use of a token filter is to lowercase all characters using a lowercase token filter. Another common use is filtering out [stopwords](#), such as `the`, `and`, or `is`.

While you don't need to use either of those filters for this scenario, use an nGram token filter to allow for partial searches of phone numbers.

JSON

```
"tokenFilters": [  
  {
```

```
"@odata.type": "#Microsoft.Azure.Search.NGramTokenFilterV2",
"name": "custom_ngram_filter",
"minGram": 3,
"maxGram": 20
}
]
```

NGramTokenFilterV2

The [nGram_v2 token filter](#) splits tokens into n-grams of a given size based on the `minGram` and `maxGram` parameters.

For the phone analyzer, `minGram` is set to `3` because that's the shortest substring users are expected to search. `maxGram` is set to `20` to ensure that all phone numbers, even with extensions, fit into a single n-gram.

The unfortunate side effect of n-grams is that some false positives are returned. You fix this in a later step by building out a separate analyzer for searches that doesn't include the n-gram token filter.

[] Expand table

Input	Output
[12345]	[123, 1234, 12345, 234, 2345, 345]
[3215550199]	[321, 3215, 32155, 321555, 3215550, 32155501, 321555019, 3215550199, 215, 2155, 21555, 215550, ...]

Analyzer

With the character filters, tokenizer, and token filters in place, you're ready to define the analyzer.

JSON

```
"analyzers": [
{
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "name": "phone_analyzer",
    "tokenizer": "keyword_v2",
    "tokenFilters": [
        "custom_ngram_filter"
    ],
    "charFilters": [
        "phone_char_mapping"
    ]
}]
```

```
    ]  
}  
]
```

From the Analyze API, given the following inputs, outputs from the custom analyzer are as follows:

 Expand table

Input	Output
12345	[123, 1234, 12345, 234, 2345, 345]
(321) 555-0199	[321, 3215, 32155, 321555, 3215550, 32155501, 321555019, 3215550199, 215, 2155, 21555, 215550, ...]

All of the tokens in the output column exist in the index. If your query includes any of those terms, the phone number is returned.

Rebuild using the new analyzer

1. Delete the current index.

HTTP

```
### Delete the index  
DELETE {{baseUrl}}/indexes/phone-numbers-index?api-version=2025-09-01 HTTP/1.1  
api-key: {{apiKey}}
```

2. Recreate the index using the new analyzer. This index schema adds a custom analyzer definition and a custom analyzer assignment on the phone number field.

HTTP

```
### Create a new index  
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1  
Content-Type: application/json  
api-key: {{apiKey}}  
  
{  
  "name": "phone-numbers-index-2",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true,  
      "searchable": true,  
      "filterable": false,
```

```

    "facetable": false,
    "sortable": true
  },
  {
    "name": "phone_number",
    "type": "Edm.String",
    "sortable": false,
    "searchable": true,
    "filterable": false,
    "facetable": false,
    "analyzer": "phone_analyzer"
  }
],
"analyzers": [
  {
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "name": "phone_analyzer",
    "tokenizer": "keyword_v2",
    "tokenFilters": [
      "custom_ngram_filter"
    ],
    "charFilters": [
      "phone_char_mapping"
    ]
  }
],
"charFilters": [
  {
    "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",
    "name": "phone_char_mapping",
    "mappings": [
      "-=>",
      "(=>",
      ")=>",
      "+=>",
      ".=>",
      "\u0020=>"
    ]
  }
],
"tokenFilters": [
  {
    "@odata.type": "#Microsoft.Azure.Search.NGramTokenFilterV2",
    "name": "custom_ngram_filter",
    "minGram": 3,
    "maxGram": 20
  }
]
}

```

Test the custom analyzer

After you recreate the index, test the analyzer using the following request:

HTTP

```
### Test custom analyzer
POST {{baseUrl}}/indexes/phone-numbers-index-2/analyze?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
  "text": "+1 (321) 555-0199",
  "analyzer": "phone_analyzer"
}
```

You should now see the collection of tokens resulting from the phone number.

JSON

```
{
  "tokens": [
    {
      "token": "132",
      "startOffset": 1,
      "endOffset": 17,
      "position": 0
    },
    {
      "token": "1321",
      "startOffset": 1,
      "endOffset": 17,
      "position": 0
    },
    {
      "token": "13215",
      "startOffset": 1,
      "endOffset": 17,
      "position": 0
    },
    ...
    ...
    ...
  ]
}
```

Revise the custom analyzer to handle false positives

After using the custom analyzer to make sample queries against the index, you should see that recall has improved and all matching phone numbers are now returned. However, the n-gram

token filter also causes some false positives to be returned. This is a common side effect of an n-gram token filter.

To prevent false positives, create a separate analyzer for querying. This analyzer is identical to the previous one, except that it omits the `custom_ngram_filter`.

JSON

```
{  
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",  
    "name": "phone_analyzer_search",  
    "tokenizer": "custom_tokenizer_phone",  
    "tokenFilters": [],  
    "charFilters": [  
        "phone_char_mapping"  
    ]  
}
```

In the index definition, specify both an `indexAnalyzer` and a `searchAnalyzer`.

JSON

```
{  
    "name": "phone_number",  
    "type": "Edm.String",  
    "sortable": false,  
    "searchable": true,  
    "filterable": false,  
    "facetable": false,  
    "indexAnalyzer": "phone_analyzer",  
    "searchAnalyzer": "phone_analyzer_search"  
}
```

With this change, you're all set. Here are your next steps:

1. Delete the index.
2. Recreate the index after you add the new custom analyzer (`phone_analyzer-search`) and assign that analyzer to the `phone-number` field's `searchAnalyzer` property.
3. Reload the data.
4. Retest the queries to verify that the search works as expected. If you're using the sample file, this step creates the third index named `phone-number-index-3`.

Alternate approaches

The analyzer described in the previous section is designed to maximize the flexibility for search. However, it does so at the cost of storing many potentially unimportant terms in the index.

The following example shows an alternative analyzer that's more efficient in tokenization, but it has drawbacks.

Given an input of `14255550100`, the analyzer can't logically chunk the phone number. For example, it can't separate the country code, `1`, from the area code, `425`. This discrepancy leads to the phone number not being returned if a user doesn't include a country code in their search.

JSON

```
"analyzers": [
  {
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "name": "phone_analyzer_shingles",
    "tokenizer": "custom_tokenizer_phone",
    "tokenFilters": [
      "custom_shingle_filter"
    ]
  }
],
"tokenizers": [
  {
    "@odata.type": "#Microsoft.Azure.Search.StandardTokenizerV2",
    "name": "custom_tokenizer_phone",
    "maxTokenLength": 4
  }
],
"tokenFilters": [
  {
    "@odata.type": "#Microsoft.Azure.Search.ShingleTokenFilter",
    "name": "custom_shingle_filter",
    "minShingleSize": 2,
    "maxShingleSize": 6,
    "tokenSeparator": ""
  }
]
```

In the following example, the phone number is split into the chunks you normally expect a user to be search for.

 Expand table

Input	Output
(321) 555-0199	[321, 555, 0199, 321555, 5550199, 3215550199]

Depending on your requirements, this might be a more efficient approach to the problem.

Takeaways

This tutorial demonstrated the process of building and testing a custom analyzer. You created an index, indexed data, and then queried against the index to see what search results were returned. From there, you used the Analyze API to see the lexical analysis process in action.

While the analyzer defined in this tutorial offers an easy solution for searching against phone numbers, this same process can be used to build a custom analyzer for any scenario that shares similar characteristics.

Clean up resources

When you're working in your own subscription, it's a good idea to remove the resources that you no longer need at the end of a project. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the All resources or Resource groups link in the left-navigation pane.

Next steps

Now that you know how to create a custom analyzer, take a look at all of the different filters, tokenizers, and analyzers available for building a rich search experience:

[Custom analyzers in Azure AI Search](#)

Last updated on 11/21/2025

Tutorial: Index and enrich encrypted blobs for full-text search in Azure AI Search

10/09/2025

Learn how to use [Azure AI Search](#) to index documents that were encrypted with a customer-managed key in [Azure Blob Storage](#).

Normally, an indexer can't extract content from blobs that were encrypted using [client-side encryption](#) in the Azure Blob Storage client library. This is because the indexer doesn't have access to the customer-managed encryption key in [Azure Key Vault](#). However, using the [DecryptBlobFile custom skill](#) and the [Document Extraction skill](#), you can provide controlled access to the key to decrypt the files and then extract content from them. This unlocks the ability to index and enrich these documents without compromising the encryption status of your stored documents.

Starting with previously encrypted whole documents (unstructured text) such as PDF, HTML, DOCX, and PPTX in Azure Blob Storage, this tutorial uses a REST client and the Search REST APIs to:

- ✓ Define a pipeline that decrypts the documents and extracts text from them
- ✓ Define an index to store the output
- ✓ Execute the pipeline to create and load the index
- ✓ Explore results using full-text search and a rich query syntax

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Azure AI Search](#) on any tier or region.
- [Azure Storage](#), Standard performance (general-purpose v2).
- Blobs encrypted with a customer-managed key. To create sample data, see [Tutorial: Encrypt and decrypt blobs using Azure Key Vault](#).
- [Azure Key Vault](#) in the same subscription as Azure AI Search. The key vault must have [soft-delete](#) and [purge protection](#) enabled.

Custom skill deployment creates an Azure Function app and an Azure Storage account. These resources are created for you, so they aren't listed as a prerequisite. When you finish this tutorial, remember to clean up the resources so that you aren't billed for services you're not using.

(!) Note

Skillsets often require [attaching an Azure AI services multi-service resource](#). As written, this skillset has no dependency on Azure AI services, so no key is required. If you later add enrichments that invoke built-in skills, remember to update your skillset accordingly.

Deploy the custom skill

This tutorial uses the sample [DecryptBlobFile](#) project from the [Azure Search Power Skills](#) GitHub repository. In this section, you deploy the skill to an Azure Function so that it can be used in a skillset. A built-in deployment script creates an Azure Function resource with a **psdbf-function-app-** prefix and loads the skill. You're prompted to provide a subscription and resource group. Be sure to choose the subscription that contains your Azure Key Vault instance.

Operationally, the DecryptBlobFile skill takes the URL and SAS token for each blob as inputs. It outputs the downloaded, decrypted file using the file reference contract that Azure AI Search expects. Recall that DecryptBlobFile needs the encryption key to perform the decryption. As part of setup, you also create an access policy that grants DecryptBlobFile function access to the encryption key in Azure Key Vault.

1. On the [DecryptBlobFile landing page](#), select **Deploy to Azure** to open the Resource Manager template in the Azure portal.
2. Choose the subscription where your Azure Key Vault instance exists. This tutorial doesn't work if you choose a different subscription.
3. Select an existing resource group or create a new one. A dedicated resource group makes cleanup easier later.
4. Select **Review + create**, agree to the terms, and then select **Create** to deploy the Azure Function.

Home >

Custom deployment

Deploy from a custom template

Resource group * (New) demo-group Create new

Instance details

Region * West Central US

Resource Prefix psdbf

Storage Account Type Standard_LRS

Review + create < Previous Next : Review + create >

5. Wait for the deployment to finish.

You should have an Azure Function app that contains the decryption logic and an Azure Storage resource that will store application data. In the next steps, you give the app permissions to access the key vault and collect information that you'll need for the REST calls.

Grant permissions in Azure Key Vault

1. Go to your Azure Key Vault service in the Azure portal. [Create an access policy](#) in the Azure Key Vault that grants key access to the custom skill.
2. From the left pane, select **Access policies**, and then select **+ Create** to start the [Create an access policy](#) wizard.

The screenshot shows the Microsoft Azure Key Vault interface. In the left sidebar, under 'my-demo-key-vault', the 'Access policies' option is selected and highlighted with a red box. At the top right, there is a 'Create' button, which is also highlighted with a red box. The main content area displays a table of access policies. The first row shows a user named 'Jane Doe' with the email 'jadoe@mycompany.co'. The permissions listed are 'Get, List, Update, Create, Import, D...' and 'Get, List, Set, Delete, Recover, Back...'. There are also tabs for 'Secret Permissions' and 'Certificate Permissions'.

3. On the **Permissions** page, under **Configure from template**, select **Azure Data Lake Storage or Azure Storage**.

4. Select **Next**.

5. On the **Principal** page, select the Azure Function instance you deployed. You can search for it using its resource prefix, which has a default value of **psdbf-function-app**.

6. Select **Next**.

7. On **Review + create**, select **Create**.

Collect app information

1. Go to the **psdbf-function-app** function in the Azure portal. Make a note of the following properties you'll need for the REST calls.

2. Get the function URL, which can be found under **Essentials** on the main page for the function.

The screenshot shows the Azure Function App details page for 'psdbf-function-app- 00001111-aaaa'. The 'Essentials' section is expanded. The 'URL' field is highlighted with a red box and contains the value '<https://psdbf-function-app.azurewebsites.net>'. Other visible properties include Resource group (encryption-demo), Status (Running), Location (West Central US), Subscription (Applied AI Docs Team), Subscription ID, Tags, Operating System (Windows), App Service Plan (WestCentralUSPlan (Y1:0)), Properties (See More), and Runtime version (3.3.1.0).

3. Get the host key code, which can be found by going to **App keys** and showing the **default** key, and copying the value.

The screenshot shows the Azure portal interface for a Function App named "psdbf-function-app-0000000000000000". The left sidebar has sections for Security, Events (preview), Functions (with "Functions" and "App keys" selected), App files, Proxies, Deployment (Deployment slots, Deployment Center), Settings (Configuration), and Configuration. The main content area is titled "Host keys (all functions)" and contains instructions about using host keys for HTTP functions. It features a "New host key" button, a "Show values" link, and a "Filter host keys" input field. A table lists host keys: "_master" and "default". Both rows have "Value" columns with "Hidden value. Click to show value" and "Renew key value" links. The "default" row is highlighted with a red box. Below this is a section titled "System keys" with a note about automatic management by the Function runtime.

Get an admin key and URL for Azure AI Search

1. Sign in to the [Azure portal](#).
2. On your search service **Overview** page, get the name of your search service. You can confirm your service name by reviewing the endpoint URL. For example, if your endpoint URL is `https://mydemo.search.windows.net`, your service name is `mydemo`.
3. In **Settings > Keys**, get an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either the primary or secondary key on requests for adding, modifying, and deleting objects.

An API key is required in the header of every request sent to your service. A valid key establishes trust, on a per-request basis, between the application sending the request and the service that handles it.

Set up a REST client

Create the following variables for endpoints and keys.

 Expand table

Variable	Where to get it
admin-key	On the Keys page of the Azure AI Search service.
search-service-name	The name of the Azure AI Search service. The URL is <code>https://{{search-service-name}}.search.windows.net</code> .
storage-connection-string	In the storage account, on the Access Keys tab, select key1 > Connection string .
storage-container-name	The name of the blob container that has the encrypted files to be indexed.
function-uri	In the Azure Function, under Essentials on the main page.
function-code	In the Azure Function, by going to App keys , showing the default key, and copying the value.
api-version	Leave as 2020-06-30 .
datasource-name	Leave as encrypted-blobs-ds .
index-name	Leave as encrypted-blobs-idx .
skillset-name	Leave as encrypted-blobs-ss .
indexer-name	Leave as encrypted-blobs-ixr .

Review and run each request

Use the following HTTP requests to create the objects of an enrichment pipeline.

- **PUT request to create the index:** This search index holds the data that Azure AI Search uses and returns.
- **POST request to create the data source:** This data source specifies the connection to your storage account containing the encrypted blob files.
- **PUT request to create the skillset:** The skillset specifies the custom skill definition for the Azure Function that will decrypt the blob file data. It also specifies a [DocumentExtractionSkill](#) to extract the text from each document after it's decrypted.
- **PUT request to create the indexer:** Running the indexer retrieves the blobs, applies the skillset, and indexes and stores the results. You must run this request last. The custom skill in the skillset invokes the decryption logic.

Monitor indexing

Indexing and enrichment commence as soon as you submit the Create Indexer request. Depending on how many documents are in your storage account, indexing can take a while. To find out whether the indexer is still running, send a **Get Indexer Status** request and review the response to learn whether the indexer is running or view error and warning information.

If you're using the Free tier, expect the following message: "Could not extract content or metadata from your document. Truncated extracted text to '32768' characters". This message appears because blob indexing on the Free tier has a [32,000 limit on character extraction](#). You don't see this message for this data set on higher tiers.

Search your content

After indexer execution is finished, you can run queries to verify that the data is successfully decrypted and indexed. Go to your Azure AI Search service in the Azure portal and use the [Search Explorer](#) to run queries over the indexed data.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the All resources or Resource groups link in the left-navigation pane.

Next steps

Now that you've indexed encrypted files, you can [iterate on this pipeline by adding more skills](#) to enrich and gain more insights into your data.

If you're working with doubly encrypted data, you might want to investigate the index encryption features available in Azure AI Search. Although the indexer needs decrypted data for indexing purposes, once the index exists, it can be encrypted in a search index using a customer-managed key. This ensures that your data is always encrypted when at rest. For more information, see [Configure customer-managed keys for data encryption in Azure AI Search](#).

Tutorial: Index permission metadata from ADLS Gen2 and query with permission-filtered results

09/03/2025

This tutorial demonstrates how to index Azure Data Lake Storage (ADLS) Gen2 [Access Control Lists \(ACLs\)](#) and [role-based access control \(RBAC\)](#) scope into a search index using an indexer.

It also shows you how to structure a query that respects user access permissions. A successful query outcome confirms the permission transfer that occurred during index.

For more information about indexing ACLs, see [Use an ADLS Gen2 indexer to ingest permission metadata](#).

In this tutorial, you learn how to:

- ✓ Configure RBAC scope and ACLs on an `adlsgen2` data source
- ✓ Create an Azure AI Search index containing permission information fields
- ✓ Create and run an indexer to ingest permission information into an index from a data source
- ✓ Search the index you just created

Use a REST client to complete this tutorial and the [latest preview REST API](#). Currently, there's no support for ACL indexing in the Azure portal.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#) .
- Microsoft Entra ID authentication and authorization. Services and apps must be in the same tenant. Role assignments are used for each authenticated connection. Users and groups must be in the same tenant. You should have user and groups to work with. Creating tenants and security principals is out-of-scope for this tutorial.
- [ADLS Gen2](#) with a hierarchical namespace.
- Files in a hierarchical folder structure. This tutorial assumes the ADLS Gen2 demo of folder structure for file [/Oregon/Portland/Data.txt](#). This tutorial guides you through ACL assignment on folders and files so that you can complete the exercise successfully.
- [Azure AI Search](#), any region. Basic tier or higher is required for managed identity support.

- Visual Studio Code [with a REST client](#) or a [Python client](#) and [Jupyter package](#).

Prepare sample data

Upload the [state parks sample data](#) to a container in ADLS Gen2. The container name should be "parks" and it should have two folders: "Oregon" and "Washington".

Check search service configuration

You search service must be configured for Microsoft Entra ID authentication and authorization. Review this checklist to make sure you're prepared.

- [Enable role-based access](#)
- [Configure a system-assigned managed identity.](#)

Get a personal identity token for local testing

This tutorial assumes a REST client on a local system, connecting to Azure over a public internet connection.

[Follow these steps](#) to acquire a personal identity token and set up Visual Studio Code for local connections to your Azure resources.

Set permissions in ADLS Gen2

As a best practice, use [Group sets](#) rather than directly assigning [User](#) sets.

1. Grant the search service identity read access to the container. The indexer connects to Azure Storage under the search service identity. The search service must have **Storage Blob Data Reader** permissions to retrieve data.
2. Grant per-group or user permissions in the file hierarchy. In the file hierarchy, identify all [Group](#) and [User](#) sets that are assigned to containers, directories, and files.
3. You can use the Azure portal to manage ACLs. In Storage Browser, select the Oregon directory and then select **Manage ACL** from the context menu.
4. Add new security principals for users and groups.
5. Remove existing principals for owning groups, owning users, and other. These principals aren't supported for ACL indexing during the public preview.

Create a search index for permission metadata

Create an index that contains fields for content and [permission metadata](#).

Be sure to use the [latest preview REST API](#) or a prerelease Azure SDK that provides equivalent functionality. The permission filter properties are only available in the preview APIs.

For demo purposes, the permission field has `retrievable` enabled so that you can check the values from the index. In a production environment, you should disable `retrievable` to avoid leaking sensitive information.

JSON

```
{
  "name" : "my-adlsgen2-acl-index",
  "fields": [
    {
      "name": "name", "type": "Edm.String",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "description", "type": "Edm.String",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "location", "type": "Edm.String",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "state", "type": "Edm.String",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "AzureSearch_DocumentKey", "type": "Edm.String",
      "searchable": true, "filterable": false, "retrievable": true
      "stored": true,
      "key": true
    },
    {
      "name": "UserIds", "type": "Collection(Edm.String)",
      "permissionFilter": "userIds",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "GroupIds", "type": "Collection(Edm.String)",
      "permissionFilter": "groupIds",
      "searchable": true, "filterable": false, "retrievable": true
    },
    {
      "name": "RbacScope", "type": "Edm.String",
      "permissionFilter": "rbacScope",
      "searchable": true, "filterable": false, "retrievable": true
    }
  ]
}
```

```
        },
    ],
    "permissionFilterOption": "enabled"
}
```

Create a data source

Modify [data source configuration](#) to specify indexer permission ingestion and the types of permission metadata that you want to index.

A data source needs `indexerPermissionOptions`.

In this tutorial, use a system-assigned managed identity for the authenticated connection.

JSON

```
{
    "name" : "my-adlsgen2-acl-datasource",
    "type": "adlsgen2",
    "indexerPermissionOptions": ["userIds", "groupIds", "rbacScope"],
    "credentials": {
        "connectionString": "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>;"
    },
    "container": {
        "name": "parks",
        "query": null
    }
}
```

Create and run the indexer

Indexer configuration for permission ingestion is primarily about defining `fieldMappings` from [permission metadata](#).

JSON

```
{
    "name" : "my-adlsgen2-acl-indexer",
    "dataSourceName" : "my-adlsgen2-acl-datasource",
    "targetIndexName" : "my-adlsgen2-acl-index",
    "parameters": {
        "batchSize": null,
        "maxFailedItems": 0,
        "maxFailedItemsPerBatch": 0,
        "configuration": {
            "storageAccountName": "mystorageaccount",
            "storageContainerName": "parks"
        }
    }
}
```

```
        "dataToExtract": "contentAndMetadata",
        "parsingMode": "delimitedText",
        "firstLineContainsHeaders": true,
        "delimitedTextDelimiter": ",",
        "delimitedTextHeaders": ""
    },
    "fieldMappings": [
        { "sourceFieldName": "metadata_user_ids", "targetFieldName": "UserIds" },
        { "sourceFieldName": "metadata_group_ids", "targetFieldName": "GroupIds" },
        { "sourceFieldName": "metadata_rbac_scope", "targetFieldName": "RbacScope" }
    ]
}
```

After indexer creation and immediate run, the file content along with permission metadata information are indexed into the index.

Run a query to check results

Now that documents are loaded, you can issue queries against them by using [Documents - Search Post \(REST\)](#).

The URI is extended to include a query input, which is specified by using the `/docs/search` operator. The query token is passed in the request header. For more information, see [Query-Time ACL and RBAC enforcement](#).

HTTP

```
POST {{endpoint}}/indexes/stateparks/docs/search?api-version=2025-08-01-preview
Authorization: Bearer {{search-token}}
x-ms-query-source-authorization: {{search-token}}
Content-Type: application/json

{
    "search": "*",
    "select": "name,description,location,GroupIds",
    "orderby": "name asc"
}
```

Tutorial: Vectorize images and text

Azure AI Search can extract and index both text and images from PDF documents stored in Azure Blob Storage. This tutorial shows you how to build a multimodal indexing pipeline in Azure AI Search that *chunks data using the built-in Text Split skill* and *uses multimodal embeddings* to vectorize text and images from the same document. Cropped images are stored in a knowledge store, and both text and visual content are vectorized and ingested in a searchable index.

In this tutorial, you use:

- A 36-page PDF document that combines rich visual content, such as charts, infographics, and scanned pages, with traditional text.
- An indexer and skillset to create an indexing pipeline that includes AI enrichment through skills.
- The [Document Extraction skill](#) for extracting normalized images and text. The [Text Split skill](#) chunks the data.
- The [Azure Vision multimodal embeddings skill](#) to vectorize text and images.
- A search index configured to store extracted text and image content. Some content is vectorized for vector-based similarity search.

This tutorial demonstrates a lower-cost approach for indexing multimodal content using the Document Extraction skill. It enables extraction and search over both text and images from documents pulled from Azure Blob Storage. However, it doesn't include locational metadata for text, such as page numbers or bounding regions. For a more comprehensive solution that includes structured text layout and spatial metadata, see [Tutorial: Vectorize from a structured document layout](#).

(!) Note

Image extraction by the Document Extraction skill isn't free. Setting `imageAction` to `generateNormalizedImages` in the skillset triggers image extraction, which is an extra charge. For billing information, see [Azure AI Search pricing](#).

Prerequisites

- [Microsoft Foundry resource](#). This resource provides access to the Azure Vision multimodal embedding model used in this tutorial. You must use a Foundry resource for skillset

access to this resource.

- [Azure AI Search](#). Configure your search service for role-based access control and a managed identity for connections to Azure Storage and Azure Vision. Your service must be on the Basic tier or higher. This tutorial isn't supported on the Free tier.
- [Azure Storage](#), used for storing sample data and for creating a [knowledge store](#).
- [Visual Studio Code](#) with a [REST client](#).

Limitations

- The [Azure Vision multimodal embeddings skill](#) has limited regional availability. When you create a Foundry resource, choose a region that provides multimodal embeddings. For an updated list of regions that provide multimodal embeddings, see the [Azure Vision documentation](#).

Prepare data

The following instructions apply to Azure Storage which provides the sample data and also hosts the knowledge store. A search service identity needs read access to Azure Storage to retrieve the sample data, and it needs write access to create the knowledge store. The search service creates the container for cropped images during skillset processing, using the name you provide in an environment variable.

1. Download the following sample PDF: [sustainable-ai-pdf](#)
2. In Azure Storage, create a new container named **sustainable-ai-pdf**.
3. [Upload the sample data file](#).
4. [Create role assignments and specify a managed identity in a connection string](#):
 - a. Assign **Storage Blob Data Reader** for data retrieval by the indexer. Assign **Storage Blob Data Contributor** and **Storage Table Data Contributor** to create and load the knowledge store. You can use either a system-assigned managed identity or a user-assigned managed identity for your search service role assignment.
 - b. For connections made using a system-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/;"  
}
```

- c. For connections made using a user-assigned managed identity, get a connection string that contains a ResourceId, with no account key or password. The ResourceId must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. Provide an identity using the syntax shown in the following example. Set userAssignedIdentity to the user-assigned managed identity. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/;"  
},  
"identity" : {  
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",  
    "userAssignedIdentity" : "/subscriptions/00000000-0000-0000-  
00000000/resourcegroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.ManagedIdentity/userAssignedIdentities/MY-DEMO-  
USER-MANAGED-IDENTITY"  
}
```

Prepare models

This tutorial assumes you have an existing Foundry resource through which the skill calls the Azure Vision multimodal 4.0 embedding model. The search service connects to the model during skillset processing using its managed identity. This section gives you guidance and links for assigning roles for authorized access.

1. Sign in to the Azure portal (not the Foundry portal) and find the Foundry resource. Make sure it's in a region that provides the [multimodal 4.0 API](#).
2. Select **Access control (IAM)**.
3. Select **Add** and then **Add role assignment**.
4. Search for **Cognitive Services User** and then select it.
5. Choose **Managed identity** and then assign your [search service managed identity](#).

Set up your REST file

For this tutorial, your local REST client connection to Azure AI Search requires an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Connect to a search service](#).

For authenticated connections that occur during indexer and skillset processing, the search service uses the role assignments you previously defined.

1. Start Visual Studio Code and create a new file.
2. Provide values for variables used in the request. For `@storageConnection`, make sure your connection string doesn't have a trailing semicolon or quotation marks. For `@imageProjectionContainer`, provide a container name that's unique in blob storage. Azure AI Search creates this container for you during skills processing.

HTTP

```
@searchUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE  
@searchApiKey = PUT-YOUR-ADMIN-API-KEY-HERE  
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE  
@cognitiveServicesUrl = PUT-YOUR-AZURE-AI-FOUNDRY-ENDPOINT-HERE  
@modelVersion = 2023-04-15  
@imageProjectionContainer=sustainable-ai-pdf-images
```

3. Save the file using a `.rest` or `.http` file extension. For help with the REST client, see [Quickstart: Full-text search using REST](#).

To get the Azure AI Search endpoint and API key:

1. Sign in to the [Azure portal](#), navigate to the search service **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

Create a data source

[Create Data Source \(REST\)](#) creates a data source connection that specifies what data to index.

HTTP

```
POST {{searchUrl}}/datasources?api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}
```

```
{
  "name": "doc-extraction-multimodal-embedding-ds",
  "description": null,
  "type": "azureblob",
  "subtype": null,
  "credentials": {
    "connectionString": "{{storageConnection}}"
  },
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Location: https://<YOUR-SEARCH-SERVICE-NAME>.search.windows-
int.net:443/datasources('doc-extraction-multimodal-embedding-ds')?api-version=2025-
11-01-preview -Preview
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 4eb8bcc3-27b5-44af-834e-295ed078e8ed
elapsed-time: 346
Date: Sat, 26 Apr 2025 21:25:24 GMT
Connection: close

{
  "name": "doc-extraction-multimodal-embedding-ds",
  "description": null,
  "type": "azureblob",
  "subtype": null,
  "indexerPermissionOptions": [],
  "credentials": {
    "connectionString": null
  },
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the parameters and their attributes.

For nested JSON, the index fields must be identical to the source fields. Currently, Azure AI Search doesn't support field mappings to nested JSON, so field names and data types must match completely. The following index aligns to the JSON elements in the raw content.

HTTP

```
### Create an index
POST {{searchUrl}}/indexes?api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
```

```
api-key: {{searchApiKey}}
```

```
{
```

```
    "name": "doc-extraction-multimodal-embedding-index",
```

```
    "fields": [
```

```
        {
```

```
            "name": "content_id",
```

```
            "type": "Edm.String",
```

```
            "retrievable": true,
```

```
            "key": true,
```

```
            "analyzer": "keyword"
```

```
        },
```

```
        {
```

```
            "name": "text_document_id",
```

```
            "type": "Edm.String",
```

```
            "searchable": false,
```

```
            "filterable": true,
```

```
            "retrievable": true,
```

```
            "stored": true,
```

```
            "sortable": false,
```

```
            "facetable": false
```

```
        },
```

```
        {
```

```
            "name": "document_title",
```

```
            "type": "Edm.String",
```

```
            "searchable": true
```

```
        },
```

```
        {

        "configurations": [
            {
                "name": "semanticconfig",
                "prioritizedFields": {
                    "titleField": {
                        "fieldName": "document_title"
                    },
                    "prioritizedContentFields": [
                    ],
                    "prioritizedKeywordsFields": []
                }
            }
        ]
    }
}

```

Key points:

- Text and image embeddings are stored in the `content_embedding` field and must be configured with appropriate dimensions, such as 1024, and a vector search profile.
- `location_metadata` captures bounding polygon and page number metadata for each normalized image, enabling precise spatial search or UI overlays. `location_metadata` only exists for images in this scenario. If you'd like to capture locational metadata for text as well, consider using [Document Layout skill](#). An in-depth tutorial is linked at the bottom of the page.
- For more information on vector search, see [Vectors in Azure AI Search](#).
- For more information on semantic ranking, see [Semantic ranking in Azure AI Search](#)

Create a skillset

[Create Skillset \(REST\)](#) creates a skillset on your search service. A skillset defines the operations that chunk and embed content prior to indexing. This skillset uses the built-in Document Extraction skill to extract text and images. It uses Text Split skill to chunk large text. It uses Azure Vision multimodal embeddings skill to vectorize image and text content.

HTTP

```

### Create a skillset
POST {{searchUrl}}/skillsets?api-version=2025-11-01-preview   HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

"knowledgeStore": {
    "storageConnectionString": "{{storageConnection}}",
    "identity": null,
    "projections": [
        {
            "files": [
                {
                    "storageContainer": "{{imageProjectionContainer}}",
                    "source": "/document/normalized_images/*"
                }
            ]
        }
    ]
}
}
}

```

This skillset extracts text and images, vectorizes both, and shapes the image metadata for projection into the index.

Key points:

- The `content_text` field is populated with text extracted using the Document Extraction Skill and chunked using the Split Skill
- `content_path` contains the relative path to the image file within the designated image projection container. This field is generated only for images extracted from PDFs when `imageAction` is set to `generateNormalizedImages`, and can be mapped from the enriched document from the source field `/document/normalized_images/*/imagePath`.
- The Azure Vision multimodal embeddings skill enables embedding of both textual and visual data using the same skill type, differentiated by input (text vs image). For more information, see [Azure Vision multimodal embeddings skill](#).

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads data, runs a skillset, and indexes the enriched data.

HTTP

```
### Create and run an indexer
POST {{searchUrl}}/indexers?api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-extraction-multimodal-embedding-indexer",
  "dataSourceName": "doc-extraction-multimodal-embedding-ds",
  "targetIndexName": "doc-extraction-multimodal-embedding-index",
  "skillsetName": "doc-extraction-multimodal-embedding-skillset",
  "parameters": {
    "maxFailedItems": -1,
    "maxFailedItemsPerBatch": 0,
    "batchSize": 1,
    "configuration": {
      "allowSkillsetToReadFileData": true
    }
  },
  "fieldMappings": [
    {
      "sourceFieldName": "metadata_storage_name",
      "targetFieldName": "document_title"
    }
  ],
  "outputFieldMappings": []
}
```

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```
### Query the index
POST {{searchUrl}}/indexes/doc-extraction-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "*",
  "count": true
}
```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
HTTP/1.1 200 OK
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Content-Encoding: gzip
Vary: Accept-Encoding
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 712ca003-9493-40f8-a15e-cf719734a805
elapsed-time: 198
Date: Wed, 30 Apr 2025 23:20:53 GMT
Connection: close

{
  "@odata.count": 100,
  "@search.nextPageParameters": {
    "search": "*",
    "count": true,
    "skip": 50
  },
  "value": [
  ],
  "@odata.nextLink": "https://<YOUR-SEARCH-SERVICE-
NAME>.search.windows.net/indexes/doc-extraction-multimodal-embedding-
index/docs/search?api-version=2025-11-01-preview "
}
```

100 documents are returned in the response.

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case-sensitive. For more information and examples, see [Examples of simple search queries](#).

⚠ Note

The `$filter` parameter only works on fields that were marked filterable during index creation.

HTTP

```
### Query for only images
POST {{searchUrl}}/indexes/doc-extraction-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{

  "search": "*",
  "count": true,
  "filter": "image_document_id ne null"
}
```

HTTP

```
### Query for text or images with content related to energy, returning the id,
parent document, and text (only populated for text chunks), and the content path
where the image is saved in the knowledge store (only populated for images)
POST {{searchUrl}}/indexes/doc-extraction-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{

  "search": "energy",
  "count": true,
  "select": "content_id, document_title, content_text, content_path"
}
```

Reset and rerun

Indexers can be reset to clear the high-water mark, which allows a full rerun. The following POST requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{searchUrl}}/indexers/doc-extraction-multimodal-embedding-indexer/reset?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

HTTP

```
### Run the indexer
POST {{searchUrl}}/indexers/doc-extraction-multimodal-embedding-indexer/run?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

HTTP

```
### Check indexer status
GET {{searchUrl}}/indexers/doc-extraction-multimodal-embedding-indexer/status?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

See also

Now that you're familiar with a sample implementation of a multimodal indexing scenario, check out:

- [Azure Vision multimodal embeddings skill](#)
- [Vectors in Azure AI Search](#)
- [Semantic ranking in Azure AI Search](#)
- [Tutorial: Verbalize images from a structured document layout](#)

Tutorial: Vectorize from a structured document layout

Azure AI Search can extract and index both text and images from PDF documents stored in Azure Blob Storage. This tutorial shows you how to build a multimodal indexing pipeline that *chunks data based on document structure* and *uses multimodal embeddings* to vectorize text and images from the same document. Cropped images are stored in a knowledge store, and both text and visual content are vectorized and ingested in a searchable index. Chunking is based on the [Azure Document Intelligence in Foundry Tools layout model](#) that recognizes document structure.

In this tutorial, you use:

- A 36-page PDF document that combines rich visual content, such as charts, infographics, and scanned pages, with traditional text.
- An indexer and skillset to create an indexing pipeline that includes AI enrichment through skills.
- The [Document Layout skill](#) for extracting text and normalized images with its `locationMetadata` from various documents, such as page numbers or bounding regions.
- The [Azure Vision multimodal embeddings skill](#) to vectorize text and images.
- A search index configured to store extracted text and image content. Some content is vectorized for vector-based similarity search.

Prerequisites

- [Microsoft Foundry resource](#). This resource provides access to both the Azure Vision multimodal embedding model and the Azure Document Intelligence Layout model used by the skills in this tutorial. You must use a Foundry resource for skillset access to these resources.
- [Azure AI Search](#). [Configure your search service](#) for role-based access control and a managed identity. Your service must be on the Basic tier or higher. This tutorial isn't supported on the Free tier.
- [Azure Storage](#), used for storing sample data and for creating a [knowledge store](#).
- [Visual Studio Code](#) with a [REST client](#).

Limitations

- The [Document Layout skill](#) has limited regional availability. When you create the Foundry resource, choose a region that provides multimodal embeddings. For a list of supported regions, see [Document Layout skill supported regions](#).
- The [Azure Vision multimodal embeddings skill](#) also has limited regional availability. For an updated list of regions that provide multimodal embeddings, see the [Azure Vision documentation](#).

Prepare data

The following instructions apply to Azure Storage which provides the sample data and also hosts the knowledge store. A search service identity needs read access to Azure Storage to retrieve the sample data, and it needs write access to create the knowledge store. The search service creates the container for cropped images during skillset processing, using the name you provide in an environment variable.

1. Download the following sample PDF: [sustainable-ai-pdf](#)
2. In Azure Storage, create a new container named **sustainable-ai-pdf**.
3. [Upload the sample data file](#).
4. [Create role assignments and specify a managed identity in a connection string](#):
 - a. Assign **Storage Blob Data Reader** for data retrieval by the indexer. Assign **Storage Blob Data Contributor** and **Storage Table Data Contributor** to create and load the knowledge store. You can use either a system-assigned managed identity or a user-assigned managed identity for your search service role assignment.
 - b. For connections made using a system-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-0000-  
    00000000/resourceGroups/MY-DEMO-RESOURCE-  
    GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/;"  
}
```

c. For connections made using a user-assigned managed identity, get a connection string that contains a ResourceId, with no account key or password. The ResourceId must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. Provide an identity using the syntax shown in the following example. Set userAssignedIdentity to the user-assigned managed identity. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-0000-  
00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-ACCOUNT/ ;"  
},  
"identity" : {  
    "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",  
    "userAssignedIdentity" : "/subscriptions/00000000-0000-0000-0000-  
00000000/resourcegroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.ManagedIdentity/userAssignedIdentities/MY-DEMO-  
USER-MANAGED-IDENTITY"  
}
```

Prepare models

This tutorial assumes you have an existing Foundry resource through which the skill calls the Azure Vision multimodal 4.0 embedding model. The search service connects to the model during skillset processing using its managed identity. This section gives you guidance and links for assigning roles for authorized access.

The same role assignment is also used for accessing the Azure Document Intelligence layout model via a Foundry resource.

1. Sign in to the Azure portal (not the Foundry portal) and find the Foundry resource. Make sure it's in a region that provides the [multimodal 4.0 API](#) and the [Azure Document Intelligence layout model](#).
2. Select **Access control (IAM)**.
3. Select **Add** and then **Add role assignment**.
4. Search for **Cognitive Services User** and then select it.
5. Choose **Managed identity** and then assign your [search service managed identity](#).

Set up your REST file

For this tutorial, your local REST client connection to Azure AI Search requires an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Connect to a search service](#).

For authenticated connections that occur during indexer and skillset processing, the search service uses the role assignments you previously defined.

1. Start Visual Studio Code and create a new file.
2. Provide values for variables used in the request. For `@storageConnection`, make sure your connection string doesn't have a trailing semicolon or quotation marks. For `@imageProjectionContainer`, provide a container name that's unique in blob storage. Azure AI Search creates this container for you during skills processing.

HTTP

```
@searchUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE  
@searchApiKey = PUT-YOUR-ADMIN-API-KEY-HERE  
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE  
@cognitiveServicesUrl = PUT-YOUR-AZURE-AI-FOUNDRY-ENDPOINT-HERE  
@modelVersion = 2023-04-15  
@imageProjectionContainer=sustainable-ai-pdf-images
```

3. Save the file using a `.rest` or `.http` file extension. For help with the REST client, see [Quickstart: Full-text search using REST](#).

To get the Azure AI Search endpoint and API key:

1. Sign in to the [Azure portal](#), navigate to the search service **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

Create a data source

[Create Data Source \(REST\)](#) creates a data source connection that specifies what data to index.

HTTP

```
### Create a data source using system-assigned managed identities
POST {{searchUrl}}/datasources?api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-intelligence-multimodal-embedding-ds",
  "description": "A data source to store multimodal documents",
  "type": "azureblob",
  "subtype": null,
  "credentials": {
    "connectionString": "{{storageConnection}}"
  },
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Location: https://<YOUR-SEARCH-SERVICE-NAME>.search.windows-
int.net:443/datasources('doc-extraction-multimodal-embedding-ds')?api-version=2025-
11-01-preview -Preview
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 4eb8bcc3-27b5-44af-834e-295ed078e8ed
elapsed-time: 346
Date: Sat, 26 Apr 2025 21:25:24 GMT
Connection: close

{
  "name": "doc-extraction-multimodal-embedding-ds",
  "description": null,
  "type": "azureblob",
  "subtype": null,
  "indexerPermissionOptions": [],
  "credentials": {
    "connectionString": null
  },
  "container": {
    "name": "sustainable-ai-pdf",

  "identity": null
}
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the parameters and their attributes.

For nested JSON, the index fields must be identical to the source fields. Currently, Azure AI Search doesn't support field mappings to nested JSON, so field names and data types must match completely. The following index aligns to the JSON elements in the raw content.

HTTP

```
### Create an index
POST {{searchUrl}}/indexes?api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
```

```
api-key: {{searchApiKey}}
```

```
{
```

```
    "name": "doc-intelligence-multimodal-embedding-index",
```

```
    "fields": [
```

```
        {
```

```
            "name": "content_id",
```

```
            "type": "Edm.String",
```

```
            "retrievable": true,
```

```
            "key": true,
```

```
            "analyzer": "keyword"
```

```
        },
```

```
        {
```

```
            "name": "text_document_id",
```

```
            "type": "Edm.String",
```

```
            "searchable": false,
```

```
            "filterable": true,
```

```
            "retrievable": true,
```

```
            "stored": true,
```

```
            "sortable": false,
```

```
            "facetable": false
```

```
        },
```

```
        {
```

```
            "name": "document_title",
```

```
            "type": "Edm.String",
```

```
            "searchable": true
```

```
        },
```

```
        {
```

```
            "name": "image_document_id",
```

```
            "type": "Edm.String",
```

```
            "filterable": true,
```

```
            "retrievable": true
```

```
        },
```

                    },
                    "prioritizedContentFields": [
                    ],
                    "prioritizedKeywordsFields": []
                }
            }
        ]
    }
}

```

Key points:

- Text and image embeddings are stored in the `content_embedding` field and must be configured with appropriate dimensions, such as 1024, and a vector search profile.
- `location_metadata` captures bounding polygon and page number metadata for each text chunk and normalized image, enabling precise spatial search or UI overlays.
- For more information on vector search, see [Vectors in Azure AI Search](#).
- For more information on semantic ranking, see [Semantic ranking in Azure AI Search](#).

Create a skillset

[Create Skillset \(REST\)](#) creates a skillset on your search service. A skillset defines the operations that chunk and embed content prior to indexing. This skillset uses the Document Layout skill to extract text and images, preserving location metadata which is useful for citations in RAG applications. It uses Azure Vision multimodal embeddings skill to vectorize image and text content.

HTTP

```

### Create a skillset
POST {{searchUrl}}/skillsets?api-version=2025-11-01-preview   HTTP/1.1
  Content-Type: application/json
  api-key: {{searchApiKey}}

{
    "name": "doc-intelligence-multimodal-embedding-skillset",

```

```
"description": "A sample skillset for multimodal using multimodal embedding",

```

```
        }
    ]
}
}
```

This skillset extracts text and images, vectorizes both, and shapes the image metadata for projection into the index.

Key points:

- The `content_text` field is populated with text extracted and chunked using the Document Layout Skill
- `content_path` contains the relative path to the image file within the designated image projection container. This field is generated only for images extracted from documents when `extractOption` is set to `["images", "locationMetadata"]` or `["images"]`, and can be mapped from the enriched document from the source field
`/document/normalized_images/*/imagePath.`
- The Azure Vision multimodal embeddings skill enables embedding of both textual and visual data using the same skill type, differentiated by input (text vs image). For more information, see [Azure Vision multimodal embeddings skill](#).

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads data, runs a skillset, and indexes the enriched data.

HTTP

```
### Create and run an indexer
POST {{searchUrl}}/indexers?api-version=2025-11-01-preview   HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "dataSourceName": "doc-intelligence-multimodal-embedding-ds",
  "targetIndexName": "doc-intelligence-multimodal-embedding-index",
  "skillsetName": "doc-intelligence-multimodal-embedding-skillset",
  "parameters": {
    "maxFailedItems": -1,
    "maxFailedItemsPerBatch": 0,
    "batchSize": 1,
    "configuration": {
      "allowSkillsetToReadFileData": true
    }
  },
}
```

```
"fieldMappings": [
  {
    "sourceFieldName": "metadata_storage_name",
    "targetFieldName": "document_title"
  }
],
"outputFieldMappings": []
}
```

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```
### Query the index
POST {{searchUrl}}/indexes/doc-intelligence-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "*",
  "count": true
}
```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
{
  "@odata.count": 100,
  "@search.nextPageParameters": {
    "search": "*",
    "count": true,
    "skip": 50
  },
  "value": [
  ],
  "@odata.nextLink": "https://<YOUR-SEARCH-SERVICE-
NAME>.search.windows.net/indexes/doc-intelligence-multimodal-embedding-
index/docs/search?api-version=2025-11-01-preview "
}
```

100 documents are returned in the response.

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case-sensitive. For more information and examples, see [Examples of simple search queries](#).

⚠ Note

The `$filter` parameter only works on fields that were marked filterable during index creation.

HTTP

```
### Query for only images
POST {{searchUrl}}/indexes/doc-intelligence-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "*",
  "count": true,
  "filter": "image_document_id ne null"
}
```

HTTP

```
### Query for text or images with content related to energy, returning the id,
parent document, and text (only populated for text chunks), and the content path
where the image is saved in the knowledge store (only populated for images)
POST {{searchUrl}}/indexes/doc-intelligence-multimodal-embedding-index/docs/search?
api-version=2025-11-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "energy",
  "count": true,
  "select": "content_id, document_title, content_text, content_path"
}
```

Reset and rerun

Indexers can be reset to clear execution history, which allows a full rerun. The following POST requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{searchUrl}}/indexers/doc-intelligence-multimodal-embedding-indexer/reset?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

HTTP

```
### Run the indexer
POST {{searchUrl}}/indexers/doc-intelligence-multimodal-embedding-indexer/run?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

HTTP

```
### Check indexer status
GET {{searchUrl}}/indexers/doc-intelligence-multimodal-embedding-indexer/status?api-version=2025-11-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

Tutorial: Verbalize images using generative AI

08/27/2025

Azure AI Search can extract and index both text and images from PDF documents stored in Azure Blob Storage. This tutorial shows you how to build a multimodal indexing pipeline that *chunks data using the built-in Text Split skill* and uses *image verbalization* to describe images. Cropped images are stored in a knowledge store, and visual content is described in natural language and ingested alongside text in a searchable index.

To get image verbalizations, each extracted image is passed to the [GenAI Prompt skill \(preview\)](#) that calls a chat completion model to generate a concise textual description. These descriptions, along with the original document text, are then embedded into vector representations using Azure OpenAI's text-embedding-3-large model. The result is a single index containing searchable content from both modalities: text and verbalized images.

In this tutorial, you use:

- A 36-page PDF document that combines rich visual content, such as charts, infographics, and scanned pages, with traditional text.
- An indexer and skillset to create an indexing pipeline that includes AI enrichment through skills.
- The [Document Extraction skill](#) for extracting normalized images and text. The [Text Split skill](#) chunks the data.
- The [GenAI Prompt skill \(preview\)](#) that calls a chat completion model to create descriptions of visual content.
- A search index configured to store text and image verbalizations. Some content is vectorized for vector-based similarity search.

This tutorial demonstrates a lower-cost approach for indexing multimodal content using the Document Extraction skill and image captioning. It enables extraction and search over both text and images from documents in Azure Blob Storage. However, it doesn't include locational metadata for text, such as page numbers or bounding regions. For a more comprehensive solution that includes structured text layout and spatial metadata, see [Tutorial: Verbalize images from a structured document layout](#).

Note

Image extraction by the Document Extraction skill isn't free. Setting `imageAction` to `generateNormalizedImages` in the skillset triggers image extraction, which is an extra charge. For billing information, see [Azure AI Search pricing](#).

Prerequisites

- [Azure AI Search](#). Configure your search service for role-based access control and a managed identity. Your service must be on the Basic tier or higher. This tutorial isn't supported on the Free tier.
- [Azure Storage](#), used for storing sample data and for creating a [knowledge store](#).
- [Azure OpenAI](#) with a deployment of
 - A chat completion model hosted in Azure AI Foundry or another source. The model is used to verbalize image content. You provide the URI to the hosted model in the GenAI Prompt skill definition. You can use [any chat completion model](#).
 - A text embedding model deployed in Azure AI Foundry. The model is used to vectorize text content pull from source documents and the image descriptions generated by the chat completion model. For integrated vectorization, the embedding model must be located in Azure AI Foundry, and it must be either text-embedding-ada-002, text-embedding-3-large, or text-embedding-3-small. If you want to use an external embedding model, use a custom skill instead of the Azure OpenAI embedding skill.
- [Visual Studio Code](#) with a [REST client](#).

Prepare data

The following instructions apply to Azure Storage which provides the sample data and also hosts the knowledge store. A search service identity needs read access to Azure Storage to retrieve the sample data, and it needs write access to create the knowledge store. The search service creates the container for cropped images during skillset processing, using the name you provide in an environment variable.

1. Download the following sample PDF: [sustainable-ai-pdf](#)
2. In Azure Storage, create a new container named **sustainable-ai-pdf**.
3. [Upload the sample data file](#).
4. [Create role assignments and specify a managed identity in a connection string](#):

- a. Assign **Storage Blob Data Reader** for data retrieval by the indexer. Assign **Storage Blob Data Contributor** and **Storage Table Data Contributor** to create and load the knowledge store. You can use either a system-assigned managed identity or a user-assigned managed identity for your search service role assignment.
- b. For connections made using a system-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
0000-00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-  
ACCOUNT/;"  
}
```

- c. For connections made using a user-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. Provide an identity using the syntax shown in the following example. Set userAssignedIdentity to the user-assigned managed identity. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
0000-00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-  
ACCOUNT/;"  
,  
    "identity" : {  
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",  
        "userAssignedIdentity" : "/subscriptions/00000000-0000-0000-  
00000000/resourcegroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.ManagedIdentity/userAssignedIdentities/MY-DEMO-  
USER-MANAGED-IDENTITY"  
    }  
}
```

Prepare models

This tutorial assumes you have an existing Azure OpenAI resource through which the skills call the text embedding model and chat completion models. The search service connects to the models during skillset processing and during query execution using its managed identity. This section gives you guidance and links for assigning roles for authorized access.

1. Sign in to the Azure portal (not the Foundry portal) and find the Azure OpenAI resource.
2. Select **Access control (IAM)**.
3. Select **Add** and then **Add role assignment**.
4. Search for **Cognitive Services OpenAI User** and then select it.
5. Choose **Managed identity** and then assign your [search service managed identity](#).

For more information, see [Role-based access control for Azure OpenAI in Azure AI Foundry Models](#).

Set up your REST file

For this tutorial, your local REST client connection to Azure AI Search requires an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Connect to a search service](#).

For authenticated connections that occur during indexer and skillset processing, the search service uses the role assignments you previously defined.

1. Start Visual Studio Code and create a new file.
2. Provide values for variables used in the request. For `@storageConnection`, make sure your connection string doesn't have a trailing semicolon or quotation marks. For `@imageProjectionContainer`, provide a container name that's unique in blob storage. Azure AI Search creates this container for you during skills processing.

HTTP

```
@searchUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE  
@searchApiKey = PUT-YOUR-ADMIN-API-KEY-HERE  
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE  
@openAIResourceUri = PUT-YOUR-OPENAI-URI-HERE  
@openAIKey = PUT-YOUR-OPENAI-KEY-HERE  
@chatCompletionResourceUri = PUT-YOUR-CHAT-COMPLETION-URI-HERE  
@chatCompletionKey = PUT-YOUR-CHAT-COMPLETION-KEY-HERE  
@imageProjectionContainer=sustainable-ai-pdf-images
```

3. Save the file using a `.rest` or `.http` file extension. For help with the REST client, see [Quickstart: Full-text search using REST](#).

To get the Azure AI Search endpoint and API key:

1. Sign in to the [Azure portal](#), navigate to the search service **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

The screenshot shows two stacked Azure portal pages. The top page is the 'new-demo-search-svc | Overview' page, where the 'Overview' tab is selected (marked with a red box and number 1). The URL `https://new-demo-search-svc.search.windows.net` is displayed in the top right. The bottom page is the 'new-demo-search-svc | Keys' page, where the 'Keys' tab is selected (marked with a red box and number 2). It shows the 'API access control' settings (radio buttons for API keys, Role-based access control, or Both) and the 'Manage admin keys' section, which contains fields for Primary admin key and Secondary admin key, each with a placeholder value like '`<your-primary-admin-key-here>`' and a 'Regenerate' button. Both the URL and the 'Manage admin keys' section are highlighted with red boxes.

Create a data source

[Create Data Source \(REST\)](#) creates a data source connection that specifies what data to index.

```
HTTP

### Create a data source
POST {{searchUrl}}/datasources?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-extraction-image-verbalization-ds",
  "description": null,
  "type": "azureblob",
  "subtype": null,
  "credentials":{
    "connectionString": "{{storageConnection}}"
}
```

```
},
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Location: https://<YOUR-SEARCH-SERVICE-NAME>.search.windows-
int.net:443/datasources('doc-extraction-multimodal-embedding-ds')?api-
version=2025-08-01-preview -Preview
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 4eb8bcc3-27b5-44af-834e-295ed078e8ed
elapsed-time: 346
Date: Sat, 26 Apr 2025 21:25:24 GMT
Connection: close

{
  "name": "doc-extraction-multimodal-embedding-ds",
  "description": null,
  "type": "azureblob",
  "subtype": null,
  "indexerPermissionOptions": [],
  "credentials": {
    "connectionString": null
  },
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the parameters and their attributes.

For nested JSON, the index fields must be identical to the source fields. Currently, Azure AI Search doesn't support field mappings to nested JSON, so field names and data types must match completely. The following index aligns to the JSON elements in the raw content.

HTTP

```
### Create an index
POST {{searchUrl}}/indexes?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-extraction-image-verbalization-index",
  "fields": [
    {
      "name": "content_id",
      "type": "Edm.String",
      " retrievable": true,
      "key": true,
      "analyzer": "keyword"
    },
    {
      "name": "text_document_id",
      "type": "Edm.String",
      "searchable": false,
      "filterable": true,
      "retrievable": true,
      "stored": true,
      "sortable": false,
      "facetable": false
    },

}
]
}
}

```

Key points:

- Text and image embeddings are stored in the `content_embedding` field and must be configured with appropriate dimensions (for example, 3072) and a vector search profile.
- `location_metadata` captures bounding polygon and page number metadata for each normalized image, enabling precise spatial search or UI overlays. `location_metadata` only exists for images in this scenario. If you'd like to capture locational metadata for text as well, consider using [Document Layout skill](#). An in-depth tutorial is linked at the bottom of the page.
- For more information on vector search, see [Vectors in Azure AI Search](#).
- For more information on semantic ranking, see [Semantic ranking in Azure AI Search](#)

Create a skillset

[Create Skillset \(REST\)](#) creates a skillset on your search service. A skillset defines the operations that chunk and embed content prior to indexing. This skillset uses the built-in Document Extraction skill to extract text and images. It uses Text Split skill to chunk large text. It uses Azure OpenAI Embedding skill to vectorize text content.

The skillset also performs actions specific to images. It uses the GenAI Prompt skill to generate image descriptions. It also creates a knowledge store that stores intact images so that you can return them in a query.

HTTP

```
### Create a skillset
POST {{searchUrl}}/skillsets?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

```

This skillset extracts text and images, vectorizes both, and shapes the image metadata for projection into the index.

Key points:

- The `content_text` field is populated in two ways:
 - From document text extracted using the Document Extraction skill and chunked using the Text Split skill
 - From image content using the GenAI Prompt skill, which generates descriptive captions for each normalized image
- The `content_embedding` field contains 3072-dimensional embeddings for both page text and verbalized image descriptions. These are generated using the text-embedding-3-large model from Azure OpenAI.
- `content_path` contains the relative path to the image file within the designated image projection container. This field is generated only for images extracted from PDFs when `imageAction` is set to `generateNormalizedImages`, and can be mapped from the enriched document from the source field `/document/normalized_images/*/imagePath`.

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads data, runs a skillset, and indexes the enriched data.

HTTP

```

### Create and run an indexer
POST {{searchUrl}}/indexers?api-version=2025-08-01-preview   HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

```

```
{  
  "dataSourceName": "doc-extraction-image-verbalization-ds",  
  "targetIndexName": "doc-extraction-image-verbalization-index",  
  "skillsetName": "doc-extraction-image-verbalization-skillset",  
  "parameters": {  
    "maxFailedItems": -1,  
    "maxFailedItemsPerBatch": 0,  
    "batchSize": 1,  
    "configuration": {  
      "allowSkillsetToReadFileData": true  
    }  
  },  
  "fieldMappings": [  
    {  
      "sourceFieldName": "metadata_storage_name",  
      "targetFieldName": "document_title"  
    }  
  ],  
  "outputFieldMappings": []  
}
```

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```
### Query the index  
POST {{searchUrl}}/indexes/doc-extraction-image-verbalization-index/docs/search?  
api-version=2025-08-01-preview HTTP/1.1  
Content-Type: application/json  
api-key: {{searchApiKey}}  
  
{  
  "search": "*",  
  "count": true  
}
```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
HTTP/1.1 200 OK  
Transfer-Encoding: chunked  
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;  
charset=utf-8
```

```
Content-Encoding: gzip
Vary: Accept-Encoding
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 712ca003-9493-40f8-a15e-cf719734a805
elapsed-time: 198
Date: Wed, 30 Apr 2025 23:20:53 GMT
Connection: close

{
    "@odata.count": 100,
    "@search.nextPageParameters": {
        "search": "*",
        "count": true,
        "skip": 50
    },
    "value": [
    ],
    "@odata.nextLink": "https://<YOUR-SEARCH-SERVICE-NAME>.search.windows.net/indexes/doc-extraction-image-verbalization-index/docs/search?api-version=2025-08-01-preview "
}
```

100 documents are returned in the response.

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case -sensitive. For more information and examples, see [Examples of simple search queries](#).

 **Note**

The `$filter` parameter only works on fields that were marked filterable during index creation.

Here are some examples of other queries:

HTTP

```
### Query for only images
POST {{searchUrl}}/indexes/doc-extraction-image-verbalization-index/docs/search?
api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
    "search": "*",
    "count": true,
```

```
        "filter": "image_document_id ne null"
    }
```

HTTP

```
### Query for text or images with content related to energy, returning the id, parent document, and text (extracted text for text chunks and verbalized image text for images), and the content path where the image is saved in the knowledge store (only populated for images)
POST {{searchUrl}}/indexes/doc-extraction-image-verbalization-index/docs/search?api-version=2025-08-01-preview HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "energy",
  "count": true,
  "select": "content_id, document_title, content_text, content_path"
}
```

Reset and rerun

Indexers can be reset to clear the high-water mark, which allows a full rerun. The following POST requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{searchUrl}}/indexers/doc-extraction-image-verbalization-indexer/reset?api-version=2025-08-01-preview HTTP/1.1
api-key: {{searchApiKey}}
```

HTTP

```
### Run the indexer
POST {{searchUrl}}/indexers/doc-extraction-image-verbalization-indexer/run?api-version=2025-08-01-preview HTTP/1.1
api-key: {{searchApiKey}}
```

HTTP

```
### Check indexer status
GET {{searchUrl}}/indexers/doc-extraction-image-verbalization-indexer/status?api-version=2025-08-01-preview HTTP/1.1
api-key: {{searchApiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

Tutorial: Verbalize images from a structured document layout

09/27/2025

Azure AI Search can extract and index both text and images from PDF documents stored in Azure Blob Storage. This tutorial shows you how to build a multimodal indexing pipeline that *chunks data based on document structure* and uses *image verbalization* to describe images. Cropped images are stored in a knowledge store, and visual content is described in natural language and ingested alongside text in a searchable index. Chunking is based on the Azure AI Document Intelligence Layout model that recognizes document structure.

To get image verbalizations, each extracted image is passed to the [GenAI Prompt skill \(preview\)](#) that calls a chat completion model to generate a concise textual description. These descriptions, along with the original document text, are then embedded into vector representations using Azure OpenAI's text-embedding-3-large model. The result is a single index containing searchable content from both modalities: text and verbalized images.

In this tutorial, you use:

- A 36-page PDF document that combines rich visual content, such as charts, infographics, and scanned pages, with traditional text.
- An indexer and skillset to create an indexing pipeline that includes AI enrichment through skills.
- The [Document Layout skill](#) for extracting text and normalized images with its `locationMetadata` from various documents, such as page numbers or bounding regions.
- The [GenAI Prompt skill \(preview\)](#) that calls a chat completion model to create descriptions of visual content.
- A search index configured to store extracted text and image verbalizations. Some content is vectorized for vector-based similarity search.

Prerequisites

- [Azure AI services multi-service account](#). This account provides access to the Document Intelligence Layout model used in this tutorial. You must use an Azure AI multi-service account for skillset access to this resource.
- [Azure AI Search](#). [Configure your search service](#) for role-based access control and a managed identity. Your service must be on the Basic tier or higher. This tutorial isn't

supported on the Free tier.

- [Azure Storage](#), used for storing sample data and for creating a [knowledge store](#).
- [Azure OpenAI](#) with a deployment of
 - A chat completion model hosted in Azure AI Foundry or another source. The model is used to verbalize image content. You provide the URI to the hosted model in the GenAI Prompt skill definition. You can use [any chat completion model](#).
 - A text embedding model deployed in Azure AI Foundry. The model is used to vectorize text content pull from source documents and the image descriptions generated by the chat completion model. For integrated vectorization, the embedding model must be located in Azure AI Foundry, and it must be either text-embedding-ada-002, text-embedding-3-large, or text-embedding-3-small. If you want to use an external embedding model, use a custom skill instead of the Azure OpenAI embedding skill.
- [Visual Studio Code](#) with a [REST client](#).

Limitations

- The [Document Layout skill](#) has limited regional availability. For a list of supported regions, see [Document Layout skill > Supported regions](#).

Prepare data

The following instructions apply to Azure Storage which provides the sample data and also hosts the knowledge store. A search service identity needs read access to Azure Storage to retrieve the sample data, and it needs write access to create the knowledge store. The search service creates the container for cropped images during skillset processing, using the name you provide in an environment variable.

1. Download the following sample PDF: [sustainable-ai-pdf](#)
2. In Azure Storage, create a new container named **sustainable-ai-pdf**.
3. [Upload the sample data file](#).
4. [Create role assignments and specify a managed identity in a connection string](#):
 - a. Assign **Storage Blob Data Reader** for data retrieval by the indexer. Assign **Storage Blob Data Contributor** and **Storage Table Data Contributor** to create and load the knowledge store. You can use either a system-assigned managed identity or a user-assigned managed identity for your search service role assignment.

- b. For connections made using a system-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
0000-00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-  
ACCOUNT/;"  
}
```

- c. For connections made using a user-assigned managed identity, get a connection string that contains a Resourceld, with no account key or password. The Resourceld must include the subscription ID of the storage account, the resource group of the storage account, and the storage account name. Provide an identity using the syntax shown in the following example. Set userAssignedIdentity to the user-assigned managed identity. The connection string is similar to the following example:

JSON

```
"credentials" : {  
    "connectionString" : "ResourceId=/subscriptions/00000000-0000-0000-  
0000-00000000/resourceGroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.Storage/storageAccounts/MY-DEMO-STORAGE-  
ACCOUNT/;"  
,  
    "identity" : {  
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",  
        "userAssignedIdentity" : "/subscriptions/00000000-0000-0000-  
00000000/resourcegroups/MY-DEMO-RESOURCE-  
GROUP/providers/Microsoft.ManagedIdentity/userAssignedIdentities/MY-DEMO-  
USER-MANAGED-IDENTITY"  
    }  
}
```

Prepare models

This tutorial assumes you have an existing Azure OpenAI resource through which the skills a chat completion model for GenAI Prompt and also a text embedding model for vectorization. The search service connects to the models during skillset processing and during query execution using its managed identity. This section gives you guidance and links for assigning roles for authorized access.

You also need a role assignment for accessing the Document Intelligence Layout model via an Azure AI multi-service account.

Assign roles in Azure AI multi-service

1. Sign in to the Azure portal (not the Foundry portal) and find the Azure AI multi-service account. Make sure it's in a region that provides the [Document Intelligence Layout model](#).
2. Select **Access control (IAM)**.
3. Select **Add** and then **Add role assignment**.
4. Search for **Cognitive Services User** and then select it.
5. Choose **Managed identity** and then assign your [search service managed identity](#).

Assign roles in Azure OpenAI

1. Sign in to the Azure portal (not the Foundry portal) and find the Azure OpenAI resource.
2. Select **Access control (IAM)**.
3. Select **Add** and then **Add role assignment**.
4. Search for **Cognitive Services OpenAI User** and then select it.
5. Choose **Managed identity** and then assign your [search service managed identity](#).

For more information, see [Role-based access control for Azure OpenAI in Azure AI Foundry Models](#).

Set up your REST file

For this tutorial, your local REST client connection to Azure AI Search requires an endpoint and an API key. You can get these values from the Azure portal. For alternative connection methods, see [Connect to a search service](#).

For authenticated connections that occur during indexer and skillset processing, the search service uses the role assignments you previously defined.

1. Start Visual Studio Code and create a new file.
2. Provide values for variables used in the request. For `@storageConnection`, make sure your connection string doesn't have a trailing semicolon or quotation marks. For

@imageProjectionContainer , provide a container name that's unique in blob storage.

Azure AI Search creates this container for you during skills processing.

```
HTTP

@searchUrl = PUT-YOUR-SEARCH-SERVICE-ENDPOINT-HERE
@searchApiKey = PUT-YOUR-ADMIN-API-KEY-HERE
@storageConnection = PUT-YOUR-STORAGE-CONNECTION-STRING-HERE
@cognitiveServicesUrl = PUT-YOUR-AZURE-AI-MULTI-SERVICE-ENDPOINT-HERE
@openAIResourceUri = PUT-YOUR-OPENAI-URI-HERE
@openAIKey = PUT-YOUR-OPENAI-KEY-HERE
@chatCompletionResourceUri = PUT-YOUR-CHAT-COMPLETION-URI-HERE
@chatCompletionKey = PUT-YOUR-CHAT-COMPLETION-KEY-HERE
@imageProjectionContainer=sustainable-ai-pdf-images
```

3. Save the file using a `.rest` or `.http` file extension. For help with the REST client, see [Quickstart: Full-text search using REST](#).

To get the Azure AI Search endpoint and API key:

1. Sign in to the [Azure portal](#), navigate to the search service **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

The image contains two screenshots of the Microsoft Azure portal. The top screenshot shows the 'new-demo-search-svc' search service in the 'Overview' tab. A red box highlights the 'Overview' link in the left sidebar, and another red box highlights the 'Url' field which contains the value `https://new-demo-search-svc.search.windows.net`. The bottom screenshot shows the 'new-demo-search-svc | Keys' settings page. A red box highlights the 'Keys' link in the left sidebar, and another red box highlights the 'Primary admin key' input field which contains the placeholder text `<your-primary-admin-key-here>`. Both screenshots show the Azure navigation bar at the top.

Create a data source

Create Data Source (REST) creates a data source connection that specifies what data to index.

HTTP

```
### Create a data source using system-assigned managed identities
POST {{searchUrl}}/datasources?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-intelligence-image-verbalization-ds",
  "description": "A data source to store multi-modality documents",
  "type": "azureblob",
  "subtype": null,
  "credentials": {
    "connectionString": "{{storageConnection}}"
  },
  "container": {
    "name": "sustainable-ai-pdf",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

Send the request. The response should look like:

JSON

```
HTTP/1.1 201 Created
Transfer-Encoding: chunked
Content-Type: application/json; odata.metadata=minimal; odata.streaming=true;
charset=utf-8
Location: https://<YOUR-SEARCH-SERVICE-NAME>.search.windows-
int.net:443/datasources('doc-extraction-multimodal-embedding-ds')?api-
version=2025-08-01-preview -Preview
Server: Microsoft-IIS/10.0
Strict-Transport-Security: max-age=2592000, max-age=15724800; includeSubDomains
Preference-Applied: odata.include-annotations="*"
OData-Version: 4.0
request-id: 4eb8bcc3-27b5-44af-834e-295ed078e8ed
elapsed-time: 346
Date: Sat, 26 Apr 2025 21:25:24 GMT
Connection: close

{
  "name": "doc-extraction-multimodal-embedding-ds",
  "description": null,
  "type": "azureblob",
```

```
"subtype": null,
"indexerPermissionOptions": [],
"credentials": {
    "connectionString": null
},
"container": {
    "name": "sustainable-ai-pdf",
    "query": null
},
"dataChangeDetectionPolicy": null,
"dataDeletionDetectionPolicy": null,
"encryptionKey": null,
"identity": null
}
```

Create an index

[Create Index \(REST\)](#) creates a search index on your search service. An index specifies all the parameters and their attributes.

For nested JSON, the index fields must be identical to the source fields. Currently, Azure AI Search doesn't support field mappings to nested JSON, so field names and data types must match completely. The following index aligns to the JSON elements in the raw content.

HTTP

```
### Create an index
POST {{searchUrl}}/indexes?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
    "name": "doc-intelligence-image-verbalization-index",
    "fields": [
        {
            "name": "content_id",
            "type": "Edm.String",
            "retrievable": true,
            "key": true,
            "analyzer": "keyword"
        },
        {
            "name": "text_document_id",
            "type": "Edm.String",
            "searchable": false,
            "filterable": true,
            "retrievable": true,
            "stored": true,
            "sortable": false,
            "facetable": false
        }
    ]
}
```

```
},
{
    "name": "document_title",

            }
        }
    ],
    "vectorizers": [
        {
            "name": "demo-vectorizer",
            "kind": "azureOpenAI",
            "azureOpenAIParameters": {
                "resourceUri": "{{openAIResourceUri}}",
                "deploymentId": "text-embedding-3-large",
                "apiKey": "{{openAIKey}}",
                "modelName": "text-embedding-3-large"
            }
        }
    ]
},
"semantic": {
    "defaultConfiguration": "semanticconfig",
    "configurations": [
        {
            "name": "semanticconfig",
            "prioritizedFields": {
                "titleField": {
                    "fieldName": "document_title"
                },
                "prioritizedContentFields": [
                ],
                "prioritizedKeywordsFields": []
            }
        }
    ]
}
}
```

Key points:

- Text and image embeddings are stored in the `content_embedding` field and must be configured with appropriate dimensions, such as 3072, and a vector search profile.
- `location_metadata` captures bounding polygon and page number metadata for each text chunk and normalized image, enabling precise spatial search or UI overlays.
- For more information on vector search, see [Vectors in Azure AI Search](#).
- For more information on semantic ranking, see [Semantic ranking in Azure AI Search](#)

Create a skillset

[Create Skillset \(REST\)](#) creates a skillset on your search service. A skillset defines the operations that chunk and embed content prior to indexing. This skillset uses the Document Layout skill to extract text and images, preserving location metadata which is useful for citations in RAG applications. It uses Azure OpenAI Embedding skill to vectorize text content.

The skillset also performs actions specific to images. It uses the GenAI Prompt skill to generate image descriptions. It also creates a knowledge store that stores intact images so that you can return them in a query.

HTTP

```
### Create a skillset
POST {{searchUrl}}/skillsets?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "name": "doc-intelligence-image-verbalization-skillset",
  "description": "A sample skillset for multi-modality using image verbalization",
  "skills": [
    {
      "@odata.type": "#Microsoft.Skills.Util.DocumentIntelligenceLayoutSkill",
      "name": "document-cracking-skill",

            ]
        }
    ]
}
}

```

This skillset extracts text and images, verbalizes images, and shapes the image metadata for projection into the index.

Key points:

- The `content_text` field is populated in two ways:

- From document text extracted and chunked using the Document Layout skill.
- From image content using the GenAI Prompt skill, which generates descriptive captions for each normalized image
- The `content_embedding` field contains 3072-dimensional embeddings for both page text and verbalized image descriptions. These are generated using the text-embedding-3-large model from Azure OpenAI.
- `content_path` contains the relative path to the image file within the designated image projection container. This field is generated only for images extracted from documents when `extractOption` is set to `["images", "locationMetadata"]` or `["images"]`, and can be mapped from the enriched document from the source field
`/document/normalized_images/*/imagePath.`
- The Azure OpenAI embeddings skill enables embedding of textual data. For more information, see [Azure OpenAI Embedding skill](#).

Create and run an indexer

[Create Indexer](#) creates an indexer on your search service. An indexer connects to the data source, loads data, runs a skillset, and indexes the enriched data.

HTTP

```
### Create and run an indexer
POST {{searchUrl}}/indexers?api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "dataSourceName": "doc-intelligence-image-verbalization-ds",
  "targetIndexName": "doc-intelligence-image-verbalization-index",
  "skillsetName": "doc-intelligence-image-verbalization-skillset",
  "parameters": {
    "maxFailedItems": -1,
    "maxFailedItemsPerBatch": 0,
    "batchSize": 1,
    "configuration": {
      "allowSkillsetToReadFileData": true
    }
  },
  "fieldMappings": [
    {
      "sourceFieldName": "metadata_storage_name",
      "targetFieldName": "document_title"
    }
  ],
}
```

```
"outputFieldMappings": []  
}
```

Run queries

You can start searching as soon as the first document is loaded.

HTTP

```
### Query the index  
POST {{searchUrl}}/indexes/doc-intelligence-image-verbalization-index/docs/search?  
api-version=2025-08-01-preview    HTTP/1.1  
Content-Type: application/json  
api-key: {{searchApiKey}}  
  
{  
  "search": "*",  
  "count": true  
}
```

Send the request. This is an unspecified full-text search query that returns all of the fields marked as retrievable in the index, along with a document count. The response should look like:

JSON

```
{  
  "@odata.count": 100,  
  "@search.nextPageParameters": {  
    "search": "*",  
    "count": true,  
    "skip": 50  
  },  
  "value": [  
  ],  
  "@odata.nextLink": "https://<YOUR-SEARCH-SERVICE-  
NAME>.search.windows.net/indexes/doc-intelligence-image-verbalization-  
index/docs/search?api-version=2025-08-01-preview "  
}
```

100 documents are returned in the response.

For filters, you can also use Logical operators (and, or, not) and comparison operators (eq, ne, gt, lt, ge, le). String comparisons are case -sensitive. For more information and examples, see [Examples of simple search queries](#).

(!) Note

The `$filter` parameter only works on fields that were marked filterable during index creation.

HTTP

```
### Query for only images
POST {{searchUrl}}/indexes/doc-intelligence-image-verbalization-index/docs/search?
api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "*",
  "count": true,
  "filter": "image_document_id ne null"
}
```

HTTP

```
### Query for text or images with content related to energy, returning the id,
parent document, and text (only populated for text chunks), and the content path
where the image is saved in the knowledge store (only populated for images)
POST {{searchUrl}}/indexes/doc-intelligence-image-verbalization-index/docs/search?
api-version=2025-08-01-preview    HTTP/1.1
Content-Type: application/json
api-key: {{searchApiKey}}

{
  "search": "energy",
  "count": true,
  "select": "content_id, document_title, content_text, content_path"
}
```

Reset and rerun

Indexers can be reset to clear execution history, which allows a full rerun. The following POST requests are for reset, followed by rerun.

HTTP

```
### Reset the indexer
POST {{searchUrl}}/indexers/doc-intelligence-image-verbalization-indexer/reset?
api-version=2025-08-01-preview    HTTP/1.1
api-key: {{searchApiKey}}
```

```
HTTP
```

```
### Run the indexer
POST {{searchUrl}}/indexers/doc-intelligence-image-verbalization-indexer/run?api-version=2025-08-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

```
HTTP
```

```
### Check indexer status
GET {{searchUrl}}/indexers/doc-intelligence-image-verbalization-indexer/status?
api-version=2025-08-01-preview HTTP/1.1
    api-key: {{searchApiKey}}
```

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can use the Azure portal to delete indexes, indexers, and data sources.

Tutorial: Build an end-to-end agentic retrieval solution using Azure AI Search

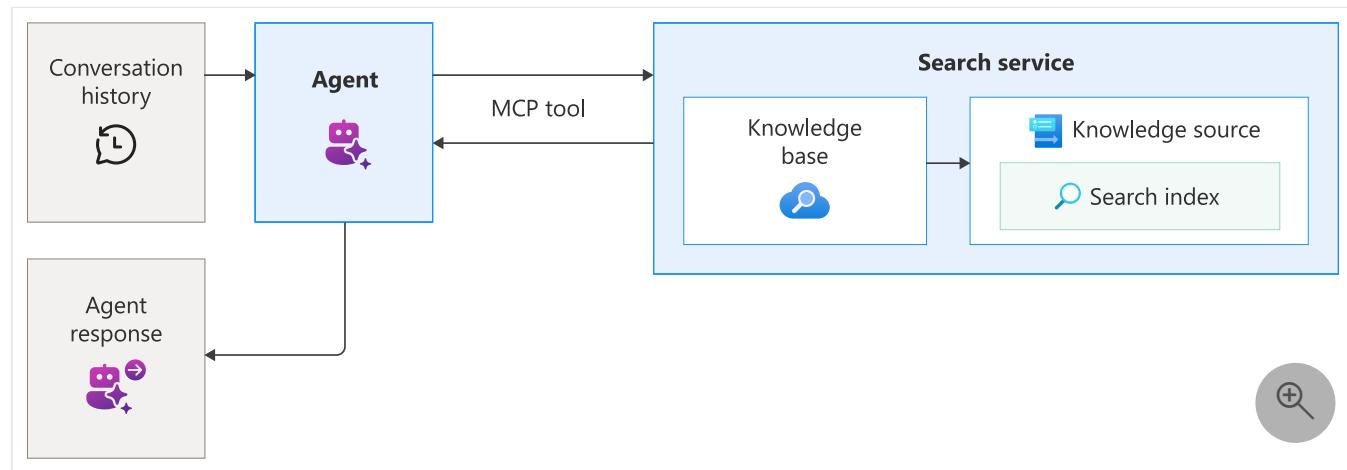

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In this tutorial, you learn how to build a solution that integrates Azure AI Search and Foundry Agent Service for intelligent knowledge retrieval.

This solution uses Model Context Protocol (MCP) to establish a standardized connection between your agentic retrieval pipeline in Azure AI Search, which consists of a *knowledge base* that references a *knowledge source*, and your agent in Foundry Agent Service. You can use this architecture for conversational applications that require complex reasoning over large knowledge domains, such as customer support or technical troubleshooting.

The following diagram shows the high-level architecture of this agentic retrieval solution:

💡 Tip

- Want to get started right away? See the [agentic-retrieval-pipeline-example](#) source code.
- Want a simpler introduction to agentic retrieval? See [Quickstart: Use agentic retrieval](#).

Prerequisites

- An Azure AI Search service in any region that provides agentic retrieval.
- A [Microsoft Foundry project](#) and resource. When you create a project, the resource is automatically created.
- A [supported LLM](#) deployed to your project. We recommend a minimum token capacity of 100,000. You can find the LLM's capacity and rate limit in the Foundry portal. If you want [vectorization at query time](#), you should also deploy a text embedding model.
- [Authentication and permissions](#) on your search service and project.
- Preview package versions. For a complete list of versions used in this solution, see the [requirements.txt](#) file.

Authentication and permissions

Before you begin, make sure you have permissions to access content and operations. We recommend Microsoft Entra ID authentication and role-based access for authorization. You must be an **Owner** or **User Access Administrator** to assign roles. If roles aren't feasible, you can use [key-based authentication](#) instead.

To configure access for this solution, select both of the following tabs.

Azure AI Search

1. [Enable role-based access.](#)
2. [Configure a managed identity.](#)
3. [Assign roles:](#)
 - You must have the **Search Service Contributor**, **Search Index Data Contributor**, and **Search Index Data Reader** roles to create, load, and retrieve on Azure AI Search.
 - For integrated operations, ensure that all clients using the retrieval pipeline have the **Search Index Data Reader** role for sending retrieval requests.

Understand the solution

This section pairs each component of the solution with its corresponding development tasks. For deeper guidance, see the linked how-to articles.

Azure AI Search

Azure AI Search hosts your indexed content and the agentic retrieval pipeline.

Development tasks include:

- Create a [knowledge source](#). Agentic retrieval supports multiple types of knowledge sources, but this solution creates a [search index knowledge source](#).
- [Create a knowledge base](#) that maps to your LLM deployment and uses the extractive data output mode. We recommend this output mode for interaction with Foundry Agent Service because it provides the agent with verbatim, unprocessed content for grounding and reasoning.

A user initiates query processing by interacting with a client app, such as a chatbot, that calls the agent. The agent uses the MCP tool to orchestrate requests to the knowledge base and synthesize responses. When the chatbot calls the agent, the MCP tool calls the knowledge base in Azure AI Search and sends it back to the agent and chatbot.

Build the solution

Follow these steps to create an end-to-end agentic retrieval solution.

Get endpoints

For this solution, you need the following endpoints:

Azure AI Search

- The endpoint for your search service, which you can find on the [Overview](#) page in the Azure portal. It should look like this: `https://{your-service-name}.search.windows.net/`

Create agentic retrieval objects

This section omits code snippets for creating the knowledge source and knowledge base in Azure AI Search, skipping ahead to the Foundry Agent Service integration. For more

information about the omitted steps, see the [Understand the solution](#) section.

Create a project connection

Before you can use the MCP tool in an agent, you must create a project connection in Foundry that points to the `mcp_endpoint` of your knowledge base. This endpoint allows the agent to access your knowledge base.

Python

```
import requests
from azure.identity import DefaultAzureCredential, get_bearer_token_provider

# Provide connection details
credential = DefaultAzureCredential()
project_resource_id = "{project_resource_id}" # e.g.
/subscriptions/{subscription}/resourceGroups/{resource_group}/providers/Microsoft.Ma
chineLearningServices/workspaces/{account_name}/projects/{project_name}
project_connection_name = "{project_connection_name}"
mcp_endpoint = "{search_service_endpoint}/knowledgebases/{knowledge_base_name}/mcp?
api-version=2025-11-01-preview" # This endpoint enables the MCP connection between
the agent and knowledge base

# Get bearer token for authentication
bearer_token_provider = get_bearer_token_provider(credential,
"https://management.azure.com/.default")
headers = {
    "Authorization": f"Bearer {bearer_token_provider()}",

}

# Create project connection
response = requests.put(
    f"https://management.azure.com{project_resource_id}/connections/{project_connection_
name}?api-version=2025-10-01-preview",
    headers = headers,
    json = {
        "name": "project_connection_name",
        "type": "Microsoft.MachineLearningServices/workspaces/connections",
        "properties": {
            "authType": "ProjectManagedIdentity",
            "category": "RemoteTool",
            "target": mcp_endpoint,
            "isSharedToAll": True,
            "audience": "https://search.azure.com/",
            "metadata": { "ApiType": "Azure" }
        }
    }
)
```

```
response.raise_for_status()
print(f"Connection '{project_connection_name}' created or updated successfully.")
```

Set up an AI project client

Use [AIProjectClient](#) to create a client connection to your Foundry project.

Python

```
from azure.ai.projects import AIProjectClient

project_client = AIProjectClient(endpoint=project_endpoint, credential=credential)

list(project_client.agents.list())
```

Create an agent that uses the MCP tool

The next step is to create an agent configured with the MCP tool. When the agent receives a user query, it can call your knowledge base through the MCP tool to retrieve relevant content for response grounding.

The agent definition includes instructions that specify its behavior and the project connection you previously created. For more information, see [Quickstart: Create a new agent](#).

Python

```
from azure.ai.projects.models import PromptAgentDefinition, MCPTool

# Define agent instructions
instructions = """
A Q&A agent that can answer questions based on the attached knowledge base.
Always provide references to the ID of the data source used to answer the question.
If you don't have the answer, respond with "I don't know".
"""

# Create MCP tool with knowledge base connection
mcp_kb_tool = MCPTool(
    server_label = "knowledge-base",
    server_url = mcp_endpoint,
    require_approval = "never",
    allowed_tools = ["knowledge_base_retrieve"],
    project_connection_id = project_connection_name
)

# Create agent with MCP tool
agent = project_client.agents.create_version(
    agent_name = agent_name,
    definition = PromptAgentDefinition(
        model = agent_model,
```

```
        instructions = instructions,
        tools = [mcp_kb_tool]
    )

print(f"Agent '{agent_name}' created or updated successfully.")
```

Chat with the agent

Your client app uses the Conversations and [Responses](#) APIs from Azure OpenAI to send user input to the agent. The client creates a conversation and passes each user message to the agent through the Responses API, resembling a typical chat experience.

The agent manages the conversation, determines when to call your knowledge base through the MCP tool, and returns a natural-language response (with references to the retrieved content) to the client app.

Python

```
# Get the OpenAI client for responses and conversations
openai_client = project_client.get_openai_client()

# Create conversation
conversation = openai_client.conversations.create()

# Send request to trigger the MCP tool
response = openai_client.responses.create(
    conversation = conversation.id,
    input = """
        Why do suburban belts display larger December brightening than urban cores
        even though absolute light levels are higher downtown?
        Why is the Phoenix nighttime street grid is so sharply visible from space,
        whereas large stretches of the interstate between midwestern cities remain
        comparatively dim?
        """,
    extra_body = {"agent": {"name": agent.name, "type": "agent_reference"}},
)

print(f"Response: {response.output_text}")
```

Improve data quality

By default, search results from your knowledge base are consolidated into a large unified string that can be passed to the agent for grounding. Azure AI Search provides the following indexing and relevance-tuning features to help you generate high-quality results. You can implement these features in the search index, and the improvements in search relevance are evident in the quality of retrieval responses.

- [Scoring profiles](#) provide built-in boosting criteria. Your index must specify a default scoring profile, which is used by the retrieval engine when queries include fields associated with that profile.
- [Semantic configuration](#) is required, but you determine which fields are prioritized and used for ranking.
- For plain-text content, you can use [analyzers](#) to control tokenization during indexing.
- For [multimodal or image content](#), you can use image verbalization for LLM-generated descriptions of your images or classic OCR and image analysis via skillsets during indexing.

Control the number of subqueries

The LLM that powers your knowledge base determines the number of subqueries based on the following factors:

- User query
- Chat history
- Semantic ranker input constraints

As the developer, you can control the number of subqueries by [setting the retrieval reasoning effort](#). The reasoning effort determines the level of LLM processing for query planning, ranging from minimal (no LLM processing) to medium (deeper search and follow-up iterations).

Control the context sent to the agent

The Responses API controls what is sent to the agent and knowledge base. To optimize performance and relevance, adjust your agent instructions to summarize or filter the chat history before sending it to the MCP tool.

Control costs and limit operations

For insights into the query plan, look at output tokens in the [activity array](#) of knowledge base responses.

Improve performance

To optimize performance and reduce latency, consider the following strategies:

- Summarize message threads.
- Use `gpt-4.1-mini` or a smaller model that performs faster.
- Set `maxOutputSize` on the [retrieve action](#) to govern the size of the response or `maxRuntimeInSeconds` for time-bound processing.

Clean up resources

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can also delete individual objects:

Python

```
# Delete the agent
project_client.agents.delete_version(agent.name, agent.version)
print(f"AI agent '{agent.name}' version '{agent.version}' deleted successfully")

# Delete the knowledge base
index_client.delete_knowledge_base(base_name)
print(f"Knowledge base '{base_name}' deleted successfully")

# Delete the knowledge source
index_client.delete_knowledge_source(knowledge_source=knowledge_source_name) # This
is new feature in 2025-08-01-Preview api version
print(f"Knowledge source '{knowledge_source_name}' deleted successfully.")

# Delete the search index
index_client.delete_index(index)
print(f"Index '{index_name}' deleted successfully")
```

Tutorial: Skillsets in Azure AI Search

Learn how to use the [Azure SDK for .NET](#) to create an [AI enrichment pipeline](#) for content extraction and transformations during indexing.

Skillsets add AI processing to raw content, making it more uniform and searchable. Once you know how skillsets work, you can support a broad range of transformations, from image analysis to natural language processing to customized processing that you provide externally.

In this tutorial, you:

- ✓ Define objects in an enrichment pipeline.
- ✓ Build a skillset. Invoke OCR, language detection, entity recognition, and key phrase extraction.
- ✓ Execute the pipeline. Create and load a search index.
- ✓ Check the results using full-text search.

Overview

This tutorial uses C# and the [Azure.Search.Documents](#) client library to create a data source, index, indexer, and skillset.

The [indexer](#) drives each step in the pipeline, starting with content extraction of sample data (unstructured text and images) in a blob container on Azure Storage.

Once content is extracted, the [skillset](#) executes built-in skills from Microsoft to find and extract information. These skills include Optical Character Recognition (OCR) on images, language detection on text, key phrase extraction, and entity recognition (organizations). New information created by the skillset is sent to fields in an [index](#). Once the index is populated, you can use the fields in queries, facets, and filters.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Azure Storage](#).
- [Azure AI Search](#).
- [Azure.Search.Documents package](#).
- [Visual Studio](#).

(!) Note

You can use a free search service for this tutorial. The Free tier limits you to three indexes, three indexers, and three data sources. This tutorial creates one of each. Before you start, make sure you have room on your service to accept the new resources.

Download files

- Download a zip file of the sample data repository and extract the contents. [Learn how ↗](#).
- Download the [sample data files \(mixed media\) ↗](#)

Upload sample data to Azure Storage

1. In Azure Storage, [create a new container](#) and name it *mixed-content-types*.
2. Upload the sample data files.
3. Get a storage connection string so that you can formulate a connection in Azure AI Search.
 - a. On the left, select **Access keys**.
 - b. Copy the connection string for either key one or key two. The connection string is similar to the following example:

```
DefaultEndpointsProtocol=https;AccountName=<your account name>;AccountKey=<your  
account key>;EndpointSuffix=core.windows.net
```

Foundry Tools

Built-in AI enrichment is backed by Foundry Tools, including Azure Language and Azure Vision for natural language and image processing. For small workloads like this tutorial, you can use the free allocation of 20 transactions per indexer. For larger workloads, [attach a Microsoft Foundry resource to a skillset](#) for Standard pricing.

Copy a search service URL and API key

For this tutorial, connections to Azure AI Search require an endpoint and an API key. You can get these values from the Azure portal.

1. Sign in to the [Azure portal ↗](#) and select your search service.

2. From the left pane, select **Overview** and copy the endpoint. It should be in this format:

`https://my-service.search.windows.net`

3. From the left pane, select **Settings > Keys** and copy an admin key for full rights on the service. There are two interchangeable admin keys, provided for business continuity in case you need to roll one over. You can use either key on requests to add, modify, or delete objects.

Set up your environment

Begin by opening Visual Studio and creating a new Console App project.

Install Azure.Search.Documents

The [Azure AI Search .NET SDK](#) consists of a client library that enables you to manage your indexes, data sources, indexers, and skillsets, as well as upload and manage documents and execute queries, all without having to deal with the details of HTTP and JSON. This client library is distributed as a NuGet package.

For this project, install version 11 or later of the `Azure.Search.Documents` and the latest version of `Microsoft.Extensions.Configuration`.

1. In Visual Studio, select **Tools > NuGet Package Manager > Manage NuGet Packages for Solution...**
2. Browse for [Azure.Search.Document](#).
3. Select the latest version and then select **Install**.
4. Repeat the previous steps to install [Microsoft.Extensions.Configuration](#) and [Microsoft.Extensions.Configuration.Json](#).

Add service connection information

1. Right-click on your project in the Solution Explorer and select **Add > New Item...**
2. Name the file `appsettings.json` and select **Add**.
3. Include this file in your output directory.
 - a. Right-click on `appsettings.json` and select **Properties**.
 - b. Change the value of **Copy to Output Directory** to **Copy if newer**.
4. Copy the below JSON into your new JSON file.

JSON

```
{  
    "SearchServiceUri": "<YourSearchServiceUri>",  
    "SearchServiceAdminApiKey": "<YourSearchServiceAdminApiKey>",  
    "SearchServiceQueryApiKey": "<YourSearchServiceQueryApiKey>",  
    "AzureAISServicesKey": "<YourMultiRegionAzureAISServicesKey>",  
    "AzureBlobConnectionString": "<YourAzureBlobConnectionString>"  
}
```

Add your search service and blob storage account information. Recall that you can get this information from the service provisioning steps indicated in the previous section.

For **SearchServiceUri**, enter the full URL.

Add namespaces

In `Program.cs`, add the following namespaces.

C#

```
using Azure;  
using Azure.Search.Documents.Indexes;  
using Azure.Search.Documents.Indexes.Models;  
using Microsoft.Extensions.Configuration;  
using System;  
using System.Collections.Generic;  
using System.Linq;  
  
namespace EnrichwithAI
```

Create a client

Create an instance of a `SearchIndexClient` and a `SearchIndexerClient` under `Main`.

C#

```
public static void Main(string[] args)  
{  
    // Create service client  
    IConfigurationBuilder builder = new  
    ConfigurationBuilder().AddJsonFile("appsettings.json");  
    IConfigurationRoot configuration = builder.Build();  
  
    string searchServiceUri = configuration["SearchServiceUri"];  
    string adminApiKey = configuration["SearchServiceAdminApiKey"];  
    string azureAiServicesKey = configuration["AzureAISServicesKey"];  
  
    SearchIndexClient indexClient = new SearchIndexClient(new Uri(searchServiceUri),
```

```
new AzureKeyCredential(adminApiKey));
    SearchIndexerClient indexerClient = new SearchIndexerClient(new
Uri(searchServiceUri), new AzureKeyCredential(adminApiKey));
}
```

! Note

The clients connect to your search service. In order to avoid opening too many connections, you should try to share a single instance in your application if possible. The methods are thread-safe to enable such sharing.

Add a function to exit the program during failure

This tutorial is meant to help you understand each step of the indexing pipeline. If there's a critical issue that prevents the program from creating the data source, skillset, index, or indexer the program will output the error message and exit so that the issue can be understood and addressed.

Add `ExitProgram` to `Main` to handle scenarios that require the program to exit.

C#

```
private static void ExitProgram(string message)
{
    Console.WriteLine("{0}", message);
    Console.WriteLine("Press any key to exit the program...");
    Console.ReadKey();
    Environment.Exit(0);
}
```

Create the pipeline

In Azure AI Search, AI processing occurs during indexing (or data ingestion). This part of the walkthrough creates four objects: data source, index definition, skillset, indexer.

Step 1: Create a data source

`SearchIndexerClient` has a `DataSourceName` property that you can set to a `SearchIndexerDataSourceConnection` object. This object provides all the methods you need to create, list, update, or delete Azure AI Search data sources.

Create a new `SearchIndexerDataSourceConnection` instance by calling `indexerClient.CreateOrUpdateDataSourceConnection(dataSource)`. The following code creates a data source of type `AzureBlob`.

C#

```
private static SearchIndexerDataSourceConnection
CreateOrUpdateDataSource(SearchIndexerClient indexerClient, IConfigurationRoot
configuration)
{
    SearchIndexerDataSourceConnection dataSource = new
    SearchIndexerDataSourceConnection(
        name: "demodata",
        type: SearchIndexerDataSourceType.AzureBlob,
        connectionString: configuration["AzureBlobConnectionString"],
        container: new SearchIndexerDataContainer("mixed-content-type"))
    {
        Description = "Demo files to demonstrate Azure AI Search capabilities."
    };

    // The data source does not need to be deleted if it was already created
    // since we are using the CreateOrUpdate method
    try
    {
        indexerClient.CreateOrUpdateDataSourceConnection(dataSource);
    }
    catch (Exception ex)
    {
        Console.WriteLine("Failed to create or update the data source\n Exception
message: {0}\n", ex.Message);
        ExitProgram("Cannot continue without a data source");
    }

    return dataSource;
}
```

For a successful request, the method returns the data source that was created. If there's a problem with the request, such as an invalid parameter, the method throws an exception.

Now add a line in `Main` to call the `CreateOrUpdateDataSource` function that you've just added.

C#

```
// Create or Update the data source
Console.WriteLine("Creating or updating the data source...");
```

```
SearchIndexerDataSourceConnection dataSource =
CreateOrUpdateDataSource(indexerClient, configuration);
```

Build and run the solution. Since this is your first request, check the Azure portal to confirm the data source was created in Azure AI Search. On the search service overview page, verify the

Data Sources list has a new item. You might need to wait a few minutes for the Azure portal page to refresh.

Step 2: Create a skillset

In this section, you define a set of enrichment steps that you want to apply to your data. Each enrichment step is called a *skill* and the set of enrichment steps, a *skillset*. This tutorial uses [built-in skills](#) for the skillset:

- [Optical Character Recognition](#) to recognize printed and handwritten text in image files.
- [Text Merger](#) to consolidate text from a collection of fields into a single "merged content" field.
- [Language Detection](#) to identify the content's language.
- [Entity Recognition](#) for extracting the names of organizations from content in the blob container.
- [Text Split](#) to break large content into smaller chunks before calling the key phrase extraction skill and the entity recognition skill. Key phrase extraction and entity recognition accept inputs of 50,000 characters or less. A few of the sample files need splitting up to fit within this limit.
- [Key Phrase Extraction](#) to pull out the top key phrases.

During initial processing, Azure AI Search cracks each document to extract content from different file formats. Text originating in the source file is placed into a generated `content` field, one for each document. As such, set the input as `"/document/content"` to use this text. Image content is placed into a generated `normalized_images` field, specified in a skillset as `/document/normalized_images/*`.

Outputs can be mapped to an index, used as input to a downstream skill, or both as is the case with language code. In the index, a language code is useful for filtering. As an input, language code is used by text analysis skills to inform the linguistic rules around word breaking.

For more information about skillset fundamentals, see [How to define a skillset](#).

OCR skill

The [OcrSkill](#) extracts text from images. This skill assumes that a `normalized_images` field exists. To generate this field, later in the tutorial we set the `"imageAction"` configuration in the indexer

definition to "generateNormalizedImages".

C#

```
private static OcrSkill CreateOcrSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("image")
    {
        Source = "/document/normalized_images/*"
    });

    List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>();
    outputMappings.Add(new OutputFieldMappingEntry("text")
    {
        TargetName = "text"
    });

    OcrSkill ocrSkill = new OcrSkill(inputMappings, outputMappings)
    {
        Description = "Extract text (plain and structured) from image",
        Context = "/document/normalized_images/*",
        DefaultLanguageCode = OcrSkillLanguage.En,
        ShouldDetectOrientation = true
    };

    return ocrSkill;
}
```

Merge skill

In this section, you create a [MergeSkill](#) that merges the document content field with the text that was produced by the OCR skill.

C#

```
private static MergeSkill CreateMergeSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("text")
    {
        Source = "/document/content"
    });
    inputMappings.Add(new InputFieldMappingEntry("itemsToInsert")
    {
        Source = "/document/normalized_images/*/text"
    });
    inputMappings.Add(new InputFieldMappingEntry("offsets")
    {
        Source = "/document/normalized_images/*/contentOffset"
    });
}
```

```

    });

    List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>();
    outputMappings.Add(new OutputFieldMappingEntry("mergedText")
    {
        TargetName = "merged_text"
    });

    MergeSkill mergeSkill = new MergeSkill(inputMappings, outputMappings)
    {
        Description = "Create merged_text which includes all the textual representation of each image inserted at the right location in the content field.",
        Context = "/document",
        InsertPreTag = " ",
        InsertPostTag = " "
    };

    return mergeSkill;
}

```

Language detection skill

The [LanguageDetectionSkill](#) detects the language of the input text and reports a single language code for every document submitted on the request. We use the output of the **Language Detection** skill as part of the input to the **Text Split** skill.

C#

```

private static LanguageDetectionSkill CreateLanguageDetectionSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("text")
    {
        Source = "/document/merged_text"
    });

    List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>();
    outputMappings.Add(new OutputFieldMappingEntry("languageCode")
    {
        TargetName = "languageCode"
    });

    LanguageDetectionSkill languageDetectionSkill = new
    LanguageDetectionSkill(inputMappings, outputMappings)
    {
        Description = "Detect the language used in the document",
        Context = "/document"
    };
}

```

```
    return languageDetectionSkill;
}
```

Text split skill

The below [SplitSkill](#) splits text by pages and limits the page length to 4,000 characters as measured by `String.Length`. The algorithm tries to split the text into chunks that are at most `maximumPageLength` in size. In this case, the algorithm does its best to break the sentence on a sentence boundary, so the size of the chunk might be slightly less than `maximumPageLength`.

C#

```
private static SplitSkill CreateSplitSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("text")
    {
        Source = "/document/merged_text"
    });
    inputMappings.Add(new InputFieldMappingEntry("languageCode")
    {
        Source = "/document/languageCode"
    });

    List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>();
    outputMappings.Add(new OutputFieldMappingEntry("textItems")
    {
        TargetName = "pages",
    });

    SplitSkill splitSkill = new SplitSkill(inputMappings, outputMappings)
    {
        Description = "Split content into pages",
        Context = "/document",
        TextSplitMode = TextSplitMode.Pages,
        MaximumPageLength = 4000,
        DefaultLanguageCode = SplitSkillLanguage.English
    };

    return splitSkill;
}
```

Entity recognition skill

This `EntityRecognitionSkill` instance is set to recognize category type `organization`. The `EntityRecognitionSkill` can also recognize category types `person` and `location`.

Notice that the "context" field is set to `"/document/pages/*"` with an asterisk, meaning the enrichment step is called for each page under `"/document/pages"`.

C#

```
private static EntityRecognitionSkill CreateEntityRecognitionSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("text")
    {
        Source = "/document/pages/*"
    });

    List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>();
    outputMappings.Add(new OutputFieldMappingEntry("organizations")
    {
        TargetName = "organizations"
    });

    // Specify the V3 version of the EntityRecognitionSkill
    var skillVersion = EntityRecognitionSkill.SkillVersion.V3;

    var entityRecognitionSkill = new EntityRecognitionSkill(inputMappings,
    outputMappings, skillVersion)
    {
        Description = "Recognize organizations",
        Context = "/document/pages/*",
        DefaultLanguageCode = EntityRecognitionSkillLanguage.English
    };
    entityRecognitionSkill.Categories.Add(EntityCategory.Organization);
    return entityRecognitionSkill;
}
```

Key phrase extraction skill

Like the `EntityRecognitionSkill` instance that was just created, the `KeyPhraseExtractionSkill` is called for each page of the document.

C#

```
private static KeyPhraseExtractionSkill CreateKeyPhraseExtractionSkill()
{
    List<InputFieldMappingEntry> inputMappings = new List<InputFieldMappingEntry>();
    inputMappings.Add(new InputFieldMappingEntry("text")
    {
        Source = "/document/pages/*"
    });
    inputMappings.Add(new InputFieldMappingEntry("languageCode")
    {
```

```

        Source = "/document/languageCode"
    });

List<OutputFieldMappingEntry> outputMappings = new List<OutputFieldMappingEntry>()
();
outputMappings.Add(new OutputFieldMappingEntry("keyPhrases")
{
    TargetName = "keyPhrases"
});

KeyPhraseExtractionSkill keyPhraseExtractionSkill = new
KeyPhraseExtractionSkill(inputMappings, outputMappings)
{
    Description = "Extract the key phrases",
    Context = "/document/pages/*",
    DefaultLanguageCode = KeyPhraseExtractionSkillLanguage.En
};

return keyPhraseExtractionSkill;
}

```

Build and create the skillset

Build the [SearchIndexerSkillset](#) using the skills you created.

C#

```

private static SearchIndexerSkillset CreateOrUpdateDemoSkillSet(SearchIndexerClient
indexerClient, IList<SearchIndexerSkill> skills, string azureAiServicesKey)
{
    SearchIndexerSkillset skillset = new SearchIndexerSkillset("demoskillset",
skills)
    {
        // Foundry Tools was formerly known as Cognitive Services.
        // The APIs still use the old name, so we need to create a
CognitiveServicesAccountKey object.
        Description = "Demo skillset",
        CognitiveServicesAccount = new
CognitiveServicesAccountKey(azureAiServicesKey)
    };

    // Create the skillset in your search service.
    // The skillset does not need to be deleted if it was already created
    // since we are using the CreateOrUpdate method
    try
    {
        indexerClient.CreateOrUpdateSkillset(skillset);
    }
    catch (RequestFailedException ex)
    {
        Console.WriteLine("Failed to create the skillset\n Exception message:
{0}\n", ex.Message);
    }
}

```

```

        ExitProgram("Cannot continue without a skillset");
    }

    return skillset;
}

```

Add the following lines to `Main`.

C#

```

// Create the skills
Console.WriteLine("Creating the skills...");
OcrSkill ocrSkill = CreateOcrSkill();
MergeSkill mergeSkill = CreateMergeSkill();
EntityRecognitionSkill entityRecognitionSkill = CreateEntityRecognitionSkill();
LanguageDetectionSkill languageDetectionSkill = CreateLanguageDetectionSkill();
SplitSkill splitSkill = CreateSplitSkill();
KeyPhraseExtractionSkill keyPhraseExtractionSkill =
CreateKeyPhraseExtractionSkill();

// Create the skillset
Console.WriteLine("Creating or updating the skillset...");
List<SearchIndexerSkill> skills = new List<SearchIndexerSkill>();
skills.Add(ocrSkill);
skills.Add(mergeSkill);
skills.Add(languageDetectionSkill);
skills.Add(splitSkill);
skills.Add(entityRecognitionSkill);
skills.Add(keyPhraseExtractionSkill);

SearchIndexerSkillset skillset = CreateOrUpdateDemoSkillSet(indexerClient, skills,
azureAiServicesKey);

```

Step 3: Create an index

In this section, you define the index schema by specifying which fields to include in the searchable index, and the search attributes for each field. Fields have a type and can take attributes that determine how the field is used (searchable, sortable, and so forth). Field names in an index aren't required to identically match the field names in the source. In a later step, you add field mappings in an indexer to connect source-destination fields. For this step, define the index using field naming conventions pertinent to your search application.

This exercise uses the following fields and field types:

[] Expand table

Field names	Field types
id	Edm.String
content	Edm.String
languageCode	Edm.String
keyPhrases	List<Edm.String>
organizations	List<Edm.String>

Create DemoIndex Class

The fields for this index are defined using a model class. Each property of the model class has attributes that determine the search-related behaviors of the corresponding index field.

We'll add the model class to a new C# file. Right select on your project and select **Add > New Item...**, select "Class" and name the file `DemoIndex.cs`, then select **Add**.

Make sure to indicate that you want to use types from the `Azure.Search.Documents.Indexes` and `System.Text.Json.Serialization` namespaces.

Add the below model class definition to `DemoIndex.cs` and include it in the same namespace where you create the index.

C#

```
using Azure.Search.Documents.Indexes;
using System.Text.Json.Serialization;

namespace EnrichwithAI
{
    // The SerializePropertyNamesAsCamelCase is currently unsupported as of this
    // writing.
    // Replace it with JsonPropertyName
    public class DemoIndex
    {
        [SearchableField(IsSortable = true, IsKey = true)]
        [JsonPropertyName("id")]
        public string Id { get; set; }

        [SearchableField]
        [JsonPropertyName("content")]
        public string Content { get; set; }

        [SearchableField]
        [JsonPropertyName("languageCode")]
        public string LanguageCode { get; set; }
    }
}
```

```

[SearchableField]
[JsonPropertyName("keyPhrases")]
public string[] KeyPhrases { get; set; }

[SearchableField]
[JsonPropertyName("organizations")]
public string[] Organizations { get; set; }
}

}

```

Now that you've defined a model class, back in `Program.cs` you can create an index definition fairly easily. The name for this index will be `demoindex`. If an index already exists with that name, it's deleted.

C#

```

private static SearchIndex CreateDemoIndex(SearchIndexClient indexClient)
{
    FieldBuilder builder = new FieldBuilder();
    var index = new SearchIndex("demoindex")
    {
        Fields = builder.Build(typeof(DemoIndex))
    };

    try
    {
        indexClient.GetIndex(index.Name);
        indexClient.DeleteIndex(index.Name);
    }
    catch (RequestFailedException ex) when (ex.Status == 404)
    {
        //if the specified index not exist, 404 will be thrown.
    }

    try
    {
        indexClient.CreateIndex(index);
    }
    catch (RequestFailedException ex)
    {
        Console.WriteLine("Failed to create the index\n Exception message: {0}\n",
ex.Message);
        ExitProgram("Cannot continue without an index");
    }

    return index;
}

```

During testing, you might find that you're attempting to create the index more than once. Because of this, check to see if the index that you're about to create already exists before

attempting to create it.

Add the following lines to `Main`.

```
C#
```

```
// Create the index
Console.WriteLine("Creating the index...");
SearchIndex demoIndex = CreateDemoIndex(indexClient);
```

Add the following using statement to resolve the disambiguated reference.

```
C#
```

```
using Index = Azure.Search.Documents.Indexes.Models;
```

To learn more about index concepts, see [Create Index \(REST API\)](#).

Step 4: Create and run an indexer

So far you have created a data source, a skillset, and an index. These three components become part of an [indexer](#) that pulls each piece together into a single multi-phased operation. To tie these together in an indexer, you must define field mappings.

- The `fieldMappings` are processed before the skillset, mapping source fields from the data source to target fields in an index. If field names and types are the same at both ends, no mapping is required.
- The `outputFieldMappings` are processed after the skillset, referencing `sourceFieldNames` that don't exist until document cracking or enrichment creates them. The `targetFieldName` is a field in an index.

In addition to hooking up inputs to outputs, you can also use field mappings to flatten data structures. For more information, see [How to map enriched fields to a searchable index](#).

```
C#
```

```
private static SearchIndexer CreateDemoIndexer(SearchIndexerClient indexerClient,
SearchIndexerDataSourceConnection dataSource, SearchIndexerSkillset skillSet,
SearchIndex index)
{
    IndexingParameters indexingParameters = new IndexingParameters()
    {
        MaxFailedItems = -1,
        MaxFailedItemsPerBatch = -1,
    };
    indexingParameters.Configuration.Add("dataToExtract", "contentAndMetadata");
```

```
indexingParameters.Configuration.Add("imageAction", "generateNormalizedImages");

SearchIndexer indexer = new SearchIndexer("demoindexer", dataSource.Name,
index.Name)
{
    Description = "Demo Indexer",
    SkillsetName = skillSet.Name,
    Parameters = indexingParameters
};

FieldMappingFunction mappingFunction = new FieldMappingFunction("base64Encode");
mappingFunction.Parameters.Add("useHttpServerUtilityUrlTokenEncode", true);

indexer.FieldMappings.Add(new FieldMapping("metadata_storage_path")
{
    TargetFieldName = "id",
    MappingFunction = mappingFunction
});

indexer.FieldMappings.Add(new FieldMapping("content")
{
    TargetFieldName = "content"
});

indexer.OutputFieldMappings.Add(new
FieldMapping("/document/pages/*/organizations/*")
{
    TargetFieldName = "organizations"
});
indexer.OutputFieldMappings.Add(new
FieldMapping("/document/pages/*/keyPhrases/*")
{
    TargetFieldName = "keyPhrases"
});
indexer.OutputFieldMappings.Add(new FieldMapping("/document/languageCode")
{
    TargetFieldName = "languageCode"
});

try
{
    indexerClient.GetIndexer(indexer.Name);
    indexerClient.DeleteIndexer(indexer.Name);
}
catch (RequestFailedException ex) when (ex.Status == 404)
{
    //if the specified indexer not exist, 404 will be thrown.
}

try
{
    indexerClient.CreateIndexer(indexer);
}
catch (RequestFailedException ex)
{
```

```
        Console.WriteLine("Failed to create the indexer\n Exception message: {0}\n",  
    ex.Message);  
        ExitProgram("Cannot continue without creating an indexer");  
    }  
  
    return indexer;  
}
```

Add the following lines to `Main`.

C#

```
// Create the indexer, map fields, and execute transformations  
Console.WriteLine("Creating the indexer and executing the pipeline...");  
SearchIndexer demoIndexer = CreateDemoIndexer(indexerClient, dataSource, skillset,  
demoIndex);
```

Expect indexer processing to take some time to complete. Even though the data set is small, analytical skills are computation-intensive. Some skills, such as image analysis, are long-running.

💡 Tip

Creating an indexer invokes the pipeline. If there are problems reaching the data, mapping inputs and outputs, or order of operations, they appear at this stage.

Explore creating the indexer

The code sets `"maxFailedItems"` to -1, which instructs the indexing engine to ignore errors during data import. This is useful because there are so few documents in the demo data source. For a larger data source, you would set the value to greater than 0.

Also notice the `"dataToExtract"` is set to `"contentAndMetadata"`. This statement tells the indexer to automatically extract the content from different file formats as well as metadata related to each file.

When content is extracted, you can set `imageAction` to extract text from images found in the data source. The `"imageAction"` set to `"generateNormalizedImages"` configuration, combined with the OCR Skill and Text Merge Skill, tells the indexer to extract text from the images (for example, the word "stop" from a traffic Stop sign), and embed it as part of the content field. This behavior applies to both the images embedded in the documents (think of an image inside a PDF), as well as images found in the data source, for instance a JPG file.

Monitor indexing

Once the indexer is defined, it runs automatically when you submit the request. Depending on which skills you defined, indexing can take longer than you expect. To find out whether the indexer is still running, use the `GetStatus` method.

C#

```
private static void CheckIndexerOverallStatus(SearchIndexerClient indexerClient,
SearchIndexer indexer)
{
    try
    {
        var demoIndexerExecutionInfo = indexerClient.GetIndexerStatus(indexer.Name);

        switch (demoIndexerExecutionInfo.Value.Status)
        {
            case IndexerStatus.Error:
                ExitProgram("Indexer has error status. Check the Azure portal to
further understand the error.");
                break;
            case IndexerStatus.Running:
                Console.WriteLine("Indexer is running");
                break;
            case IndexerStatus.Unknown:
                Console.WriteLine("Indexer status is unknown");
                break;
            default:
                Console.WriteLine("No indexer information");
                break;
        }
    }
    catch (RequestFailedException ex)
    {
        Console.WriteLine("Failed to get indexer overall status\n Exception message:
{0}\n", ex.Message);
    }
}
```

`demoIndexerExecutionInfo` represents the current status and execution history of an indexer.

Warnings are common with some source file and skill combinations and don't always indicate a problem. In this tutorial, the warnings are benign (for example, no text inputs from the JPEG files).

Add the following lines to `Main`.

C#

```
// Check indexer overall status
Console.WriteLine("Check the indexer overall status...");
CheckIndexerOverallStatus(indexerClient, demoIndexer);
```

Search

In Azure AI Search tutorial console apps, we typically add a 2-second delay before running queries that return results, but because enrichment takes several minutes to complete, we'll close the console app and use another approach instead.

The easiest option is [Search Explorer](#) in the Azure portal. You can first run an empty query that returns all documents, or a more targeted search that returns new field content created by the pipeline.

1. In the Azure portal, in the search service pages, expand **Search Management > Indexes**.
2. Find **demoindex** in the list. It should have 14 documents. If the document count is zero, the indexer is either still running or the page hasn't been refreshed yet.
3. Select **demoindex**. Search Explorer is the first tab.
4. Content is searchable as soon as the first document is loaded. To verify content exists, run an unspecified query by clicking **Search**. This query returns all currently indexed documents, giving you an idea of what the index contains.
5. For more manageable results, switch to JSON view and set parameters to select the fields:

JSON

```
{
  "search": "*",
  "count": true,
  "select": "id, languageCode, organizations"
}
```

Reset and rerun

In the early experimental stages of development, the most practical approach for design iteration is to delete the objects from Azure AI Search and allow your code to rebuild them. Resource names are unique. Deleting an object lets you recreate it using the same name.

The sample code for this tutorial checks for existing objects and deletes them so that you can rerun your code. You can also use the Azure portal to delete indexes, indexers, data sources, and skillsets.

Takeaways

This tutorial demonstrated the basic steps for building an enriched indexing pipeline through the creation of component parts: a data source, skillset, index, and indexer.

[Built-in skills](#) were introduced, along with skillset definition and the mechanics of chaining skills together through inputs and outputs. You also learned that `outputFieldMappings` in the indexer definition is required for routing enriched values from the pipeline into a searchable index on an Azure AI Search service.

Finally, you learned how to test results and reset the system for further iterations. You learned that issuing queries against the index returns the output created by the enriched indexing pipeline. You also learned how to check indexer status, and which objects to delete before rerunning a pipeline.

Clean up resources

When you're working in your own subscription, at the end of a project, it's a good idea to remove the resources that you no longer need. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the All resources or Resource groups link in the left-navigation pane.

Next steps

Now that you're familiar with all of the objects in an AI enrichment pipeline, let's take a closer look at skillset definitions and individual skills.

[How to create a skillset](#)

Last updated on 11/21/2025

Tutorial: Fix a skillset using Debug Sessions

Article • 12/03/2024

In Azure AI Search, a skillset coordinates the actions of skills that analyze, transform, or create searchable content. Frequently, the output of one skill becomes the input of another. When inputs depend on outputs, mistakes in skillset definitions and field associations can result in missed operations and data.

Debug Sessions is an Azure portal tool that provides a holistic visualization of a skillset that executes on Azure AI Search. Using this tool, you can drill down to specific steps to easily see where an action might be falling down.

In this article, use **Debug Sessions** to find and fix missing inputs and outputs. The tutorial is all-inclusive. It provides sample data, a REST file that creates objects, and instructions for debugging problems in the skillset.

If you don't have an Azure subscription, create a [free account](#) before you begin.

Prerequisites

- Azure AI Search. [Create a service](#) or [find an existing service](#) under your current subscription. You can use a free service for this tutorial. The free tier doesn't provide managed identity support for an Azure AI Search service. You must use keys for connections to Azure Storage.
- Azure Storage account with [Blob storage](#), used for hosting sample data, and for persisting cached data created during a debug session. If you're using a free search service, the storage account must have shared access keys enabled and it must allow public network access.
- [Visual Studio Code](#) with a [REST client](#).
- [Sample PDFs \(clinical trials\)](#).
- [Sample debug-sessions.rest file](#) used to create the enrichment pipeline.

Note

This tutorial also uses [Azure AI services](#) for language detection, entity recognition, and key phrase extraction. Because the workload is so small, Azure AI

services is tapped behind the scenes for free processing for up to 20 transactions. This means that you can complete this exercise without having to create a billable Azure AI services resource.

Set up the sample data

This section creates the sample data set in Azure Blob Storage so that the indexer and skillset have content to work with.

1. Download sample data ([clinical-trials-pdf-19](#)), consisting of 19 files.
2. [Create an Azure Storage account](#) or [find an existing account](#).
 - Choose the same region as Azure AI Search to avoid bandwidth charges.
 - Choose the StorageV2 (general purpose V2) account type.
3. Navigate to the Azure Storage services pages in the Azure portal and create a Blob container. Best practice is to specify the access level "private". Name your container `clinicaltrialdataset`.
4. In container, select **Upload** to upload the sample files you downloaded and unzipped in the first step.
5. While in the Azure portal, copy the connection string for Azure Storage. You can get the connection string from **Settings > Access Keys** in the Azure portal.

Copy a key and URL

This tutorial uses API keys for authentication and authorization. You need the search service endpoint and an API key, which you can get from the Azure portal.

1. Sign in to the [Azure portal](#), navigate to the **Overview** page, and copy the URL. An example endpoint might look like `https://mydemo.search.windows.net`.
2. Under **Settings > Keys**, copy an admin key. Admin keys are used to add, modify, and delete objects. There are two interchangeable admin keys. Copy either one.

A valid API key establishes trust, on a per request basis, between the application sending the request and the search service handling it.

Create data source, skillset, index, and indexer

In this section, create a "buggy" workflow that you can fix in this tutorial.

1. Start Visual Studio Code and open the `debug-sessions.rest` file.
2. Provide the following variables: search service URL, search services admin API key, storage connection string, and the name of the blob container storing the PDFs.
3. Send each request in turn. Creating the indexer takes several minutes to complete.
4. Close the file.

Check results in the Azure portal

The sample code intentionally creates a buggy index as a consequence of problems that occurred during skillset execution. The problem is that the index is missing data.

1. In Azure portal, on the search service **Overview** page, select the **Indexes** tab.
2. Select *clinical-trials*.
3. Enter this JSON query string in Search explorer's JSON view. It returns fields for specific documents (identified by the unique `metadata_storage_path` field).

JSON

```
"search": "*",
"select": "metadata_storage_path, organizations, locations",
"count": true
```

- Run the query. You should see empty values for `organizations` and `locations`.

These fields should have been populated through the skillset's [Entity Recognition skill](#), used to detect organizations and locations anywhere within the blob's content. In the next exercise, you'll debug the skillset to determine what went wrong.

Another way to investigate errors and warnings is through the Azure portal.

- Open the **Indexers** tab and select *clinical-trials-idxr*.

Notice that while the indexer job succeeded overall, there were warnings.

- Select **Success** to view the warnings (if there were mostly errors, the detail link would be **Failed**). You'll see a long list of every warning emitted by the indexer.

Status	Last run	Duration	Docs succeeded	Errors/Warnings
✓ Success	1/1/2022, 11:42:52	20.01 s	19/19	0/59

Start your debug session

- From the search service left-navigation pane, under **Search management**, select **Debug sessions**.
- Select **+ Add Debug Session**.
- Give the session a name.
- In Indexer template, provide the indexer name. The indexer has references to the data source, the skillset, and index.
- Select the storage account.
- Save the session.

Create debug session

X

Debug session name

Description

Indexer template

Specify a blob storage location where the debug session can write output artifacts. Prior debug session data may be overwritten.

Subscription

Storage account

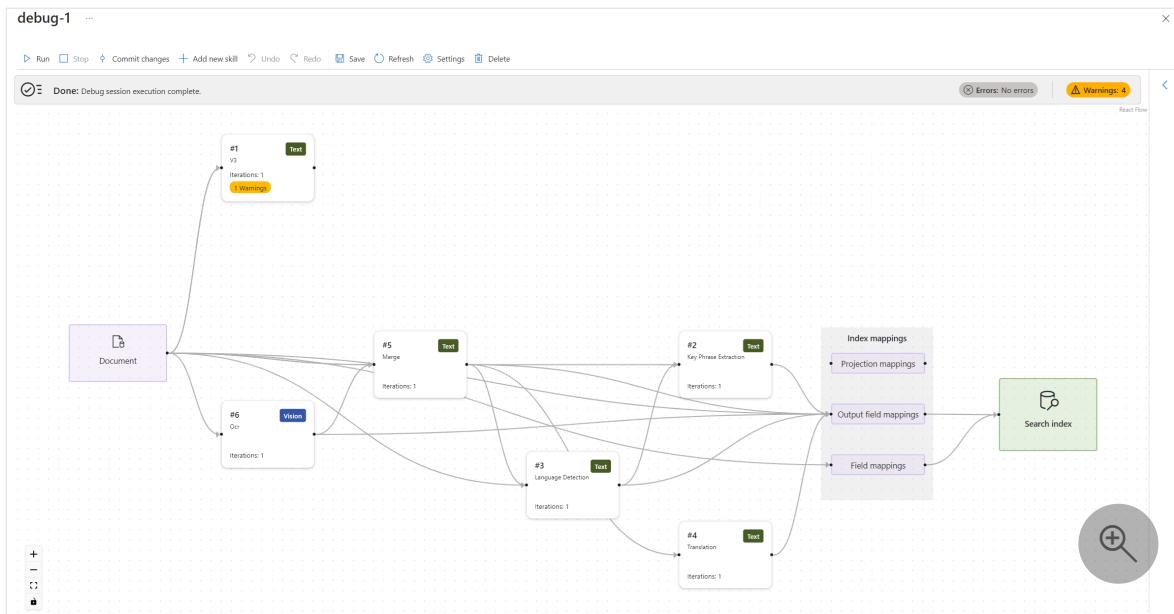

Authenticate using managed identity. [Learn more](#)

Save

Cancel

7. A debug session opens to the settings page. You can make modifications to the initial configuration and override any defaults. A debug session only works with a single document. The default is to accept the first document in the collection as the basis of your debug sessions. You can [choose a specific document to debug](#) by providing its URI in Azure Storage.
8. When the debug session has finished initializing, you should see a skills workflow with mappings and a search index. The enriched document data structure appears in a details pane on the side. We excluded it from the following screenshot so that you could see more of the workflow.

Find issues with the skillset

Any issues reported by the indexer are indicated as **Errors** and **Warnings**.

Notice that the number of errors and warning is a much smaller list than the one displayed earlier because this list is only detailing the errors for a single document. Like the list displayed by the indexer, you can select on a warning message and see the details of this warning.

Select **Warnings** to review the notifications. You should see four:

- "Could not execute skill because one or more skill inputs were invalid. Required skill input is missing. Name: 'text', Source: '/document/content'."
- "Could not map output field 'locations' to search index. Check the 'outputFieldMappings' property of your indexer. Missing value '/document/merged_content/locations'."
- "Could not map output field 'organizations' to search index. Check the 'outputFieldMappings' property of your indexer. Missing value '/document/merged_content/organizations'."
- "Skill executed but may have unexpected results because one or more skill inputs were invalid. Optional skill input is missing. Name: 'languageCode', Source: '/document/languageCode'. Expression language parsing issues: Missing value '/document/languageCode'."

Many skills have a "languageCode" parameter. By inspecting the operation, you can see that this language code input is missing from the `EntityRecognitionSkill.#1`, which is

the same entity recognition skill that is having trouble with 'locations' and 'organizations' output.

Because all four notifications are about this skill, your next step is to debug this skill. If possible, start by solving input issues first before moving on to output issues.

Fix missing skill input values

1. On the work surface, select the skill that's reporting the warnings. In this tutorial, it's the entity recognition skill.
2. The Skill details pane opens to the right with sections for iterations and their respective inputs and outputs, skill settings for the JSON definition of the skill, and messages for any errors and warnings that this skill is emitting.

The screenshot shows the 'Skill: #1' details pane. At the top, there are three tabs: 'Iterations (1)', 'Skill Settings', and 'Errors/Warnings (1)'. The 'Iterations (1)' tab is selected and underlined. Below the tabs is a table with the following data:

Iteration	Property	Name	Path
0	Inputs	text	=\${/document/content}
		languageCode	=\${/document/languageCode}
	Outputs	organizations	/document/organizations
		locations	/document/locations

At the bottom of the pane are two buttons: 'Save' (blue) and 'Cancel'.

3. Hover over each input (or select an input) to show the values in the **Expression evaluator**. Notice that the displayed result for this input doesn't look like a text input. It looks like a series of new line characters `\n \n\n\n\n` instead of text. The lack of text means that no entities can be identified, so either this document fails to meet the prerequisites of the skill, or there's another input that should be used instead.

The screenshot shows the 'Expression evaluator' interface. On the left, under 'Value', there is a red warning icon followed by the text "\n \n\n\n\n\n". Below this, under 'Path', several paths are listed: \$(/document/content), \$(/document/languageCode), /document/organizations, and /document/locations.

- Switch back to **Enriched data structure** and review the enrichment nodes for this document. Notice the `\n \n\n\n\n` for "content" has no originating source, but another value for "merged_content" has OCR output. Although there's no indication, the content of this PDF appears to be a JPEG file, as evidenced by the extracted and processed text in "merged_content".

Enriched data structure

content	"\n \n\n\n\n\n"
language	"en"
locations	[]
➤ merged_content	"\n \n\n Study of BMN 110 in Pediatric Patients < 5 Years of Age With Mucopolysaccharidosis IVA (Morquio..."

metadata_storage_file_extension	".pdf"
metadata_storage_last_modified	"2024-04-19T22:11:32Z"
metadata_storage_name	"ICT01515956.pdf"
metadata_storage_path	"aHR0cHM6Ly9oZWlkaXN0b3JhZ2VkZW1vLmJsb2luY29yZS?sv=2019-07-07&sr=b&sig=yzYt6jU47Ie%2F0ImavixERtl2nkWeysMV3Jb08-21T18%3A10%3A4..."
metadata_storage_size	76451
metadata_title	"Study of BMN 110 in Pediatric Patients < 5 Years of Age With"

- Switch back to the skill and select **Skillset settings** to open the JSON definition.
- Change the expression from `/document/content` to `/document/merged_content`, and then select **Save**. Notice that the warning is no longer listed.

```

Skill: #1
Iterations (1) Skill Settings Errors/Warnings (1)

1 {
2   "odataType": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
3   "name": "#1",
4   "context": "/document",
5   "inputs": [
6     {
7       "name": "text",
8       "source": "/document/content",
9       "inputs": []
10    },

```

```

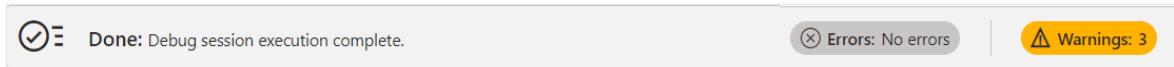

Skill: #1
Iterations (1) Skill Settings Errors/Warnings (1)

1 {
2   "odataType": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
3   "name": "#1",
4   "context": "/document",
5   "inputs": [
6     {
7       "name": "text",
8       "source": "/document/merged_content",
9       "inputs": []
10    },

```

7. Select **Run** in the session's window menu. This kicks off another execution of the skillset using the document.

8. Once the debug session execution completes, notice that the warnings count has reduced by one. Warnings show that the error for text input is gone, but the other warnings remain. The next step is to address the warning about the missing or empty value `/document/languageCode`.

9. Select the skill and hover over `/document/languageCode`. The value for this input is null, which isn't a valid input.

10. As with the previous issue, start by reviewing the **Enriched data structure** for evidence of its nodes. Notice that there's no "languageCode" node, but there's one for "language". So, there's a typo in the skill settings.

11. Copy the expression `/document/language`.

12. In the Skill details pane, select **Skill Settings** for the #1 skill and paste the new value, `/document/language`.

13. Select **Save**.

14. Select **Run**.

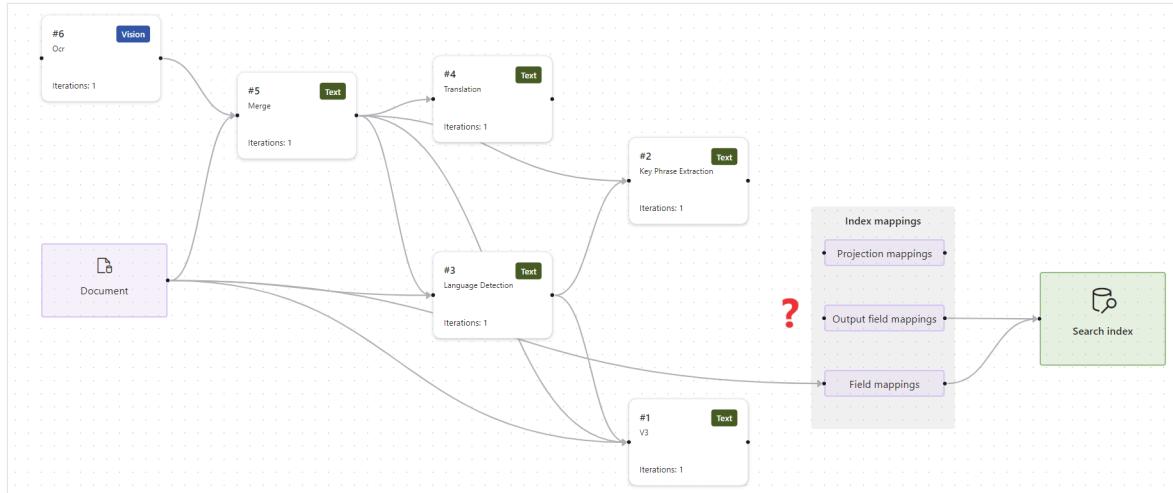

15. After the debug session execution completes, you can check the results in the Skills detail pane. When you hover over `/document/language`, you should see `en` as the value in the **Expression evaluator**.

Notice that the input warnings are gone. There now remain just the two warnings about output fields for organizations and locations.

Fix missing skill output values

The messages say to check the 'outputFieldMappings' property of your indexer, so lets start there.

1. Select **Output Field Mappings** on the work surface. Notice that the output field mappings are missing.

2. As a first step, confirm that the search index has the expected fields. In this case, the index has fields for "locations" and "organizations".
3. If there's no problem with the index, the next step is to check skill outputs. As before, select the **Enriched data structure**, and scroll the nodes to find "locations" and "organizations". Notice that the parent is "content" instead of "merged_content". The context is wrong.
4. Switch back to Skills detail pane for the entity recognition skill.
5. In **Skill Settings**, change `context` to `document/merged_content`. At this point, you should have three modifications to the skill definition altogether.

Skill: #1

X

Iterations (1) Skill Settings Errors/Warnings (0)

```
1  {
2      "odataType": "#Microsoft.Skills.Text.V3.EntityRecognitionSkill",
3      "name": "#1",
4      "context": "/document/merged_content",
5      "inputs": [
6          {
7              "name": "text",
8              "source": "/document/merged_content",
9              "inputs": []
10         },
11         {
12             "name": "languageCode",
13             "source": "/document/language",
14             "inputs": []
15         }
16     ],
17     "outputs": [
18         {
19             "name": "organizations",
20             "targetName": "organizations"
21         },
22         {
23             "name": "locations",
24             "targetName": "locations"
25         }
26     ],
27     "categories": [
28         "Organization",
29         "Location"
30     ],
31     "defaultLanguageCode": "en"
32 }
```

Save

Cancel

6. Select Save.

7. Select Run.

All of the errors have been resolved.

Commit changes to the skillset

When the debug session was initiated, the search service created a copy of the skillset. This was done to protect the original skillset on your search service. Now that you have

finished debugging your skillset, the fixes can be committed (overwrite the original skillset).

Alternatively, if you aren't ready to commit changes, you can save the debug session and reopen it later.

1. Select **Commit changes** in the main Debug sessions menu.
2. Select **OK** to confirm that you wish to update your skillset.
3. Close Debug session and open **Indexers** from the left pane.
4. Select 'clinical-trials-idxr'.
5. Select **Reset**.
6. Select **Run**.
7. Select **Refresh** to show the status of the reset and run commands.

When the indexer has finished running, there should be a green checkmark and the word Success next to the time stamp for the latest run in the **Execution history** tab. To ensure that the changes have been applied:

1. In the left pane, open **Indexes**.
2. Select 'clinical-trials' index and in the Search explorer tab, enter this query string:
`$select=metadata_storage_path, organizations, locations&$count=true` to return fields for specific documents (identified by the unique `metadata_storage_path` field).
3. Select **Search**.

The results should show that organizations and locations are now populated with the expected values.

Clean up resources

When you're working in your own subscription, it's a good idea at the end of a project to identify whether you still need the resources you created. Resources left running can cost you money. You can delete resources individually or delete the resource group to delete the entire set of resources.

You can find and manage resources in the Azure portal, using the **All resources** or **Resource groups** link in the left-navigation pane.

The free service is limited to three indexes, indexers, and data sources. You can delete individual items in the Azure portal to stay under the limit.

Next steps

This tutorial touched on various aspects of skillset definition and processing. To learn more about concepts and workflows, refer to the following articles:

- [How to map skillset output fields to fields in a search index](#)
 - [Skillsets in Azure AI Search](#)

Create an Azure AI Search service in the Azure portal

09/30/2025

Azure AI Search is an information retrieval platform for the enterprise. It supports traditional search and conversational, AI-driven search for "chat with your data" experiences across your proprietary content.

The easiest way to create a search service is through the [Azure portal](#), which is covered in this article.

You can also use:

- [Azure PowerShell](#)
- [Azure CLI](#)
- [Management REST API](#)
- [Azure Resource Manager template](#)
- [Bicep](#)
- [Terraform](#)

Before you start

Some properties are fixed for the lifetime of the search service. Before you create your service, decide on the following properties:

Property	Description
Name	Becomes part of the URL endpoint. The name must be unique and follow naming rules.
Region	Determines data residency and availability of certain features. For example, semantic ranker and Azure AI integration have region requirements. Choose a region that supports the features you need.
Tier	Determines infrastructure, service limits, and billing. Some features aren't available on lower or specialized tiers. After you create your service, you can switch between Basic and Standard (S1, S2, and S3) tiers .
Compute type	Determines virtualization and security model. You can choose between standard VMs (recommended) and confidential VMs, which are intended for select workloads requiring data-in-use privacy and isolation.

Subscribe to Azure

Azure AI Search requires a free or Standard Azure subscription.

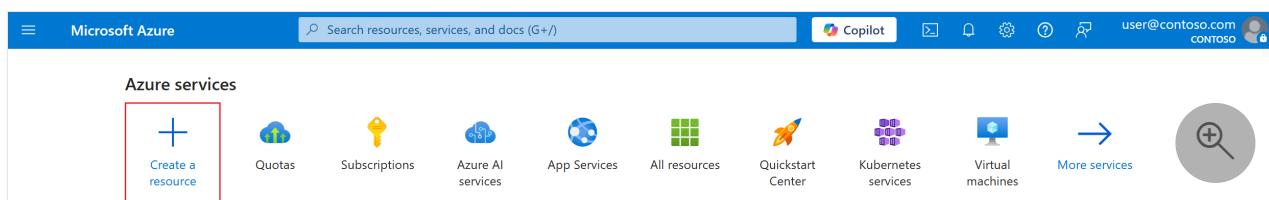

To try Azure AI Search for free, [start a trial subscription](#) and then [create your search service on the Free tier](#). Each Azure subscription can have one free search service, which is intended for short-term, non-production evaluation of the product. You can complete all of our quickstarts and most of our tutorials on the Free tier. For more information, see [Try Azure AI Search for free](#).

ⓘ Important

To make room for other services, Microsoft might delete free services that are inactive for an extended period of time.

Find the Azure AI Search offering

1. Sign in to the [Azure portal](#).
2. In the upper-left corner of your dashboard, select **Create a resource**.

3. Use the search box to find Azure AI Search.

Create new

A resource group is a container that holds related resources for an Azure solution.

Name * my-resource-group

OK Cancel

Over time, you can track current and projected costs for individual resources and for the overall resource group. The following screenshot shows the cost information that's available when you combine multiple resources into one group:

Name your service

Enter a name for your search service. The name is part of the endpoint against which API calls are issued: <https://your-service-name.search.windows.net>. For example, if you enter `myservice`, the endpoint becomes <https://myservice.search.windows.net>.

When naming your service, follow these rules:

- Use a name that's unique within the `search.windows.net` namespace.
- Use between 2 and 60 characters.
- Use only lowercase letters, digits, and dashes (-).
- Don't use dashes as the first two characters or the last character.
- Don't use consecutive dashes.

Tip

If you have multiple search services, it's helpful to include the region in the service name. For example, when deciding how to combine or attach resources, the name `myservice-westus` might save you a trip to the Properties page.

Choose a region

Important

Due to high demand, Azure AI Search is currently unavailable for new instances in some regions.

If you use multiple Azure services, putting all of them in the same region minimizes or voids bandwidth charges. There are no charges for data egress among same-region services.

In most cases, choose a region near you, unless any of the following apply:

- Your nearest region is [at capacity](#), which is indicated by the footnotes of each table. The Azure portal has the advantage of hiding unavailable regions and tiers during resource setup.
- You want to use integrated data chunking and vectorization or built-in skills for AI enrichment. Integrated operations have region requirements.
- You want to use Azure Storage for indexer-based indexing, or you want to store application data that isn't in an index. Debug session state, enrichment caches, and knowledge stores are Azure AI Search features that depend on Azure Storage. The region you choose for Azure Storage has implications for network security. If you're setting up a firewall, you should place the resources in separate regions. For more information, see [Outbound connections from Azure AI Search to Azure Storage](#).

Checklist for choosing a region

1. Is Azure AI Search available in a nearby region? Check the [list of supported regions](#).
2. Do you have a specific tier in mind? Check [region availability by tier](#).
3. Do you have business continuity and disaster recovery (BCDR) requirements? Create two or more search services in different Azure regions, each with two or more replicas so that they can be spread across multiple [availability zones](#). For example, if you're operating in North America, you might choose East US and West US, or North Central US and South Central US, for each search service. For more information, see [Multi-region deployments in Azure AI Search](#).
4. Do you need [AI enrichment](#), [integrated data chunking and vectorization](#), or [multimodal search](#)? For [billing purposes](#), Azure AI Search and Azure AI services multi-service must coexist in the same region.
 - Check [Azure AI Search regions](#). If you're using OCR, entity recognition, or other skills backed by Azure AI, the **AI enrichment** column indicates whether Azure AI Search and Azure AI services multi-service are in the same region.
 - Check [Azure AI Vision regions](#) for multimodal APIs that enable text and image vectorization. These APIs are powered by Azure AI Vision and accessed through an Azure AI services multi-service resource. However, they're generally available in fewer regions than the multi-service resource itself.

Choose a tier

Azure AI Search is offered in multiple [pricing tiers](#):

- Free
- Basic
- Standard
- Storage Optimized

Each tier has its own [capacity and limits](#), and some features are tier dependent. For information about computing characteristics, feature availability, and region availability, see [Choose a service tier for Azure AI Search](#).

The Basic and Standard tiers are the most common for production workloads, but many customers start with the Free tier. The billable tiers differ primarily in partition size, partition speed, and limits on the number of objects you can create.

Select Pricing Tier

Browse available skus and their features

Sku	Offering	Indexes	Indexers	Vector quota	Total storage	Search units	Replicas	Partitions
F	Free	3	3	25 MB 	50 MB	1	1	1
B	Basic	15	15	5 GB/Partition	15 GB/Partition	9	3	3
S	Standard	50	50	35 GB/Partition	160 GB/Partition	36	12	12
S2	Standard	200	200	150 GB/Partition	512 GB/Partition	36	12	12
S3	Standard	200	200	300 GB/Partition	1 TB/Partition	36	12	12
S3HD	High-density	1000	0	300 GB/Partition	1 TB/Partition	36	12	3
L1	Storage Optimized	10	10	150 GB/Partition	2 TB/Partition	36	12	12
L2	Storage Optimized	10	10	300 GB/Partition	4 TB/Partition	36	12	12

 Higher storage limits are available for new services in this region at no additional cost.

Note

Services created after April 3, 2024 have larger partitions and higher vector quotas at every billable tier.

Choose a compute type

The compute type determines the virtualization and security model used to deploy your search service. There are two compute types:

- **Default** (base cost) deploys your search service on standard Azure infrastructure, encrypting data at rest and in transit but not in use. Recommended for most search workloads.
- **Confidential** (10% surcharge) uses [Azure confidential computing](#) to isolate processing in a hardware-based trusted execution environment, protecting unencrypted data in use from unauthorized access. Recommended only if you have advanced privacy, compliance, or regulatory requirements.

Confidential computing has limited regional availability, disables or restricts certain features, and increases the cost of running your search service. For a detailed comparison of both compute types, see [Data in use](#).

Create your service

After providing the necessary inputs, create your search service.

[Change Pricing Tier](#)[Review + create](#)[Previous](#)[Next: Scale](#)

Your service is deployed within minutes, and you can monitor its progress with Azure notifications. Consider pinning the service to your dashboard for easy access in the future.

The screenshot shows the Azure Notifications panel. At the top, there are icons for a file, a bell (highlighted with a red box), a gear, a question mark, and a user profile. To the right of the icons, it displays the email address user@contoso.com and the name **CONTOSO**. Below the header, the title "Notifications" is displayed next to a close button ("X").

Below the title, there is a message: "More events in the activity log →" followed by a "Dismiss all" button with a dropdown arrow.

A single notification is listed: "Deployment succeeded" (indicated by a green checkmark icon). The message states: "Deployment 'my-search-service' to resource group 'my-resource-group' was successful."

At the bottom of the notification, there are two buttons: "Go to resource" (highlighted with a red box) and "Pin to dashboard". A timestamp "29 minutes ago" is shown at the bottom right, along with a circular search icon.

Configure authentication

When you create a search service, key-based authentication is the default, but it's not the most secure option. We recommend that you replace it with role-based access.

To enable role-based access for your service:

1. Go to your search service in the [Azure portal](#).
2. From the left pane, select **Settings > Keys**. You can connect to your service using [API keys](#), [Azure roles](#), or both. Select **Both** until you assign roles, after which you can select **Role-based access control**.

The screenshot shows the Azure portal interface for managing a search service named 'my-search-service'. The left sidebar lists various service management options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Search management, Settings, Semantic ranker, Knowledge Center, and Keys. The 'Keys' option is currently selected and highlighted with a red box. On the right, under the 'Keys' section, there's a 'Manage admin keys' area with fields for Primary admin key and Secondary admin key, each with a 'Regenerate' button. Below this is a 'Manage query keys' area with 'Add' and 'Delete' buttons, and a table showing columns for Name and Key. A circular icon with a magnifying glass and a download arrow is located at the bottom right of the table.

Scale your service

After deploying your search service, you can [scale it to meet your needs](#). Azure AI Search offers two scaling dimensions: *replicas* and *partitions*. Replicas allow your service to handle a higher load of search queries, while partitions allow your service to store and search through more documents.

Scaling is available only on billable tiers. On the Free tier, you can't scale your service or configure replicas and partitions.

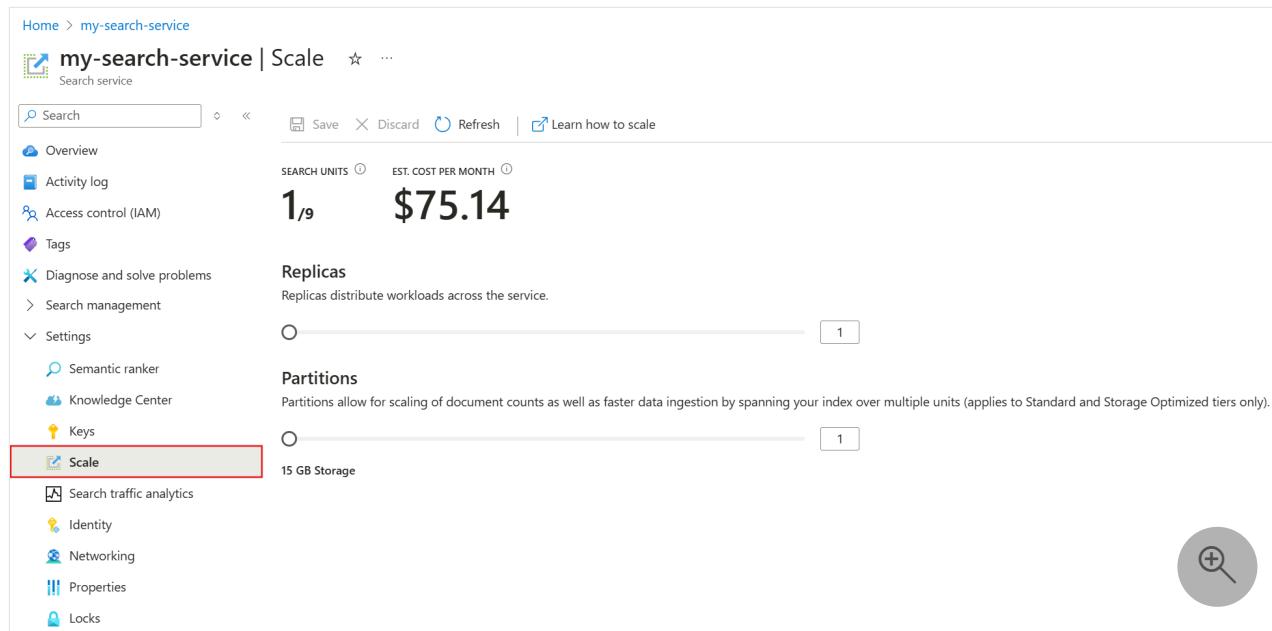

i Important

Your service must have [two replicas for read-only SLA](#) and [three replicas for read/write SLA](#).

Adding resources will increase your monthly bill. Use the [pricing calculator](#) to understand the billing implications. You can adjust resources based on load, such as increasing resources for initial indexing and decreasing them later for incremental indexing.

To scale your service:

1. Go to your search service in the [Azure portal](#).
2. From the left pane, select **Settings > Scale**.

The screenshot shows the Azure portal interface for scaling a search service. At the top, it says "Home > my-search-service". Below that is the title "my-search-service | Scale". On the left, there's a sidebar with various options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Search management, Semantic ranker, Knowledge Center, Keys, and Scale. The "Scale" option is highlighted with a red box. The main area shows "SEARCH UNITS" at 1,9 and "EST. COST PER MONTH" at \$75.14. There are two sliders: one for "Replicas" set to 1, and another for "Partitions" also set to 1. A note below the partitions slider says "Partitions allow for scaling of document counts as well as faster data ingestion by spanning your index over multiple units (applies to Standard and Storage Optimized tiers only)". At the bottom right is a magnifying glass icon.

3. Use the sliders to add replicas and partitions.

When to add a second service

Most customers use a single search service at a tier [sufficient for the expected load](#). One service can host multiple indexes, each isolated from the others, within the [maximum limits of your chosen tier](#). In Azure AI Search, you can direct requests to only one index, reducing the chance of retrieving data from other indexes in the same service.

However, you might need a second service for the following operational requirements:

- Region outages. In the unlikely event of a full region outage, Azure AI Search doesn't provide instant failover. You must implement your own multi-region solution and failover approach. For more information, see [Multi-region deployments in Azure AI Search](#).
- [Multitenant architectures](#) that require two or more services.

- Globally deployed applications that require services in each geography to minimize latency.

! Note

In Azure AI Search, you can't separate indexing and querying operations, so don't create multiple services for separate workloads. An index is always queried on the service in which it was created, and you can't copy an index to another service.

A second service isn't required for high availability. You achieve high availability for queries by using two or more replicas in the same service. Because the replicas are updated sequentially, at least one is operational when a service update is rolled out. For more information about uptime, see [Service Level Agreements](#).

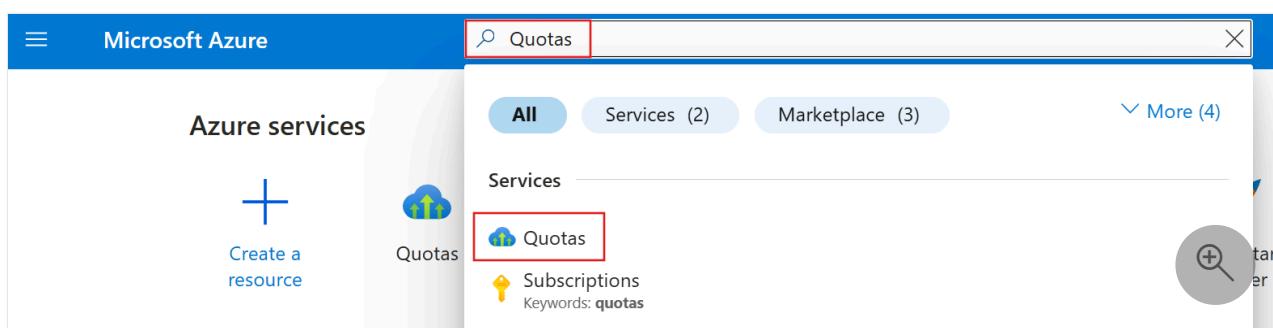

Add more services to your subscription

Azure AI Search limits the [number of search services](#) you can initially create in a subscription. If you reach your limit, you can request more quotas.

You must have Owner or Contributor permissions for the subscription to request quota. Depending on your region and data center capacity, you might be able to automatically request quota to add services to your subscription. If the request fails, reduce the number or file a support ticket. Expect a one-month turnaround for a large quota increase, such as more than 30 extra services.

To request more subscription quota:

1. Go to your dashboard in the [Azure portal](#).
2. Use the search box to find the **Quotas** service.

3. On the **Overview** tab, select the **Search** tile.

The screenshot shows the 'Quotas' section of the Azure portal. On the left, there's a sidebar with 'Settings' and links for 'My quotas', 'Fired alerts (Preview)', and 'Alert rules (Preview)'. The main area has tabs for 'Overview' and 'Requests'. A title 'View and adjust my quotas' is followed by a note: 'Don't see your products below? Go to Azure subscription and service limits, quotas, and constraints' and 'and check the list in the right pane for your products. For further assistance, contact the support team.' Below this are several service icons in a grid: Compute, Compute (classic), Networking, Machine learning, Storage, Storage (classic), HPC Cache, Azure HDInsight, Azure Lab Services, Microsoft Purview, Azure Container Instances, Dev Box, Azure Container Apps, App Services, and a 'Search' button which is highlighted with a red box.

- Set filters to review the existing quota for search services in your current subscription. We recommend filtering by usage.

The screenshot shows the 'Quotas | My quotas' page. The sidebar includes 'Overview', 'Settings', and 'My quotas' (which is selected). The main table shows quota details for 'Usage at or near quota' and 'Usage at low level'. A modal window titled 'Usage : Only show items with usage' is open, containing three radio button options: 'Show all' (unchecked), 'Only show items with usage' (checked), and 'Select custom usage' (unchecked). The 'Apply' button is highlighted with a red box. To the right of the modal, there's a 'Request adjustment' section with a search icon.

- Next to the tier and region that need more quotas, select Request adjustment.
- In New Quota Request, enter a new limit for your subscription quota. The new limit must be greater than your current limit. If regional capacity is constrained, your request won't be automatically approved, and an incident report will be generated on your behalf for investigation and resolution.
- Submit your request.
- Monitor notifications in the Azure portal for updates on the new limit. Most requests are approved within 24 hours.

Next steps

Now that you've deployed your search service, continue in the Azure portal to create your first index:

[Quickstart: Create an Azure AI Search index in the Azure portal](#)

Want to optimize and save on your cloud spending?

[Start analyzing costs with Cost Management](#)

Configure your Azure AI Search service in the Azure portal

Configuring your new Azure AI Search service involves several tasks to optimize security, access, and performance. This article provides a day-one checklist to help you set up your service in the [Azure portal](#).

After you create a search service, we recommend that you:

- ✓ [Configure role-based access](#)
- ✓ [Configure a managed identity](#)
- ✓ [Configure network security](#)
- ✓ [Check capacity and understand billing](#)
- ✓ [Enable diagnostic logging](#)
- ✓ [Provide connection information to developers](#)

Configure role-based access

Portal access is based on [role assignments](#). By default, new search services have at least one service administrator or owner. Service administrators, co-administrators, and owners have permission to create more administrators and assign other roles. They also have access to all portal pages and operations on default search services.

Tip

By default, any administrator or owner can create or delete services. To prevent accidental deletions, consider [locking your resources](#).

Each search service comes with [API keys](#) and uses key-based authentication by default. However, we recommend using Microsoft Entra ID and role-based access control (RBAC) for improved security. RBAC eliminates the need to store and pass API keys in plain text.

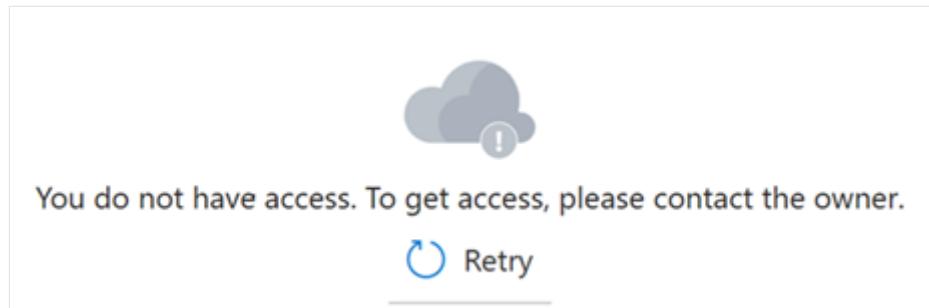

When you switch from key-based authentication to keyless authentication, service administrators must assign themselves data plane roles for full access to objects and data. These roles include Search Service Contributor, Search Index Data Contributor, and Search Index Data Reader.

To configure role-based access:

1. [Enable roles](#) on your search service. We recommend using both API keys and roles.

2. [Assign data plane roles](#) to replace the functionality lost when you disable API keys. An owner only needs Search Index Data Reader, but developers need [more roles](#).

Role assignments can take several minutes to take effect. Until then, portal pages used for data plane operations display the following message:

3. [Assign more roles](#) for solution developers and apps.

Configure a managed identity

If you plan to use indexers for automated indexing, applied AI, or integrated vectorization, you should [configure your search service to use a managed identity](#). You can then assign roles on other Azure services that authorize your search service to access data and operations.

For integrated vectorization, your search service identity needs the following roles:

- Storage Blob Data Reader on Azure Storage
- Cognitive Services Data User on a Microsoft Foundry resource

Role assignments can take several minutes to take effect.

Before you move on to network security, consider testing all points of connection to validate role assignments. Run an [import wizard](#) to test permissions.

Configure network security

By default, a search service accepts authenticated and authorized requests over public internet connections. You have two options for enhancing network security:

- [Configure firewall rules](#) to restrict network access by IP address.
- [Configure a private endpoint](#) to only allow traffic from Azure virtual networks. Note that when you turn off the public endpoint, the import wizards won't run.

To learn about inbound and outbound calls in Azure AI Search, see [Security in Azure AI Search](#).

Check capacity and understand billing

By default, a search service is created with one replica and one partition. You can [add capacity](#) by adding replicas and partitions, but we recommend waiting until volumes require it. Many customers run production workloads on the minimum configuration.

Semantic ranker can increase the cost of running your service if you opt into the standard plan. If you don't want to use this feature, you can [disable semantic ranker](#) at the service level.

To learn about other features that affect billing, see [How you're charged for Azure AI Search](#).

Enable diagnostic logging

[Enable diagnostic logging](#) to track user activity. If you skip this step, you still get [activity logs](#) and [platform metrics](#) automatically. However, if you want index and query usage information, you should enable diagnostic logging and choose a destination for logged operations. We recommend Log Analytics Workspace for durable storage so that you can run system queries in the Azure portal.

Internally, Microsoft collects telemetry data about your service and the platform. To learn more about data retention, see [Retention of metrics](#).

To learn more about data location and privacy, see [Data residency](#).

Enable semantic ranker

Semantic ranker is free for the first 1,000 requests per month. It's enabled by default on newer search services.

To enable semantic ranker in the portal, select **Settings > Premium features** from the left pane, and then select the **Free** plan. For more information, see [Enable semantic ranker](#).

Provide connection information to developers

To connect to Azure AI Search, developers need:

- An endpoint or URL from the [Overview](#) page.
- An API key from the [Keys](#) page or a role assignment. We recommend Search Service Contributor, Search Index Data Contributor, and Search Index Data Reader.

We recommend portal access for the [import wizards](#) and [Search explorer](#). You must be a contributor or higher to run the wizards.

Related content

For programmatic support for service administration, see the following APIs and modules:

- [Management REST API reference](#)
- [Az.Search PowerShell module](#)
- [az search Azure CLI module](#)

You can also use the management client libraries in the Azure SDKs for .NET, Python, Java, and JavaScript.

There's feature parity across all modalities and languages, except for preview management features. As a general rule, preview management features are released through the Management REST API first.

Last updated on 11/18/2025

Azure AI Search regions list

This article identifies the cloud regions in which Azure AI Search is available. It also lists which premium features are available in each region.

Features subject to regional availability

When you create an Azure AI Search service, your region selection might depend on features that are only available in certain regions. The following table lists those region-specific features.

 Expand table

Feature	Description	Availability
AI enrichment	Refers to built-in skills that make internal calls to Foundry Tools for enrichment and transformation during indexing. Integration requires that Azure AI Search coexists with a Microsoft Foundry resource in the same physical region. You can bypass region requirements by using identity-based connections , currently in public preview.	Regional support is noted in this article.
Availability zones	Divides a region's data centers into distinct physical location groups, providing high availability within the same geo.	Regional support is noted in this article.
Agentic retrieval	Uses the agentic retrieval engine designed for conversational search.	Regional support is noted in this article.
Confidential computing	Deploys your search service on confidential VMs to process data in a hardware-based trusted execution environment. Confidential computing disables or restricts certain features, including agentic retrieval, semantic ranker, query rewrite, and skillset execution.	Regional support is noted in this article.
Semantic ranker	Takes a dependency on Microsoft-hosted models in specific regions.	Regional support is noted in this article.
Query rewrite	Takes a dependency on Microsoft-hosted models in specific regions.	Regional support is noted in this article.
Extra capacity	Higher-capacity partitions became available in select regions starting in April 2024, with a second wave following in May 2024. Currently, there are just a few regions that <i>don't</i> offer higher-capacity partitions. If you have an older search service in a supported region, check if you can upgrade your service . Otherwise, create a	Regional support is noted in the footnotes of this article.

Feature	Description	Availability
	new search service to benefit from more capacity at the same billing rate.	
Capacity constraints	In some regions, insufficient capacity prevents you from creating search services on certain tiers. The Azure portal automatically hides regions and tiers that aren't available for new deployments.	Regional support is noted in the footnotes of this article.
Azure Vision in Foundry Tools 4.0 multimodal APIs	Refers to the Azure Vision multimodal embeddings skill and vectorizer that call the multimodal embedding API.	Check the Azure Vision region list first, and then verify Azure AI Search is available in the same region.

Azure Public regions

You can create an Azure AI Search service in any of the following Azure public regions. Almost all of these regions support [higher-capacity tiers](#). Exceptions are noted where applicable.

Choose a service tier for Azure AI Search

Part of [creating a search service](#) is choosing a pricing tier (or SKU). In the Azure portal, tier is specified in the [Select Pricing Tier](#) page when you create the service. In PowerShell or Azure CLI, the tier is specified through the `-Sku` parameter.

The tier determines the:

- Maximum number of indexes and other objects allowed on the service.
- Size and speed of partitions (physical storage).
- Billable rate as a fixed monthly cost, but also an incremental cost if you add capacity.
- Workload characteristics. Some tiers are optimized for specific workloads.

In a few instances, the tier you choose determines the availability of [premium features](#).

Billing rates are shown in the Azure portal's [Select Pricing Tier](#) page. You can check the [pricing page](#) for regional rates and review [Plan and manage costs](#) to learn more about the billing model.

(!) Note

Search services created after April 3, 2024 have larger partitions and higher vector quotas at almost every tier. For more information, see [Service limits](#).

Tier descriptions

Tiers include **Free**, **Basic**, **Standard**, and **Storage Optimized**. Standard and Storage Optimized are available with several configurations and capacities. The following screenshot from Azure portal shows the available tiers, minus pricing (which you can find in the Azure portal and on the [pricing page](#)).

Select Pricing Tier									X
Browse available skus and their features									
Sku	Offering	Indexes	Indexers	Vector quota	Total storage	Search units	Replicas	Partitions	Search unit cost/month (est.)
F	Free	3	3	25 MB ⓘ	50 MB	1	1	1	
B	Basic	15	15	5 GB	15 GB/Partition	9	3	3	
S	Standard	50	50	35 GB/Partition	160 GB/Partition	36	12	12	
S2	Standard	200	200	100 GB/Partition	350 GB/Partition	36	12	12	
S3	Standard	200	200	200 GB/Partition	700 GB/Partition	36	12	12	
S3HD	High-density	1000	0	200 GB/Partition	700 GB/Partition	36	12	3	
L1	Storage Optimized	10	10	12 GB/Partition	1 TB/Partition	36	12	12	
L2	Storage Optimized	10	10	36 GB/Partition	2 TB/Partition	36	12	12	

Estimated costs not included in this screenshot

Higher storage limits are available for new services in this region at no additional cost.

Free creates a [limited search service](#) for smaller projects, like running tutorials and code samples. Internally, system resources are shared among multiple subscribers. You can't scale a free service, run significant workloads, and some premium features aren't available. You can only have one free search service per Azure subscription. If the service is inactive for an extended period of time, it might be deleted to free up capacity, especially if the region is under capacity constraints.

The most commonly used billable tiers include:

- **Basic** has the ability to meet SLA with its support for three replicas.
- **Standard (S1, S2, S3)** is the default. It gives you more flexibility in scaling for workloads. You can scale both partitions and replicas. With dedicated resources under your control, you can deploy larger projects, optimize performance, and increase capacity.

Some tiers are designed for certain types of work:

- **Standard 3 High Density (S3 HD)** is a *hosting mode* for S3, where the underlying hardware is optimized for a large number of smaller indexes and is intended for multitenancy scenarios. S3 HD has the same per-unit charge as S3, but the hardware is optimized for fast file reads on a large number of smaller indexes.
- **Storage Optimized (L1, L2)** tiers offer larger storage capacity at a lower price per TB than the Standard tiers. These tiers are designed for large indexes that don't change very often. The primary tradeoff is higher query latency, which you should validate for your specific application requirements.

You can find out more about the various tiers on the [pricing page](#), in the [Service limits in Azure AI Search](#) article, and on the Azure portal page when you're provisioning a service.

Region availability by tier

The [regions list](#) provides the locations where Azure AI Search is offered. Some regions might have capacity constraints for certain tiers, which prevents the creation of new search services on those tiers. The list uses footnotes to indicate constrained regions and tiers.

When you create a search service in the Azure portal, unavailable region–tier combinations are automatically excluded.

Feature availability by tier

Most features are available on all tiers, including the Free tier. In a few cases, the tier determines the availability of a feature. The following table describes the constraints.

Feature	Tier considerations
Indexers	Indexers aren't available on S3 HD. Indexers have more limitations on the free tier.
indexer executionEnvironment configuration parameter	The ability to pin all indexer processing to just the search clusters allocated to your search service requires S2 and higher.
AI enrichment	Runs on the Free tier but not recommended for large workloads.
Managed or trusted identities for outbound (indexer) access	Not available on the Free tier.
Customer-managed encryption keys	Not available on the Free tier.
IP firewall access	Not available on the Free tier.
Private endpoint (integration with Azure Private Link)	For inbound connections to a search service, not available on the Free tier. For outbound connections by indexers to other Azure resources, not available on Free or S3 HD. For indexers that use skillsets, not available on Free, Basic, S1, or S3 HD.
Availability zones	Not available on the Free tier.
Semantic ranker	Runs on the Free tier but not recommended for large workloads.

Resource-intensive features might not work well unless you give it sufficient capacity. For example, [AI enrichment](#) has long-running skills that time out on a Free service unless the dataset is small.

Upper limits

Tiers determine the maximum storage of the service itself, plus the maximum number of indexes, indexers, data sources, skillsets, and synonym maps that you can create. For a full break out of all limits, see [Service limits in Azure AI Search](#).

Partition size and speed

Tier pricing includes details about per-partition storage that ranges from 15 GB for Basic, up to 2 TB for Storage Optimized (L2) tiers. Other hardware characteristics, such as speed of operations, latency, and transfer rates, aren't published, but tiers that are designed for specific

solution architectures are built on hardware that has the features to support those scenarios. For more information about partitions, see [Estimate and manage capacity](#) and [Reliability in Azure AI Search](#).

(!) Note

Higher-capacity partitions became available in select regions in April 2024. A second wave of higher-capacity partitions was released in May 2024. If you have an older search service, you might be able to [upgrade your service](#) to benefit from more capacity at the same billing rate.

Billing rates

Tiers have different billing rates, with higher rates for tiers that run on more expensive hardware or provide more expensive features. The tier billing rate can be found in the [Azure pricing pages](#) for Azure AI Search.

Once you create a service, the billing rate becomes both a *fixed cost* of running the service around the clock, and an *incremental cost* if you choose to add more capacity.

Search services are allocated computing resources in the form of *partitions* (for storage), and *replicas* (instances of the query engine). Initially, a service is created with one of each, and the billing rate is inclusive of both resources. However, if you scale capacity, the costs go up or down in increments of the billable rate.

The following example provides an illustration. Assume a hypothetical billing rate of \$100 per month. If you keep the search service at its initial capacity of one partition and one replica, then \$100 is what you can expect to pay at the end of the month. However, if you add two more replicas to achieve high availability, the monthly bill increases to \$300 (\$100 for the first replica-partition pair, followed by \$200 for the two replicas).

This billing model is based on the concept of applying the billing rate to the number *search units* (SU) used by a search service. All services are initially provisioned at one SU, but you can increase the SUs by adding either partitions or replicas to handle larger workloads. For more information, see [How to estimate costs of a search service](#).

Tier changes

(!) Note

Existing search services can switch between Basic and Standard (S1, S2, and S3) tiers. Your current service configuration can't exceed the limits of the target tier, and your region can't have capacity constraints on the target tier. For more information, see [Change your pricing tier](#).

To switch to a different tier than those previously listed:

1. [Create a search service](#) on the new tier.
2. Deploy your search content onto the new service. [Follow this checklist](#) to ensure you have all the content.
3. Delete the old service when you're sure it's no longer needed.

For large indexes that you don't want to rebuild from scratch, use one of the following backup and restore samples:

- [Backup and restore sample \(C#\)](#) ↗
- [Backup and restore sample \(Python\)](#) ↗
- [Backup and restore sample for very large indexes \(Python\)](#) ↗

Next steps

The best way to choose a pricing tier is to start with a least-cost tier, and then allow experience and testing to inform your decision to keep the service or switch to a higher tier.

For next steps, we recommend that you create a search service at a tier that can accommodate the level of testing you propose to do, and then review the following guidance on estimating cost and capacity:

- [Create a search service](#)
- [Estimate costs](#)
- [Estimate capacity](#)

Upgrade your Azure AI Search service in the Azure portal

08/01/2025

An upgrade brings older search services to the capabilities of new services created in the same region. Specifically, it upgrades the computing power of the underlying service. This one-time operation doesn't introduce breaking changes to your application, and you shouldn't need to change any code.

For [eligible services](#), an upgrade increases the [partition storage](#) and [vector index size](#) on the same tier at no extra cost.

💡 Tip

Looking to [change your pricing tier](#)? You can switch between Basic and Standard (S1, S2, and S3) tiers.

This article describes how to upgrade your service in the [Azure portal](#). Alternatively, you can use the [Search Management REST APIs](#) to upgrade your service programmatically. For more information, see [Manage your search service using REST](#).

About service upgrades

In April 2024, Azure AI Search increased the [storage capacity](#) of newly created search services. Services created before April 2024 saw no capacity changes, so if you wanted larger and faster partitions, you had to create a new service. However, some older services can now be upgraded to benefit from the higher-capacity partitions.

Currently, an upgrade only increases the [storage limit](#) and [vector index size](#) of eligible services.

Upgrade eligibility

To qualify for an upgrade, your service must:

- ✓ Have been [created before April 3, 2024](#). Services created after this date should already have higher capacity.
- ✓ Be in a [region where higher capacity is enabled](#). Most regions provide higher-capacity partitions, as noted in the table's footnotes.
- ✓ Be in a [region that doesn't have capacity constraints on your pricing tier](#). Constrained regions and tiers are noted in the footnotes of each table.

Important

Some search services created before January 1, 2019 don't support upgrades. In this situation, you must create a new service in a [high-capacity region](#) to get increased storage and vector limits.

Higher storage limits

For [eligible services](#), the following table compares the storage limit (per partition) before and after an upgrade.

 [Expand table](#)

	Basic ¹	S1	S2	S3/HD	L1	L2
Limit before upgrade	2 GB	25 GB	100 GB	200 GB	1 TB	2 TB
Limit after upgrade	15 GB	160 GB	512 GB	1 TB	2 TB	4 TB

¹ Basic services created before April 3, 2024 were originally limited to one partition, which increases to three partitions after an upgrade. [Partition counts for all other pricing tiers](#) stay the same.

Higher vector limits

For [eligible services](#), the following table compares the vector index size (per partition) before and after an upgrade.

 [Expand table](#)

	Basic	S1	S2	S3/HD	L1	L2
Limit before upgrade	0.5 GB ¹ or 1 GB ²	1 GB ¹ or 3 GB ²	6 GB ¹ or 12 GB ²	12 GB ¹ or 36 GB ²	12 GB	36 GB
Limit after upgrade	5 GB	35 GB	150 GB	300 GB	150 GB	300 GB

¹ Applies to services created before July 1, 2023.

² Applies to services created between July 1, 2023 and April 3, 2024 in all regions except Germany West Central, Qatar Central, and West India, to which the ¹ limits apply.

Check your service creation or upgrade date

On the **Overview** page, you can view various metadata about your search service, including **Date created** and **Date upgraded**.

The screenshot shows the Azure AI Search service overview page for 'my-search-service'. The 'Overview' tab is selected. In the 'Essentials' section, two fields are highlighted with red boxes: 'Date created' (Jul 7, 2020, 8:18:38 PM) and 'Date upgraded' (Apr 8, 2025, 11:26:39 PM). The page also includes a sidebar with various service management options like Activity log, Access control (IAM), Tags, Diagnose and solve problems, Resource visualizer, Search management, Settings, Semantic ranker, Knowledge Center, Keys, Scale, Search traffic analytics, Identity, and Networking.

The date you created your service partially determines its [upgrade eligibility](#). If your service has never been upgraded, **Date upgraded** doesn't appear.

Upgrade your service

You can't undo a service upgrade. Before you proceed, make sure that you want to permanently increase the [storage limit](#) and [vector index size](#) of your search service. We recommend that you test this operation in a nonproduction environment.

The availability of your search service during an upgrade depends on how many replicas you've provisioned. With two or more replicas, your service remains available while one replica is updated. For more information, see [Reliability in Azure AI Search](#).

To upgrade your service:

1. Sign in to the [Azure portal](#) and select your search service.
2. On the **Overview** page, select **Upgrade** from the command bar.

The screenshot shows the Azure portal interface for a search service named 'my-search-service'. The top navigation bar includes options like 'Add index', 'Import data', 'Import and vectorize data', 'Search explorer', 'Upgrade' (which is highlighted with a red box), 'Refresh', 'Delete', and 'Move'. Below the navigation bar, there are two status messages: one about query rewriting being available in semantic ranker for select regions, and another about an upgrade being available for the service. The main content area is titled 'Overview' and contains sections for 'Activity log', 'Access control (IAM)', 'Tags', 'Diagnose and solve problems', 'Resource visualizer', and 'Search management'. A 'View Cost' and 'JSON View' link is also present. On the right side, there's a search bar with a magnifying glass icon.

If this button appears dimmed, an upgrade isn't available for your service. Your service either [has the latest upgrade](#) or [doesn't qualify for an upgrade](#).

3. Review the upgrade details for your service, and then select **Upgrade**.

The screenshot shows a modal dialog box titled 'Upgrade a search service'. It contains the following text:
The following search service will be permanently upgraded, and this operation can't be undone.
Search service name: (with a cloud icon)
Created or last upgraded on: Aug 17, 2023, 1:07:27 PM
After the search service is upgraded, you'll have a **higher total storage limit**.
[Learn more](#) about the upgrade available for your service based on when it was created or last upgraded.
At the bottom, there are two buttons: 'Upgrade' (highlighted with a red box) and 'Cancel'. There is also a search bar with a magnifying glass icon in the bottom right corner.

A confirmation appears reminding you that the upgrade can't be undone.

4. To permanently upgrade your service, select **Upgrade**.

Upgrade confirmation

Upgrading the search service is a permanent action and can't be undone.

Upgrade

Go back

5. Check your notifications to confirm that the operation started.

Depending on the size of your service, this operation can take several hours to complete. If the upgrade fails, your service returns to its original state.

Next step

After you upgrade your search service, you might want to reconsider your scale configuration:

[Estimate and manage capacity of an Azure AI Search service](#)

Service limits in Azure AI Search

Maximum limits on storage, workloads, and quantities of indexes and other objects depend on the [pricing tier](#) of your Azure AI Search service:

- **Free** is a multitenant shared service that comes with your Azure subscription.
- **Basic** provides dedicated computing resources for production workloads at a smaller scale.
- **Standard** runs on dedicated machines with more storage and processing capacity at every level. Standard comes in four levels: S1, S2, S3, and S3 HD. S3 High Density (S3 HD) is engineered for [multi-tenancy](#) and large quantities of small indexes (3,000 indexes per service). S3 HD doesn't support [indexers](#), so data ingestion must use APIs that push data from the source to the index.
- **Storage Optimized** runs on dedicated machines with more total storage, storage bandwidth, and memory than **Standard**. This tier targets large, slow-changing indexes. Storage Optimized comes in two levels: L1 and L2.

Subscription limits

You can create multiple *billable* search services (Basic and higher), up to the maximum number of services allowed at each tier, per region. For example, you could create up to 16 services at the Basic tier and another 16 services at the S1 tier within the same subscription and region. You could then create an additional 16 Basic services in another region for a combined total of 32 Basic services under the same subscription. For more information about tiers, see [Choose a tier \(or SKU\) for Azure AI Search](#).

Maximum service limits can be raised upon request. If you need more services within the same subscription, [file a support request](#).

[+] [Expand table](#)

Resource	Free ¹	Basic	S1	S2	S3	S3 HD	L1	L2
Maximum services per region	1	16	16	8	6	6	6	6
Maximum search units (SU) ²	N/A	3 SU	36 SU	36 SU	36 SU	36 SU	36 SU	36 SU

¹ You can have one free search service per Azure subscription. The free tier is based on infrastructure shared with other customers. Because the hardware isn't dedicated, scale-up isn't supported, and storage is limited to 50 MB. A free search service might be deleted after extended periods of inactivity to make room for more services.

² Search units (SU) are billing units, allocated as either a *replica* or a *partition*. You need both. To learn more about SU combinations, see [Estimate and manage capacity of a search service](#).

Service limits

The following table covers SLA, partition counts, and replica counts at the service level.

[+] [Expand table](#)

Resource	Free	Basic	S1	S2	S3	S3 HD	L1	L2
Service level agreement (SLA)	No	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Partitions	N/A	3 ¹	12	12	12	3	12	12
Replicas	N/A	3	12	12	12	12	12	12

¹ Basic tier supports three partitions and three replicas, for a total of nine search units (SU) on [new search services](#) created after April 3, 2024. Older basic services are limited to one partition and three replicas.

A search service is subject to a maximum storage limit (partition size multiplied by the number of partitions) or by a hard limit on the [maximum number of indexes](#) or [indexers](#), whichever comes first.

Service-level agreements (SLAs) apply to billable services that have two or more replicas for query workloads, or three or more replicas for query and indexing workloads. The number of partitions isn't an SLA consideration. For more information, see [Reliability in Azure AI Search](#).

Free services don't have fixed partitions or replicas and share resources with other subscribers.

Partition storage (GB)

Per-service storage limits vary by two things: [service creation date](#) and [region](#). There are higher limits for [newer services](#) in most supported regions.

This table shows the progression of storage quota increases in GB over time. Starting in April 2024, higher capacity partitions were brought online in the regions listed in the footnotes. If you have an older service in a supported region, check if you can [upgrade your service](#) to the higher storage limits.

[+] [Expand table](#)

Service creation date	Basic	S1	S2	S3/HD	L1	L2
Before April 3, 2024	2	25	100	200	1,024	2,048
April 3, 2024 through May 17, 2024 ¹	15	160	512	1,024	1,024	2,048
After May 17, 2024 ²	15	160	512	1,024	2,048	4,096
After February 10, 2025 ³	15	160	512	1,024	2,048	4,096

¹ Higher capacity storage for Basic, S1, S2, S3 in these regions. **Americas:** Brazil South, Canada Central, Canada East, East US, East US 2, Central US, North Central US, South Central US, West US, West US 2, West US 3, West Central US. **Europe:** France Central, Italy North, North Europe, Norway East, Poland Central, Switzerland North, Sweden Central, UK South, UK West. **Middle East:** UAE North. **Africa:** South Africa North. **Asia Pacific:** Australia East, Australia Southeast, Central India, Jio India West, East Asia, Southeast Asia, Japan East, Japan West, Korea Central, Korea South.

² Higher capacity storage for L1 and L2. More regions provide higher capacity at every billable tier. **Americas:** East US 2 EUAP. **Europe:** Germany North, Germany West Central, Switzerland West. **Azure Government:** Texas, Arizona, Virginia. **Africa:** South Africa North. **Asia Pacific:** China North 3, China East 3.

³ Higher capacity storage is available in West Europe.

ⓘ Important

Currently, higher storage limits aren't available in the following regions, which are subject to the pre-April 3 limits.

- Israel Central
- Qatar Central
- Spain Central
- South India

Index limits

Expand table

Resource	Free	Basic ¹	S1	S2	S3	S3 HD	L1	L2
Maximum indexes	3	5 or 15	50	200	200	1000 per partition or 3000 per service	10	10

Resource	Free	Basic ¹	S1	S2	S3	S3 HD	L1	L2
Maximum simple fields per index ²	1000	100	1000	1000	1000	1000	1000	1000
Maximum dimensions per vector field	4096	4096	4096	4096	4096	4096	4096	4096
Maximum complex collections per index	40	40	40	40	40	40	40	40
Maximum elements across all complex collections per document ³	3000	3000	3000	3000	3000	3000	3000	3000
Maximum depth of complex fields	10	10	10	10	10	10	10	10
Maximum suggesters per index	1	1	1	1	1	1	1	1
Maximum scoring profiles per index	100	100	100	100	100	100	100	100
Maximum semantic configurations per index	100	100	100	100	100	100	100	100
Maximum functions per profile	8	8	8	8	8	8	8	8
Maximum index size ⁴	N/A	N/A	N/A	1.88 TB	2.34 TB	100 GB	N/A	N/A

¹ Basic services created before December 2017 have lower limits (5 instead of 15) on indexes. Basic tier is the only tier with a lower limit of 100 fields per index.

² The upper limit on fields includes both first-level fields and nested subfields in a complex collection. For example, if an index contains 15 fields and has two complex collections with five subfields each, the field count of your index is 25. Indexes with a very large fields collection can be slow. [Limit fields and attributes](#) to just those you need, and run indexing and query test to ensure performance is acceptable.

³ An upper limit exists for elements because having a large number of them significantly increases the storage required for your index. An element of a complex collection is defined as a member of that collection. For example, assume a [Hotel document with a Rooms complex collection](#). Each room in the Rooms collection is considered an element. During indexing, the indexing engine can safely process a maximum of 3,000 elements across the document as a whole. [This limit](#) was introduced in `api-version=2019-05-06` and applies to complex collections only, and not to string collections or to complex fields.

⁴ For most tiers, the maximum index size is the total available storage on your search service. For S2, S3, and S3 HD services with multiple partitions, and therefore more storage, the maximum size of a single index is provided in the table. Applies to search services created after April 3, 2024.

You might find some variation in maximum limits if your service happens to be provisioned on a more powerful cluster. The limits here represent the common denominator. Indexes built to the above specifications are portable across equivalent service tiers in any region.

Document limits

Maximum number of documents per index are:

- 24 billion on Basic, S1, S2, S3
- 2 billion on S3 HD
- 288 billion on L1
- 576 billion on L2

Maximum size of each document is approximately 16 megabytes. Document size is actually a limit on the size of the indexing API request payload, which is 16 megabytes. That payload can be a single document, or a batch of documents. For a batch with a single document, the maximum document size is 16 MB of JSON.

Document size applies to *push mode* indexing that uploads documents to a search service. If you're using an indexer for *pull mode* indexing, your source files can be any file size, subject to [indexer limits](#). For the blob indexer, file size limits are larger for higher tiers. For example, the S1 limit is 128 megabytes, S2 limit is 256 megabytes, and so forth.

When you estimate document size, remember to index only the fields that add value to your search scenarios. Exclude source fields that have no purpose in the queries you intend to run.

Vector index size limits

When you index documents with vector fields, Azure AI Search constructs internal vector indexes using the algorithm parameters you provide. The size of these vector indexes is restricted by the memory reserved for vector search for your service's tier (or [SKU](#)). For guidance on managing and maximizing vector storage, see [Vector index size and staying under limits](#).

Vector limits vary by:

- [Service creation date](#)
- [Region](#)

Higher vector limits from April 2024 onwards exist on *new search services* in regions providing the extra capacity, which is most of them. If you have an older service in a supported region, check if

you can [upgrade your service](#) to the higher vector limits.

This table shows the progression of vector quota increases in GB over time. The quota is per partition, so if you scale a new Standard (S1) service to 6 partitions, the total vector quota is 35 multiplied by 6.

[+] [Expand table](#)

Service creation date	Basic	S1	S2	S3/HD	L1	L2
Before July 1, 2023 ¹	0.5	1	6	12	12	36
July 1, 2023 through April 3, 2024 ²	1	3	12	36	12	36
April 3, 2024 through May 17, 2024 ³	5	35	150	300	12	36
After May 17, 2024 ⁴	5	35	150	300	150	300

¹ Initial vector limits during early preview.

² Vector limits during the later preview period. Three regions didn't have the higher limits: Germany West Central, West India, Qatar Central.

³ Higher vector quota based on the larger partitions for supported tiers and regions.

⁴ Higher vector quota for more tiers and regions based on partition size updates.

The service enforces a vector index size quota *for every partition* in your search service. Each extra partition increases the available vector index size quota. This quota is a hard limit to ensure your service remains healthy, which means that further indexing attempts once the limit is exceeded results in failure. You can resume indexing once you free up available quota by either deleting some vector documents or by scaling up in partitions.

ⓘ Important

Higher vector limits are tied to [larger partition sizes](#). Currently, higher vector limits aren't available in the following regions, which are subject to the July–April limits.

- Israel Central
- Qatar Central
- Spain Central
- South India

Indexer limits

Maximum running times exist to provide balance and stability to the service as a whole, but larger data sets might need more indexing time than the maximum allows. If an indexing job can't complete within the maximum time allowed, try running it on a schedule. The scheduler keeps track of indexing status. If a scheduled indexing job is interrupted for any reason, the indexer can pick up where it last left off at the next scheduled run.

[\[+\] Expand table](#)

Resource	Free ¹	Basic ²	S1	S2	S3	S3 HD ³	L1	L2
Maximum indexers	3	5 or 15	50	200	200	N/A	10	10
Maximum datasources	3	5 or 15	50	200	200	N/A	10	10
Maximum skillsets ⁴	3	5 or 15	50	200	200	N/A	10	10
Maximum indexing load per invocation	10,000 documents	Limited only by maximum documents	Limited only by maximum documents	Limited only by maximum documents	Limited only by maximum documents	N/A	No limit	No limit
Minimum schedule	5 minutes	5 minutes	5 minutes	5 minutes	5 minutes	5 minutes	5 minutes	5 minutes
Maximum running time ⁵	1-3 or 3-10 minutes	2 or 24 hours	N/A	2 or 24 hours	2 or 24 hours			
Blob indexer: maximum blob size, MB	16	16	128	256	256	N/A	256	256
Blob indexer: maximum characters of content extracted from a blob	256,000	512,000	4 million	8 million	16 million	N/A	4 million	4 million

¹ Free services have indexer maximum execution time of 3 minutes for blob sources and 1 minute for all other data sources. Indexer invocation is once every 180 seconds. For AI indexing that calls Foundry Tools, free services are limited to 20 free transactions per indexer per day, where a

⁶

transaction is defined as a document that successfully passes through the enrichment pipeline.

(Tip: You can reset an indexer to reset its count.)

² Basic services created before December 2017 have lower limits (5 instead of 15) on indexers, data sources, and skillsets.

³ S3 HD services don't include indexer support.

⁴ Maximum of 30 skills per skillset.

⁵ Regarding the 2 or 24 hour maximum duration for indexers: a 2-hour maximum is the most common and it's what you should plan for. It refers to indexers that run in the [public environment](#), which offloads computationally intensive processing and leaves more resources for queries. The 24-hour limit applies if you configure the indexer to run in a private environment using only the infrastructure that's allocated to your search service. Some older indexers are incapable of running in the public environment, and those indexers always have a 24-hour processing range. If you have unscheduled indexers that run continuously for 24 hours, you can assume those indexers couldn't be migrated to the newer infrastructure. As a general rule, for indexing jobs that can't finish within two hours, put the indexer on a [5-minute schedule](#) so that the indexer can quickly pick up where it left off. On the Free tier, the 3-10 minute maximum running time is for indexers with skillsets.

⁶ The maximum number of characters is based on Unicode code units, specifically UTF-16.

Note

As stated in [Index limits](#), indexers also enforce the upper limit of 3,000 elements across all complex collections per document starting with the latest GA API version that supports complex types ([2019-05-06](#)) onwards. This means that if you created your indexer with a prior API version, you won't be subject to this limit. To preserve maximum compatibility, an indexer that was created with a prior API version and then updated with an API version [2019-05-06](#) or later, will still be **excluded** from the limits. Customers should be aware of the adverse impact of having very large complex collections (as stated previously) and we highly recommend creating any new indexers with the latest GA API version.

Shared private link resource limits

Indexers can access other Azure resources [over private endpoints](#) managed via the [shared private link resource API](#). This section describes the limits associated with this capability.

 Expand table

Resource	Free	Basic	S1	S2	S3	S3 HD	L1	L2
Private endpoint indexer support	No	Yes	Yes	Yes	Yes	No	Yes	Yes
Private endpoint support for indexers with a skillset ¹	No	No	Yes	Yes	Yes	No	Yes	Yes
Private endpoint support for skillsets with an embedding skill ²	No	Yes	Yes	Yes	Yes	No	Yes	Yes
Maximum private endpoints	N/A	10 or 30	100	400	400	N/A	20	20
Maximum distinct resource types ³	N/A	4	7	15	15	N/A	4	4

¹ AI enrichment and image analysis are computationally intensive and consume disproportionate amounts of available processing power. For this reason, private connections are disabled on lower tiers to ensure the performance and stability of the search service itself. On Basic services, private connections to a Microsoft Foundry resource are unsupported to preserve service stability. For the S1 tier, make sure the service was created with [higher limits](#) after April 3, 2024. Indexers with more than 2 Azure OpenAI Embedding or Azure Vision multimodal embeddings skills are restricted from running in private environment, and private connections aren't available.

² Private connections to an embedding model are supported on Basic and S1 high-capacity search services created after April 3, 2024, with the [higher limits](#) for storage and computational processing.

³ The number of distinct resource types are computed as the number of unique `groupId` values used across all shared private link resources for a given search service, irrespective of the status of the resource.

Synonym limits

Maximum number of synonym maps varies by tier. Each rule can have up to 20 expansions, where an expansion is an equivalent term. For example, given "cat", association with "kitty", "feline", and "felis" (the genus for cats) would count as 3 expansions.

[+] [Expand table](#)

Resource	Free	Basic	S1	S2	S3	S3 HD	L1	L2
Maximum synonym maps	3	3	5	10	20	20	10	10
Maximum number of rules per map	5000	20000	20000	20000	20000	20000	20000	20000

Index alias limits

Maximum number of [index aliases](#) varies by tier and [service creation date](#). On all tiers, if the service was created after October 2022, the maximum number of aliases is double the maximum number of indexes allowed. If the service was created before October 2022, the limit is the number of indexes allowed.

[Expand table](#)

Service creation date	Free	Basic	S1	S2	S3	S3 HD	L1	L2
Before October 2022	3	5 or 15 ¹	50	200	200	1000 per partition or 3000 per service	10	10
After October 2022	6	30	100	400	400	2000 per partition or 6000 per service	20	20

¹ Basic services created before December 2017 have lower limits (5 instead of 15) on indexes.

Agentic retrieval limits

Each [knowledge base](#) contains [knowledge sources](#), which are data source connections, and configurations that agents consume for [agentic retrieval](#). The following limits apply to knowledge sources and knowledge bases per service tier.

[Expand table](#)

Resource	Free	Basic ¹	S1	S2	S3	S3 HD	L1	L2
Maximum knowledge sources	3	5 or 15	50	200	200	0	10	10
Maximum knowledge bases	3	5 or 15	50	200	200	0	10	10

¹ Basic services created before April 3, 2024 have lower limits (5 instead of 15) on knowledge sources and knowledge bases.

Data limits (AI enrichment)

Data limits apply to an [AI enrichment pipeline](#) that makes calls to Azure Language in Foundry Tools for [entity recognition](#), [entity linking](#), [key phrase extraction](#), [sentiment analysis](#), [language detection](#), and [personal-information detection](#). The maximum size of a record should be 50,000 characters as measured by [String.Length](#). If you need to break up your data before sending it to the sentiment analyzer, use the [Text Split skill](#).

Throttling limits

API requests are throttled as the system approaches peak capacity. Throttling behaves differently for different APIs. Query APIs (Search/Suggest/Autocomplete) and indexing APIs throttle

dynamically based on the load on the service. Index APIs and service operations API have static request rate limits.

Static rate request limits for operations related to an index:

- List Indexes (GET /indexes): 3 per second per search unit
- Get Index (GET /indexes/myindex): 10 per second per search unit
- Create Index (POST /indexes): 12 per minute per search unit
- Create or Update Index (PUT /indexes/myindex): 6 per second per search unit
- Delete Index (DELETE /indexes/myindex): 12 per minute per search unit

Static rate request limits for operations related to a service:

- Service Statistics (GET /servicestats): 4 per second per search unit

Semantic ranker throttling limits

[Semantic ranker](#) uses a queuing system to manage concurrent requests. This system allows search services get the highest number of queries per second possible. When the limit of concurrent requests is reached, additional requests are placed in a queue. If the queue is full, further requests are rejected and must be retried.

Total semantic ranker queries per second varies based on the following factors:

- The tier of the search service. Both queue capacity and concurrent request limits vary by tier.
- The number of search units in the search service. The simplest way to increase the maximum number of concurrent semantic ranker queries is to [add more search units to your search service](#).
- The total available semantic ranker capacity in the region.
- The amount of time it takes to serve a query using semantic ranker. This varies based on how busy the search service is.

The following table describes the semantic ranker throttling limits by tier, subject to available capacity in the region. You can contact Microsoft support to request a limit increase.

 [Expand table](#)

Resource	Basic	S1	S2	S3	S3 HD	L1	L2
Maximum concurrent requests (per search unit)	2	3	4	4	4	4	4
Maximum request queue size (per search unit)	4	6	8	8	8	8	8

API request limits

Limits on queries exist because unbounded queries can destabilize your search service. Typically, such queries are created programmatically. If your application generates search queries programmatically, we recommend designing it in such a way that it doesn't generate queries of unbounded size.

Limits on payloads exist for similar reasons, ensuring the stability of your search service. The limit applies to the entire request, inclusive of all its components. For example, if the request batches several documents or commands, the entire request must fit within the supported limit.

If you must exceed a supported limit, you should [test your workload](#) so that you know what to expect.

Except where noted, the following API requests apply to all programmable interfaces, including the Azure SDKs.

General:

- Supported maximum payload limit is 16 MB for indexing and query request via REST API and SDKs.
- Maximum 8-KB URL length (applies to REST APIs only).

Indexing APIs:

- Supported maximum 1,000 documents per batch of index uploads, merges, or deletes.

Query APIs:

- Maximum 10 fields in a vector query
- Maximum 32 fields in \$orderby clause.
- Maximum 100,000 characters in a search clause.
- Maximum number of clauses in search is 3,000.
- Maximum limits on [wildcard](#) and [regular expression](#) queries, as enforced by [Lucene](#). It caps the number of patterns, variations, or matches to 1,000 instances. This limit is in place to avoid engine overload.

Search terms:

- Supported maximum search term size is 32,766 bytes (32 KB minus 2 bytes) of UTF-8 encoded text. Applies to keyword search and the text property of vector search.
- Supported maximum search term size is 1,000 characters for [prefix search](#) and [regex search](#).

API response limits

- Maximum 1,000 documents returned per page of search results
- Maximum 100 suggestions returned per Suggest API request

The search engine returns 50 results by default, but you can [override this parameter](#) up to the maximum limit.

API key limits

API keys are used for service authentication. There are two types. Admin keys are specified in the request header and grant full read-write access to the service. Query keys are read-only, specified on the URL, and typically distributed to client applications.

- Maximum of 2 admin keys per service
- Maximum of 50 query keys per service

Last updated on 11/20/2025

Estimate and manage capacity of a search service

In Azure AI Search, capacity is based on *replicas* and *partitions* that can be scaled to your workload. Replicas are copies of the search engine. Partitions are units of storage. Each new search service starts with one each, but you can add or remove replicas and partitions independently to accommodate fluctuating workloads. Adding capacity increases the [cost of running a search service](#).

The physical characteristics of replicas and partitions, such as processing speed and disk IO, vary by [pricing tier](#). On a standard search service, the replicas and partitions are faster and larger than those of a basic service.

Changing capacity isn't instantaneous. It can take up to an hour to commission or decommission partitions, especially on services with large amounts of data.

When scaling a search service, you can choose from the following tools and approaches:

- [Azure portal](#)
- [Azure PowerShell](#)
- [Azure CLI](#)
- [Management REST API](#)

(!) Note

If your service was created before April or May 2024, a one-time upgrade to higher storage limits might be available at no extra cost. For more information, see [Upgrade your search service](#).

Concepts: search units, replicas, partitions

Capacity is expressed in *search units* that can be allocated in combinations of *partitions* and *replicas*.

 Expand table

Concept	Definition
Search unit	A single increment of total available capacity. A minimum of one search unit is required to run the service. Depending on your pricing tier, the maximum ranges from one to 36 units. The number of search units equals the number of replicas multiplied by the number of

Concept	Definition
	partitions: $R \times P = SU$. Each service starts with one replica and one partition, which consumes one unit: $1 \times 1 = 1$. Adding a second replica consumes two units: $2 \times 1 = 2$. A search unit is also the billing unit for a search service.
<i>Replica</i>	Instances of the search service, used primarily to load balance query operations. Each replica hosts one copy of an index. If you allocate three replicas, you have three copies of an index available for servicing query requests.
<i>Partition</i>	Physical storage and I/O for read/write operations (for example, when rebuilding or refreshing an index). Each partition has a slice of the total index. If you allocate three partitions, your index is divided into thirds.

Review the [partitions and replicas table](#) for possible combinations that stay under the 36 unit limit.

When to add capacity

Initially, a service is allocated a minimal level of resources consisting of one partition and one replica. The [tier you choose](#) determines partition size and speed, and each tier is optimized around a set of characteristics that fit various scenarios. If you choose a higher-end tier, you might [need fewer partitions](#) than if you go with S1. One of the questions you need to answer through self-directed testing is whether a larger and more expensive partition yields better performance than two cheaper partitions on a service provisioned at a lower tier.

A single service must have sufficient resources to handle all workloads (indexing and queries). Neither workload runs in the background. You can schedule indexing for times when query requests are naturally less frequent, but the service doesn't otherwise prioritize one task over another. Additionally, a certain amount of redundancy smooths out query performance when services or nodes are updated internally.

Guidelines for determining whether to add capacity include:

- Meeting the high availability criteria for service-level agreement.
- The frequency of HTTP 503 (Service unavailable) errors is increasing.
- The frequency of HTTP 429 (Too many requests) errors is increasing, an indication of low storage.
- Large query volumes are expected.
- A [one-time upgrade](#) to newer infrastructure and larger partitions isn't sufficient.
- The current number of partitions isn't adequate for indexing workloads.

As a general rule, search applications tend to need more replicas than partitions, particularly when the service operations are biased toward query workloads. Each replica is a copy of your

index, allowing the service to load balance requests against multiple copies. Azure AI Search manages all load balancing and replication of an index, and you can alter the number of replicas allocated for your service at any time. You can allocate up to 12 replicas in a Standard search service and 3 replicas in a Basic search service. Replica allocation can be made either from the [Azure portal](#) or one of the programmatic options.

Extra partitions are helpful for intensive indexing workloads. Extra partitions spread read/write operations across a larger number of compute resources.

Finally, larger indexes take longer to query. As such, you might find that every incremental increase in partitions requires a smaller but proportional increase in replicas. The complexity of your queries and query volume factors into how quickly query execution is turned around.

Note

Adding more replicas or partitions increases the cost of running the service, and can introduce slight variations in how results are ordered. Be sure to check the [pricing calculator](#) ↗ to understand the billing implications of adding more nodes. The [chart below](#) can help you cross-reference the number of search units required for a specific configuration. For more information on how extra replicas affect query processing, see [Ordering results](#).

How to upgrade capacity

Some Azure AI Search capabilities are only available to new services. One such capability is higher storage capacity, which applies to [services created after April 2024](#). However, if you created your service before April 2024, you can get higher capacity without recreating your service by performing a one-time upgrade. For more information, see [Upgrade your search service](#).

How to change capacity

To increase or decrease the capacity of your service, you have two options:

- [Add or remove partitions and replicas](#)
- [Change your pricing tier](#)

Add or remove partitions and replicas

1. Sign in to the [Azure portal](#) ↗ and select your search service.

2. From the left pane, select **Settings > Scale**.

The following screenshot shows a Standard service provisioned with one replica and partition. The formula at the bottom indicates how many search units are being used (1). If the unit price was \$100 (not a real price), the monthly cost of running this service would be \$100 on average.

Home > my-search-service

SEARCH UNITS 1/36

Pricing tier

Standard 25 GB/Partition, max 12 replicas, max 12 partitions, max 36 search units Change Pricing Tier

Replicas

Replicas distribute workloads across the service.

Partitions

Partitions allow for scaling of document counts as well as faster data ingestion by spanning your index over multiple units.

1 Replicas x 1 Partitions = 1 of 36 available search units

3. Use the slider to increase or decrease the number of partitions, and then select **Save**.

This example adds a second replica and partition. Notice the search unit count; it's now four because the billing formula is replicas multiplied by partitions (2×2). Doubling capacity more than doubles the cost of running the service. If the search unit cost was \$100, the new monthly bill would now be \$400.

For the current per unit costs of each tier, visit the [pricing page](#).

Change your pricing tier

! Note

The Azure portal and [Services - Update \(REST API\)](#) support changes between Basic and Standard (S1, S2, and S3) tiers. You can upgrade or downgrade tiers, provided your current service configuration doesn't exceed the [limits of the target tier](#). Your region also can't have [capacity constraints on the target tier](#).

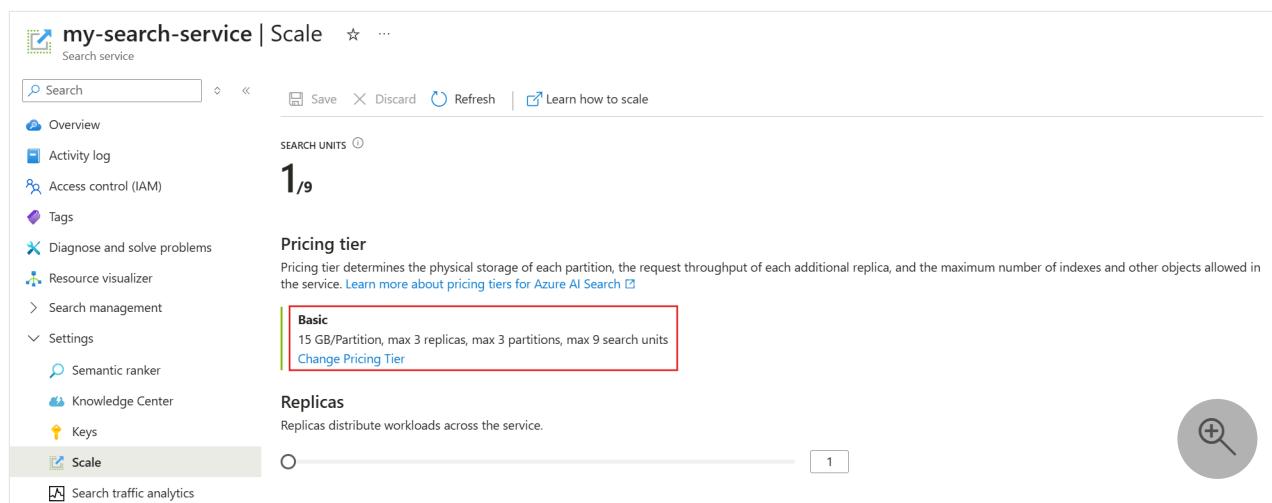

Your [pricing tier](#) determines the maximum storage of your search service. If you need more or less capacity, you can switch to a different pricing tier that accommodates your storage needs.

In addition to capacity, pricing tiers determine limits on indexes, indexers, and other search objects. Compare the [service limits](#) of your current tier and your desired tier before you proceed. Generally, switching to a higher tier increases your [storage limit](#) and [vector limit](#), increases request throughput, and decreases latency, while switching to a lower tier has the opposite effect.

Switching to a higher pricing tier also increases the cost of running your search service. For more information, see the [pricing page](#).

To change your pricing tier:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Settings > Scale**.
3. Under your current tier, select **Change Pricing Tier**.

4. On the **Select Pricing Tier** page, choose a different tier from the list.

You can switch between Basic, S1, S2, and S3, but you can't switch to or from Free, S3HD, L1, or L2. These tiers aren't selectable and appear dimmed.

SEARCH UNITS 1/36

Pricing tier Standard

160 GB/Partition, max 12 replicas, max 12 partitions, max 36 search units

[Change Pricing Tier](#)

This operation can take several hours to complete. It occurs in the background, so your search service remains fully operational and available for read and write operations.

You can't cancel the operation or monitor its progress. However, the following message displays while changes are underway:

my-search-service | Scale

Updating... This operation may take a while...

How scale requests are handled

Upon receipt of a scale request, the search service:

1. Checks whether the request is valid.

2. Starts backing up data and system information.
3. Checks whether the service is already in a provisioning state (currently adding or eliminating either replicas or partitions).
4. Starts provisioning.

Scaling a service can take as little as 15 minutes or well over an hour, depending on the size of the service and the scope of the request. Backup can take several minutes, depending on the amount of data and number of partitions and replicas.

The above steps aren't entirely consecutive. For example, the system starts provisioning when it can safely do so, which could be while backup is winding down.

Errors during scaling

The following table lists causes and solutions for errors that can occur during scaling operations.

[] Expand table

Error message	Cause	Solution
"Service update operations aren't allowed at this time because we're processing a previous request."	Another scaling operation is in progress.	Check the Overview page in the Azure portal or use the Search Management REST API , Azure PowerShell , or Azure CLI to get the status of your search service. If the status is "Provisioning," wait until it becomes "Succeeded" or "Failed" before you try again. ^{1, 2}
"Failed to scale search service <i>servicename</i> . Error: <i>Object count ActualCount</i> exceeds allowable limit: <i>MaximumCount</i> ."	Your current service configuration exceeds the limits of the target pricing tier.	Check that your storage usage, vector usage, indexes, indexers, and other objects fit within the lower tier's service limits . For example, the Basic tier supports up to 15 indexes, so you can't switch from S1 to Basic if you have 16 indexes. Adjust your resources before you try again.

¹ There's no status for backups, which are internal operations that are unlikely to disrupt a scaling exercise.

² If your search service appears to be stalled in a provisioning state, check for orphaned indexes that are unusable, with zero query volumes and no index updates. An unusable index can block changes to service capacity. In particular, look for [CMK-encrypted](#) indexes whose keys are no longer valid. Either delete the index or restore the keys to bring the index back online and unblock your scaling operation.

Partition and replica combinations

The following chart applies to Standard tier and higher. It shows all possible combinations of partitions and replicas, subject to the 36 search unit maximum per service.

[+] Expand table

	1 partition	2 partitions	3 partitions	4 partitions	6 partitions	12 partitions
1 replica	1 SU	2 SU	3 SU	4 SU	6 SU	12 SU
2 replicas	2 SU	4 SU	6 SU	8 SU	12 SU	24 SU
3 replicas	3 SU	6 SU	9 SU	12 SU	18 SU	36 SU
4 replicas	4 SU	8 SU	12 SU	16 SU	24 SU	N/A
5 replicas	5 SU	10 SU	15 SU	20 SU	30 SU	N/A
6 replicas	6 SU	12 SU	18 SU	24 SU	36 SU	N/A
12 replicas	12 SU	24 SU	36 SU	N/A	N/A	N/A

Basic search services have lower search unit counts.

- On search services created before April 3, 2024, Basic services can have exactly one partition and up to three replicas for a maximum limit of three SUs. The only adjustable resource is replicas. However, you might be able to increase your partition count by [upgrading your service](#).
- On search services created after April 3, 2024 in [supported regions](#), Basic services can have up to three partitions and three replicas. The maximum SU limit is nine to support a full complement of partitions and replicas.

For search services on any billable tier, regardless of creation date, you need a minimum of two replicas for high availability on queries.

For billing rates per tier and currency, see the [Azure AI Search pricing page](#).

Estimate capacity using a billable tier

The size of the indexes you expect to build determines storage needs. There are no solid heuristics or generalities that help with estimates. The only way to determine the size of an index is [build one](#). Its size is based on tokenization and embeddings, and whether you enable suggesters, filtering, and sorting, or can take advantage of [vector compression](#).

We recommend estimating on a billable tier, Basic or higher. The Free tier runs on physical resources shared by multiple customers and is subject to factors beyond your control. Only the dedicated resources of a billable search service can accommodate larger sampling and processing times for more realistic estimates of index quantity, size, and query volumes during development.

1. [Review service limits at each tier](#) to determine whether lower tiers can support the number of indexes you need. Consider whether you need multiple copies of an index for active development, testing, and production.

A search service is subject to object limits (maximum number of indexes, indexers, skillsets, etc.) and storage limits. Whichever limit is reached first is the effective limit.

2. [Create a service at a billable tier](#). Tiers are optimized for certain workloads. For example, the Storage Optimized tier has a limit of 10 indexes because it's designed to support a low number of large indexes.

- Start low, at Basic or S1, if you're not sure about the projected load.
- Start high, at S2 or even S3, if testing includes large-scale indexing and query loads.
- Start with Storage Optimized, at L1 or L2, if you're indexing a large amount of data and query load is relatively low, as with an internal business application.

3. [Build an initial index](#) to determine how source data translates to an index. This is the only way to estimate index size. Attributes on the field definitions affect physical storage requirements:

- For keyword search, marking fields as filterable and sortable [increases index size](#).
- For vector search, you can [set parameters to reduce vector size](#).

4. [Monitor storage, service limits, query volume, and latency](#) in the Azure portal. the Azure portal shows you queries per second, throttled queries, and search latency. All of these values can help you decide if you selected the right tier.

5. Add replicas for high availability or to mitigate slow query performance.

There are no guidelines on how many replicas are needed to accommodate query loads. Query performance depends on the complexity of the query and competing workloads. Although adding replicas clearly results in better performance, the result isn't strictly linear: adding three replicas doesn't guarantee triple throughput. For guidance in estimating QPS for your solution, see [Analyze performance](#)and [Monitor queries](#).

For an [inverted index](#), size and complexity are determined by content, not necessarily by the amount of data that you feed into it. A large data source with high redundancy could result in a smaller index than a smaller dataset that contains highly variable content. So it's rarely possible to infer index size based on the size of the original dataset.

Storage requirements can be inflated if you include data that will never be searched. Ideally, documents contain only the data that you need for the search experience.

Service-level agreement considerations

The Free tier and preview features aren't covered by [service-level agreements \(SLAs\)](#). For all billable tiers, SLAs take effect when you provision sufficient redundancy for your service.

- Two or more replicas satisfy query (read) SLAs.
- Three or more replicas satisfy query and indexing (read-write) SLAs.

The number of partitions doesn't affect SLAs.

[Plan and manage costs](#)

Last updated on 11/19/2025

Plan and manage costs of an Azure AI Search service

This article explains how Azure AI Search is billed, including fixed and variable costs, and provides guidance for cost management.

Before you create a search service, use the [Azure pricing calculator](#) to estimate costs based on your planned [capacity](#) and features. Another resource is a capacity-planning worksheet that models your expected index size, indexing throughput, and indexing costs.

As your search workload evolves, follow our tips to minimize costs during both deployment and operation. You can also use built-in metrics to monitor query requests and [Cost Management](#) to create budgets, alerts, and data exports.

! Note

Higher-capacity partitions are available at the same billing rate on services created after April and May 2024. For more information about partition-size upgrades, see [Service limits](#).

Understand the billing model

Azure AI Search has both fixed and pay-as-you-go billing. You pay a fixed rate for your search service as long as it exists, while premium features are billed according to your usage.

Costs for Azure AI Search are only a portion of the monthly costs in your Azure bill. Although this article focuses on planning and managing Azure AI Search costs, you're billed for all Azure services and resources used in your Azure subscription, including non-Microsoft services.

How you're charged for the base service

When you create or use search resources, you're charged for the minimum required replica and partition combination ($R \times P$) at the prorated hourly rate of your [pricing tier](#). As your search units increase or decrease, so do your costs. For more information and an example of the billing model, see [Billing rates](#).

How you're charged for premium features

Premium features are charged in addition to the base cost of your search service. The following table lists premium features and their billing units. All of these features are optional, so if you

don't use them, you don't incur any charges.

 Expand table

Feature	Billing unit
Image extraction (AI enrichment) ¹	Per 1,000 images. See the pricing page .
Custom Entity Lookup skill (AI enrichment)	Per 1,000 text records. See the pricing page .
Built-in or custom skills (AI enrichment) ²	Number of transactions. Billed at the rate of the model provider: Foundry Tools, Azure OpenAI, or Microsoft Foundry.
Vectorizers ²	Number of vectorization operations. Billed at the rate of the model provider: Azure Vision in Foundry Tools, Azure OpenAI, or Foundry.
Semantic ranker	Number of queries of <code>queryType=semantic</code> . Billed at a progressive rate. See the pricing page .
Agentic retrieval	Number of agentic reasoning tokens, plus number of tokens used in query planning and answer formulation. See the pricing page .
Shared private link	Billed for bandwidth as long as the shared private link exists and is used.

¹ Refers to images extracted from a file within the indexer pipeline. Text extraction is free. Image extraction is billed when you [enable the indexAction parameter](#) or when you call the [Document Extraction skill](#).

² Charges for Azure OpenAI models and Foundry models appear on your bill for those services.

How you're otherwise charged

Depending on your configuration and usage, the following charges might apply:

- Data traffic might incur networking costs. See the [bandwidth pricing](#).
- Several premium features, such as [knowledge stores](#), [debug sessions](#), and [enrichment caches](#), depend on Azure Storage and incur storage costs. Charges for these features appear on your Azure Storage bill.
- [Customer-managed keys](#), which provide double encryption of sensitive content, require a billable [Azure Key Vault](#).
- A skillset can include [billable built-in skills](#), nonbillable built-in utility skills, and custom skills. Nonbillable utility skills include [Conditional](#), [Shaper](#), [Text Merge](#), and [Text Split](#). They

don't have an API key requirement or 20-document limit.

- A custom skill is functionality you provide. Custom skills are billable only if they call other billable services. They don't have an API key requirement or 20-document limit.

 **Note**

You aren't billed for the number of full-text or vector queries, query responses, or documents ingested. However, [service limits](#) apply to each pricing tier.

Estimate and plan costs

Use the [Azure pricing calculator](#) to estimate your baseline costs for Azure AI Search. You can also find estimated costs and tier comparisons on the [Select Pricing Tier](#) page during service creation.

For initial testing, we recommend that you create a capacity-planning worksheet. The worksheet helps you understand the index-to-source ratio and the effect of enrichment or vector features on both capacity and cost.

To create a capacity-planning worksheet:

1. Index a small sample (1–5%) of your data. Include any [OCR](#), enrichment, or embedding skills you plan to use.
2. Measure the index size, indexing throughput, and indexing costs.
3. Extrapolate the results to estimate the full-scale requirements for your data.

Minimize costs

To minimize the costs of your Azure AI Search solution, use the following strategies:

Deployment and configuration

- Create a search service in a [region with more storage per partition](#).
- Create all related Azure resources in the same region (or as few regions as possible) to minimize or eliminate bandwidth charges.
- Choose the lightest [pricing tier](#) that meets your needs. Basic and S1 offer full access to the modern API at the lowest hourly rate per SU.

- Use [Azure Web Apps](#) for your front-end application to keep requests and responses within the data center boundary.

Scaling

- Add [partitions](#) only when the index size or ingestion throughput requires it.
- Add [replicas](#) only when your queries per second increase, when complex queries are throttling your service, or when high availability is required.
- Scale up for resource-intensive operations, such as indexing, and then readjust downwards for regular query workloads.
- Write code to automate scaling for predictable workload patterns.
- Remember that capacity and pricing aren't linear. Doubling capacity more than doubles costs on the same tier. For better performance at a similar price, consider [switching to a higher tier](#).

Indexing and enrichment

- Use [incremental indexing](#) to process only new or changed data.
- Use [enrichment caching](#) and a [knowledge store](#) to reuse previously enriched content. Although caching incurs a storage charge, it lowers the cumulative cost of [AI enrichment](#).
- Keep vector payloads compact. For vector search, see the [vector compression best practices](#).

Monitor costs

At the service level, you can [monitor built-in metrics](#) for your queries per second (QPS), search latency, throttled queries, and index size. You can then [create an Azure Monitor dashboard](#) that overlays QPS, latency, and cost data to determine when to add or remove replicas.

At the subscription or resource group level, [Cost Management](#) provides tools to track, analyze, and control costs. You can use Cost Management to:

- [Create budgets](#) that define and track progress against spending limits. For more granular monitoring, customize your budgets using [filters](#) for specific Azure resources or services. Filters prevent you from accidentally creating resources that incur extra costs.

- [Create alerts](#) that automatically notify stakeholders of spending anomalies or overspending risks. Alerts are based on spending compared to budget and cost thresholds. Both budgets and alerts are created for subscriptions and resource groups, making them useful for monitoring overall costs.
- [Export cost data](#) to a storage account. This is helpful when you or others need to perform more cost analysis. For example, a finance team can analyze the data using Excel or Power BI. You can export your costs on a daily, weekly, or monthly schedule and set a custom date range. Exporting cost data is the recommended method for retrieving cost datasets.

FAQ

Can I temporarily shut down a search service to save on costs?

Search runs as a continuous service. Dedicated resources are always operational and allocated for your exclusive use for the lifetime of your service. To stop billing entirely, you must delete the service. Deleting a service is permanent and also deletes its associated data.

Can I change the billing rate (tier) of an existing search service?

Existing services can switch between Basic and Standard (S1, S2, and S3) tiers. Your current service configuration can't exceed the limits of the target tier, and your region can't have capacity constraints on the target tier. For more information, see [Change your pricing tier](#).

Design patterns for multitenant SaaS applications and Azure AI Search

05/29/2025

A multitenant application is one that provides the same services and capabilities to any number of tenants who can't see or share the data of any other tenant. This article discusses tenant isolation strategies for multitenant applications built with Azure AI Search.

Azure AI Search concepts

As a search-as-a-service solution, [Azure AI Search](#) allows developers to add rich search experiences to applications without managing any infrastructure or becoming an expert in information retrieval. Data is uploaded to the service and then stored in the cloud. Using simple requests to the Azure AI Search API, the data can then be modified and searched.

Search services, indexes, fields, and documents

Before discussing design patterns, it's important to understand a few basic concepts.

When using Azure AI Search, one subscribes to a *search service*. As data is uploaded to Azure AI Search, it's stored in an *index* within the search service. There can be a number of indexes within a single service. To use the familiar concepts of databases, the search service can be likened to a database while the indexes within a service can be likened to tables within a database.

Each index within a search service has its own schema, which is defined by a number of customizable *fields*. Data is added to an Azure AI Search index in the form of individual *documents*. Each document must be uploaded to a particular index and must fit that index's schema. When searching data using Azure AI Search, the full-text search queries are issued against a particular index. To compare these concepts to those of a database, fields can be likened to columns in a table and documents can be likened to rows.

Scalability

Any Azure AI Search service in the Standard [pricing tier](#) can scale in two dimensions: storage and availability.

- *Partitions* can be added to increase the storage of a search service.
- *Replicas* can be added to a service to increase the throughput of requests that a search service can handle.

Adding and removing partitions and replicas at will allow the capacity of the search service to grow with the amount of data and traffic the application demands. In order for a search service to achieve a read [SLA](#), it requires two replicas. In order for a service to achieve a read-write [SLA](#), it requires three replicas.

Service and index limits in Azure AI Search

There are a few different [pricing tiers](#) in Azure AI Search, each of the tiers has different [limits and quotas](#). Some of these limits are at the service-level, some are at the index-level, and some are at the partition-level.

S3 High Density

In Azure AI Search's S3 pricing tier, there's an option for the High Density (HD) mode designed specifically for multitenant scenarios. In many cases, it's necessary to support a large number of smaller tenants under a single service to achieve the benefits of simplicity and cost efficiency.

S3 HD allows for the many small indexes to be packed under the management of a single search service by trading the ability to scale out indexes using partitions for the ability to host more indexes in a single service.

An S3 service is designed to host a fixed number of indexes (maximum 200) and allow each index to scale in size horizontally as new partitions are added to the service. Adding partitions to S3 HD services increases the maximum number of indexes that the service can host. The ideal maximum size for an individual S3HD index is around 50 - 80 GB, although there's no hard size limit on each index imposed by the system.

Considerations for multitenant applications

Multitenant applications must effectively distribute resources among the tenants while preserving some level of privacy between the various tenants. There are a few considerations when designing the architecture for such an application:

- *Tenant isolation:* Application developers need to take appropriate measures to ensure that no tenants have unauthorized or unwanted access to the data of other tenants. Beyond the perspective of data privacy, tenant isolation strategies require effective management of shared resources and protection from noisy neighbors.
- *Cloud resource cost:* As with any other application, software solutions must remain cost competitive as a component of a multitenant application.

- *Ease of Operations*: When developing a multitenant architecture, the impact on the application's operations and complexity is an important consideration. Azure AI Search has a [99.9% SLA](#).
- *Global footprint*: Multitenant applications often need to serve tenants who are distributed across the globe.
- *Scalability*: Application developers need to consider how they reconcile between maintaining a sufficiently low level of application complexity and designing the application to scale with number of tenants and the size of tenants' data and workload.

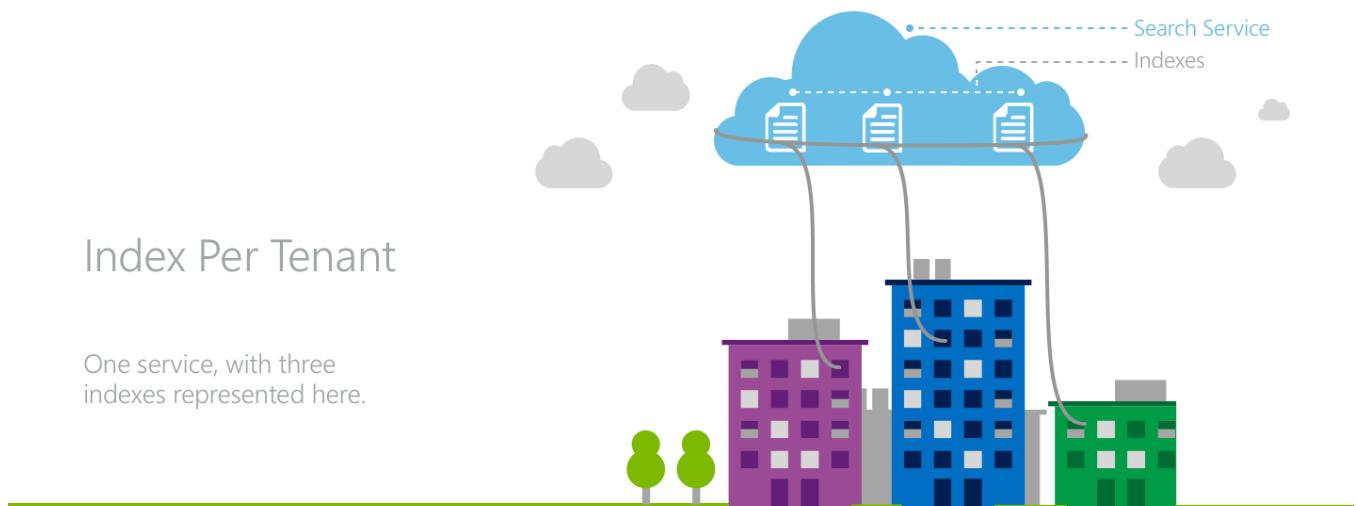

Azure AI Search offers a few boundaries that can be used to isolate tenants' data and workload.

Modeling multitenancy with Azure AI Search

In the case of a multitenant scenario, the application developer consumes one or more search services and divides their tenants among services, indexes, or both. Azure AI Search has a few common patterns when modeling a multitenant scenario:

- *One index per tenant*: Each tenant has its own index within a search service that is shared with other tenants.
- *One service per tenant*: Each tenant has its own dedicated Azure AI Search service, offering highest level of data and workload separation.
- *Mix of both*: Larger, more-active tenants are assigned dedicated services while smaller tenants are assigned individual indexes within shared services.

Model 1: One index per tenant

In an index-per-tenant model, multiple tenants occupy a single Azure AI Search service where each tenant has their own index.

Tenants achieve data isolation because all search requests and document operations are issued at an index level in Azure AI Search. In the application layer, there's the need awareness to direct the various tenants' traffic to the proper indexes while also managing resources at the service level across all tenants.

A key attribute of the index-per-tenant model is the ability for the application developer to oversubscribe the capacity of a search service among the application's tenants. If the tenants have an uneven distribution of workload, the optimal combination of tenants can be distributed across a search service's indexes to accommodate a number of highly active, resource-intensive tenants while simultaneously serving a long tail of less active tenants. The trade-off is the inability of the model to handle situations where each tenant is concurrently highly active.

The index-per-tenant model provides the basis for a variable cost model, where an entire Azure AI Search service is bought up-front and then subsequently filled with tenants. This allows for unused capacity to be designated for trials and free accounts.

For applications with a global footprint, the index-per-tenant model might not be the most efficient. If an application's tenants are distributed across the globe, a separate service can be necessary for each region, duplicating costs across each of them.

Azure AI Search allows for the scale of both the individual indexes and the total number of indexes to grow. If an appropriate pricing tier is chosen, partitions and replicas can be added to the entire search service when an individual index within the service grows too large in terms of storage or traffic.

If the total number of indexes grows too large for a single service, another service has to be provisioned to accommodate the new tenants. If indexes have to be moved between search services as new services are added, the data from the index has to be manually copied from one index to the other as Azure AI Search doesn't allow for an index to be moved.

Model 2: One service per tenant

In a service-per-tenant architecture, each tenant has its own search service.

In this model, the application achieves the maximum level of isolation for its tenants. Each service has dedicated storage and throughput for handling search requests. Each tenant has individual ownership of API keys.

For applications where each tenant has a large footprint or the workload has little variability from tenant to tenant, the service-per-tenant model is an effective choice as resources aren't shared across various tenants' workloads.

A service per tenant model also offers the benefit of a predictable, fixed cost model. There's no up-front investment in an entire search service until there's a tenant to fill it, however the cost-per-tenant is higher than an index-per-tenant model.

The service-per-tenant model is an efficient choice for applications with a global footprint. With geographically distributed tenants, it's easy to have each tenant's service in the appropriate region.

The challenges in scaling this pattern arise when individual tenants outgrow their service. Azure AI Search doesn't currently support upgrading the pricing tier of a search service, so all data would have to be manually copied to a new service.

Model 3: Hybrid

Another pattern for modeling multitenancy is mixing both index-per-tenant and service-per-tenant strategies.

By mixing the two patterns, an application's largest tenants can occupy dedicated services while the long tail of less active, smaller tenants can occupy indexes in a shared service. This

model ensures that the largest tenants have consistently high performance from the service while helping to protect the smaller tenants from any noisy neighbors.

However, implementing this strategy relies on foresight in predicting which tenants will require a dedicated service versus an index in a shared service. Application complexity increases with the need to manage both of these multitenancy models.

Achieving even finer granularity

The above design patterns to model multitenant scenarios in Azure AI Search assume a uniform scope where each tenant is a whole instance of an application. However, applications can sometimes handle many smaller scopes.

If service-per-tenant and index-per-tenant models aren't sufficiently small scopes, it's possible to model an index to achieve an even finer degree of granularity.

To have a single index behave differently for different client endpoints, a field can be added to an index, which designates a certain value for each possible client. Each time a client calls Azure AI Search to query or modify an index, the code from the client application specifies the appropriate value for that field using Azure AI Search's [filter](#) capability at query time.

This method can be used to achieve functionality of separate user accounts, separate permission levels, and even completely separate applications.

Note

Using the approach described above to configure a single index to serve multiple tenants affects the relevance of search results. Search relevance scores are computed at an index-level scope, not a tenant-level scope, so all tenants' data is incorporated in the relevance scores' underlying statistics such as term frequency.

Next steps

Azure AI Search is a compelling choice for many applications. When evaluating the various design patterns for multitenant applications, consider the [various pricing tiers](#) and the respective [service limits](#) to best tailor Azure AI Search to fit application workloads and architectures of all sizes.

Manage your Azure AI Search service using PowerShell

08/01/2025

You can run PowerShell cmdlets and scripts on Windows, Linux, or in Azure Cloud Shell to create and configure Azure AI Search.

Use the [Az.Search module](#) to perform the following tasks:

- ✓ List search services in a subscription
- ✓ Return service information
- ✓ Create or delete a service
- ✓ Create a service with a private endpoint
- ✓ Regenerate admin API-keys
- ✓ Create or delete query api-keys
- ✓ Scale up or down with replicas and partitions
- ✓ Create a shared private link resource

Occasionally, questions are asked about tasks *not* on the above list.

You can't change the name or region of a service programmatically or in the Azure portal. Dedicated resources are allocated when a service is created, so changing the underlying hardware (location or node type) requires a new service.

ⓘ Note

The [Search Management REST APIs](#) and [Azure portal](#) support changing your pricing tier. Currently, you can only switch between Basic and Standard (S1, S2, and S3) tiers.

You can't use tools or APIs to transfer content, such as an index, from one service to another. Within a service, programmatic creation of content is through [Search Service REST API](#) or an SDK such as [Azure SDK for .NET](#). While there are no dedicated commands for content migration, you can write script that calls REST API or a client library to create and load indexes on a new service.

Preview administration features are typically not available in the [Az.Search module](#). If you want to use a preview feature, [use the Management REST API](#) and a preview API version.

The [Az.Search module](#) extends [Azure PowerShell](#) with full parity to the stable versions of the [Search Management REST APIs](#).

Check versions and load modules

The examples in this article are interactive and require elevated permissions. Local PowerShell and the Azure PowerShell (the Az module) are required.

PowerShell version check

Install the latest version of PowerShell if you don't have it.

```
Azure PowerShell
```

```
$PSVersionTable.PSVersion
```

Load Azure PowerShell

If you aren't sure whether Az is installed, run the following command as a verification step.

```
Azure PowerShell
```

```
Get-InstalledModule -Name Az
```

Some systems don't autoload modules. If you got an error on the previous command, try loading the module, and if that fails, go back to the installation [Azure PowerShell installation instructions](#) to see if you missed a step.

```
Azure PowerShell
```

```
Import-Module -Name Az
```

Connect to Azure with a browser sign-in token

You can use your portal sign-in credentials to connect to a subscription in PowerShell.

Alternatively you can [authenticate non-interactively with a service principal](#).

```
Azure PowerShell
```

```
Connect-AzAccount
```

If you hold multiple Azure subscriptions, set your Azure subscription. To see a list of your current subscriptions, run this command.

```
Azure PowerShell
```

```
Get-AzSubscription | sort SubscriptionName | Select SubscriptionName
```

To specify the subscription, run the following command. In the following example, the subscription name is `ContosoSubscription`.

```
Azure PowerShell
```

```
Select-AzSubscription -SubscriptionName ContosoSubscription
```

List services in a subscription

The following commands are from [Az.Resources](#), returning information about existing resources and services already provisioned in your subscription. If you don't know how many search services are already created, these commands return that information, saving you a trip to the Azure portal.

The first command returns all search services.

```
Azure PowerShell
```

```
Get-AzResource -ResourceType Microsoft.Search/searchServices | ft
```

From the list of services, return information about a specific resource.

```
Azure PowerShell
```

```
Get-AzResource -ResourceName <service-name>
```

Results should look similar to the following output.

```
Name : my-demo-searchapp
ResourceGroupName : demo-westus
ResourceType : Microsoft.Search/searchServices
Location : westus
ResourceId : /subscriptions/<alphanumeric-subscription-ID>/resourceGroups/demo-westus/providers/Microsoft.Search/searchServices/my-demo-searchapp
```

Import Az.Search

Commands from [Az.Search](#) aren't available until you load the module.

```
Azure PowerShell
```

```
Install-Module -Name Az.Search -Scope CurrentUser
```

List all Az.Search commands

As a verification step, return a list of commands provided in the module.

```
Azure PowerShell
```

```
Get-Command -Module Az.Search
```

Results should look similar to the following output.

CommandType	Name	Version
Source		
-----	----	-----
---		---
Cmdlet	Get-AzSearchAdminKeyPair	0.10.0
Az.Search	Get-AzSearchPrivateEndpointConnection	0.10.0
Cmdlet	Get-AzSearchPrivateLinkResource	0.10.0
Az.Search	Get-AzSearchQueryKey	0.10.0
Cmdlet	Get-AzSearchService	0.10.0
Az.Search	Get-AzSearchSharedPrivateLinkResource	0.10.0
Cmdlet	New-AzSearchAdminKey	0.10.0
Az.Search	New-AzSearchQueryKey	0.10.0
Cmdlet	New-AzSearchService	0.10.0
Az.Search	New-AzSearchSharedPrivateLinkResource	0.10.0
Cmdlet	Remove-AzSearchPrivateEndpointConnection	0.10.0
Az.Search	Remove-AzSearchQueryKey	0.10.0
Cmdlet	Remove-AzSearchService	0.10.0

Az.Search		
Cmdlet	Remove-AzSearchSharedPrivateLinkResource	0.10.0
Az.Search		
Cmdlet	Set-AzSearchPrivateEndpointConnection	0.10.0
Az.Search		
Cmdlet	Set-AzSearchService	0.10.0
Az.Search		
Cmdlet	Set-AzSearchSharedPrivateLinkResource	0.10.0
Az.Search		

If you have an older version of the package, update the module to get the latest functionality.

Azure PowerShell

```
Update-Module -Name Az.Search
```

Get search service information

After **Az.Search** is imported and you know the resource group containing your search service, run [Get-AzSearchService](#) to return the service definition, including name, region, tier, and replica and partition counts. For this command, provide the resource group that contains the search service.

Azure PowerShell

```
Get-AzSearchService -ResourceGroupName <resource-group-name>
```

Results should look similar to the following output.

```
Name          : my-demo-searchapp
ResourceGroupName : demo-westus
ResourceType    : Microsoft.Search/searchServices
Location       : West US
Sku           : Standard
ReplicaCount   : 1
PartitionCount : 1
HostingMode    : Default
ResourceId     : /subscriptions/<alphanumeric-subscription-ID>/resourceGroups/demo-westus/providers/Microsoft.Search/searchServices/my-demo-searchapp
```

Create or delete a service

New-AzSearchService is used to [create a new search service](#).

Azure PowerShell

```
New-AzSearchService -ResourceGroupName <resource-group-name> -Name <search-service-name> -Sku "Standard" -Location "West US" -PartitionCount 3 -ReplicaCount 3 -HostingMode Default
```

Results should look similar to the following output.

Azure PowerShell

```
ResourceGroupName : demo-westus
Name             : my-demo-searchapp
Id               : /subscriptions/<alphanumeric-subscription-ID>/demo-westus/providers/Microsoft.Search/searchServices/my-demo-searchapp
Location         : West US
Sku              : Standard
ReplicaCount     : 3
PartitionCount   : 3
HostingMode      : Default
Tags
```

Remove-AzSearchService is used to delete a service and its data.

Azure PowerShell

```
Remove-AzSearchService -ResourceGroupName <resource-group-name> -Name <search-service-name>
```

You're asked to confirm the action.

Azure PowerShell

```
Confirm
Are you sure you want to remove Search Service 'pstestazuresearch01'?
[Y] Yes  [N] No  [S] Suspend  [?] Help (default is "Y"): y
```

Create a service with IP rules

Depending on your security requirements, you might want to create a search service with an [IP firewall configured](#). To do so, first define the IP Rules and then pass them to the `IPRuleList` parameter as shown below.

Azure PowerShell

```
$ipRules = @([pscustomobject]@{Value="55.5.63.73"},  
            [pscustomobject]@{Value="52.228.215.197"},  
            [pscustomobject]@{Value="101.37.221.205"})  
  
New-AzSearchService -ResourceGroupName <resource-group-name> `  
                    -Name <search-service-name> `  
                    -Sku Standard `  
                    -Location "West US" `  
                    -PartitionCount 3 -ReplicaCount 3 `  
                    -HostingMode Default `  
                    -IPRuleList $ipRules
```

Create a service with a system assigned managed identity

In some cases, such as when [using managed identity to connect to a data source](#), you need to turn on [system assigned managed identity](#). This is done by adding `-IdentityType SystemAssigned` to the command.

Azure PowerShell

```
New-AzSearchService -ResourceGroupName <resource-group-name> `  
                    -Name <search-service-name> `  
                    -Sku Standard `  
                    -Location "West US" `  
                    -PartitionCount 3 -ReplicaCount 3 `  
                    -HostingMode Default `  
                    -IdentityType SystemAssigned
```

Create an S3HD service

To create an [S3HD](#) service, a combination of `-Sku` and `-HostingMode` is used. Set `-Sku` to `Standard3` and `-HostingMode` to `HighDensity`.

Azure PowerShell

```
New-AzSearchService -ResourceGroupName <resource-group-name> `  
                    -Name <search-service-name> `  
                    -Sku Standard3 `  
                    -Location "West US" `  
                    -PartitionCount 1 -ReplicaCount 3 `  
                    -HostingMode HighDensity
```

Create a service with a private endpoint

[Private Endpoints](#) for Azure AI Search allow a client on a virtual network to securely access data in a search index over a [Private Link](#). The private endpoint uses an IP address from the [virtual network address space](#) for your search service. Network traffic between the client and the search service traverses over the virtual network and a private link on the Microsoft backbone network, eliminating exposure from the public internet. For more information, see [Creating a private endpoint for Azure AI Search](#).

The following example shows how to create a search service with a private endpoint.

First, deploy a search service with `PublicNetworkAccess` set to `Disabled`.

Azure PowerShell

```
$searchService = New-AzSearchService`  
    -ResourceGroupName <search-service-resource-group-name>`  
    -Name <search-service-name>`  
    -Sku Standard`  
    -Location "West US" `  
    -PartitionCount 1 -ReplicaCount 1`  
    -HostingMode Default`  
    -PublicNetworkAccess Disabled
```

Next, create a virtual network, private network connection, and the private endpoint.

Azure PowerShell

```
# Create the subnet  
$subnetConfig = New-AzVirtualNetworkSubnetConfig`  
    -Name <subnet-name>`  
    -AddressPrefix 10.1.0.0/24`  
    -PrivateEndpointNetworkPolicies Disabled`  
  
# Create the virtual network  
$virtualNetwork = New-AzVirtualNetwork`  
    -ResourceGroupName <vm-resource-group-name>`  
    -Location "West US" `  
    -Name <virtual-network-name>`  
    -AddressPrefix 10.1.0.0/16`  
    -Subnet $subnetConfig`  
  
# Create the private network connection  
$privateLinkConnection = New-AzPrivateLinkServiceConnection`  
    -Name <private-link-name>`  
    -PrivateLinkServiceId $searchService.Id`  
    -GroupId searchService`  
  
# Create the private endpoint  
$privateEndpoint = New-AzPrivateEndpoint`  
    -Name <private-endpoint-name>`  
    -ResourceGroupName <private-endpoint-resource-group-name>`
```

```
-Location "West US"
-Subnet $virtualNetwork.subnets[0]
-PrivateLinkServiceConnection $privateLinkConnection
```

Finally, create a private DNS Zone.

Azure PowerShell

```
## Create private dns zone
$zone = New-AzPrivateDnsZone
    -ResourceGroupName <private-dns-resource-group-name>
    -Name "privatelink.search.windows.net"

## Create dns network link
$link = New-AzPrivateDnsVirtualNetworkLink
    -ResourceGroupName <private-dns-link-resource-group-name>
    -ZoneName "privatelink.search.windows.net"
    -Name "myLink"
    -VirtualNetworkId $virtualNetwork.Id

## Create DNS configuration
$config = New-AzPrivateDnsZoneConfig
    -Name "privatelink.search.windows.net"
    -PrivateDnsZoneId $zone.ResourceId

## Create DNS zone group
New-AzPrivateDnsZoneGroup
    -ResourceGroupName <private-dns-zone-resource-group-name>
    -PrivateEndpointName <private-endpoint-name>
    -Name 'myZoneGroup'
    -PrivateDnsZoneConfig $config
```

For more information on creating private endpoints in PowerShell, see this [Private Link Quickstart](#).

Manage private endpoint connections

In addition to creating a private endpoint connection, you can also [Get](#), [Set](#), and [Remove](#) the connection.

[Get-AzSearchPrivateEndpointConnection](#) is used to retrieve a private endpoint connection and to see its status.

Azure PowerShell

```
Get-AzSearchPrivateEndpointConnection -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name>
```

[Set-AzSearchPrivateEndpointConnection](#) is used to update the connection. The following example sets a private endpoint connection to rejected:

```
Azure PowerShell
```

```
Set-AzSearchPrivateEndpointConnection -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name> -Name <pe-connection-name> -Status Rejected -Description "Rejected"
```

[Remove-AzSearchPrivateEndpointConnection](#) is used to delete the private endpoint connection.

```
Azure PowerShell
```

```
Remove-AzSearchPrivateEndpointConnection -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name> -Name <pe-connection-name>
```

Regenerate admin keys

[New-AzSearchAdminKey](#) is used to roll over admin [API keys](#). Two admin keys are created with each service for authenticated access. Keys are required on every request. Both admin keys are functionally equivalent, granting full write access to a search service with the ability to retrieve any information, or create and delete any object. Two keys exist so that you can use one while replacing the other.

You can only regenerate one at a time, specified as either the `primary` or `secondary` key. For uninterrupted service, remember to update all client code to use a secondary key while rolling over the primary key. Avoid changing the keys while operations are in flight.

As you might expect, if you regenerate keys without updating client code, requests using the old key will fail. Regenerating all new keys doesn't permanently lock you out of your service, and you can still access the service through the Azure portal. After you regenerate primary and secondary keys, you can update client code to use the new keys and operations will resume accordingly.

Values for the API keys are generated by the service. You can't provide a custom key for Azure AI Search to use. Similarly, there's no user-defined name for admin API-keys. References to the key are fixed strings, either `primary` or `secondary`.

```
Azure PowerShell
```

```
New-AzSearchAdminKey -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name> -KeyKind Primary
```

Results should look similar to the following output. Both keys are returned even though you only change one at a time.

Primary	Secondary
-----	-----
<alphanumeric-guid>	<alphanumeric-guid>

Create or delete query keys

[New-AzSearchQueryKey](#) is used to create query [API keys](#) for read-only access from client apps to an Azure AI Search index. Query keys are used to authenticate to a specific index for retrieving search results. Query keys don't grant read-only access to other items on the service, such as an index, data source, or indexer.

You can't provide a key for Azure AI Search to use. API keys are generated by the service.

Azure PowerShell

```
New-AzSearchQueryKey -ResourceGroupName <search-service-resource-group-name> -  
ServiceName <search-service-name> -Name <query-key-name>
```

Scale replicas and partitions

[Set-AzSearchService](#) is used to [increase or decrease replicas and partitions](#) to readjust billable resources within your service. Increasing replicas or partitions adds to your bill, which has both fixed and variable charges. If you have a temporary need for more processing power, you can increase replicas and partitions to handle the workload. The monitoring area in the Overview portal page has tiles on query latency, queries per second, and throttling, indicating whether current capacity is adequate.

It can take a while to add or remove resourcing. Adjustments to capacity occur in the background, allowing existing workloads to continue. Extra capacity is used for incoming requests as soon as it's ready, with no extra configuration required.

Removing capacity can be disruptive. Stopping all indexing and indexer jobs prior to reducing capacity is recommended to avoid dropped requests. If that isn't feasible, you might consider reducing capacity incrementally, one replica and partition at a time, until your new target levels are reached.

Once you submit the command, there's no way to terminate it midway through. You have to wait until the command is finished before revising the counts.

Azure PowerShell

```
Set-AzSearchService -ResourceGroupName <search-service-resource-group-name> -Name <search-service-name> -PartitionCount 6 -ReplicaCount 6
```

Results should look similar to the following output.

```
ResourceGroupName : demo-westus
Name             : my-demo-searchapp
Location         : West US
Sku              : Standard
ReplicaCount     : 6
PartitionCount   : 6
HostingMode      : Default
Id               : /subscriptions/aaaa0a0a-bb1b-cc2c-dd3d-
eeeeee4e4e/resourceGroups/demo-
westus/providers/Microsoft.Search/searchServices/my-demo-searchapp
```

Create a shared private link resource

Private endpoints of secured resources that are created through Azure AI Search APIs are referred to as *shared private link resources*. This is because you're "sharing" access to a resource, such as a storage account that has been integrated with the [Azure Private Link service](#).

If you're using an indexer to index data in Azure AI Search, and your data source is on a private network, you can create an outbound [private endpoint connection](#) to reach the data.

A full list of the Azure Resources for which you can create outbound private endpoints from Azure AI Search can be found [here](#) along with the related **Group ID** values.

[New-AzSearchSharedPrivateLinkResource](#) is used to create the shared private link resource. Keep in mind that some configuration might be required for the data source before running this command.

Azure PowerShell

```
New-AzSearchSharedPrivateLinkResource -ResourceGroupName <search-service-resource-
group-name> -ServiceName <search-service-name> -Name <spl-name> -
PrivateLinkResourceId /subscriptions/<alphanumeric-subscription-
ID>/resourceGroups/<storage-resource-group-
```

```
name>/providers/Microsoft.Storage/storageAccounts/myBlobStorage -GroupId <group-id> -RequestMessage "Please approve"
```

[Get-AzSearchSharedPrivateLinkResource](#) allows you to retrieve the shared private link resources and view their status.

Azure PowerShell

```
Get-AzSearchSharedPrivateLinkResource -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name> -Name <spl-name>
```

You need to approve the connection with the following command before it can be used.

Azure PowerShell

```
Approve-AzPrivateEndpointConnection  
-Name <spl-name>  
-ServiceName <search-service-name>  
-ResourceGroupName <search-service-resource-group-name>  
-Description = "Approved"
```

[Remove-AzSearchSharedPrivateLinkResource](#) is used to delete the shared private link resource.

Azure PowerShell

```
$job = Remove-AzSearchSharedPrivateLinkResource -ResourceGroupName <search-service-resource-group-name> -ServiceName <search-service-name> -Name <spl-name> -Force -AsJob  
  
$job | Get-Job
```

For full details on setting up shared private link resources, see the documentation on [making indexer connections through a private endpoint](#).

Next steps

Build an [index](#), [query an index](#) using the Azure portal, REST APIs, or the .NET SDK.

- [Create an Azure AI Search index in the Azure portal](#)
- [Set up an indexer to load data from other services](#)
- [Query an Azure AI Search index using Search explorer in the Azure portal](#)
- [How to use Azure AI Search in .NET](#)

Manage your Azure AI Search service using the Azure CLI

09/30/2025

You can run Azure CLI commands and scripts on Windows, macOS, Linux, or in Azure Cloud Shell to create and configure Azure AI Search.

Use the [az search module](#) to perform the following tasks:

- ✓ List search services in a subscription
- ✓ Return service information
- ✓ Create or delete a service
- ✓ Create a service with a private endpoint
- ✓ Create a service with confidential computing
- ✓ Regenerate admin API-keys
- ✓ Create or delete query api-keys
- ✓ Scale up or down with replicas and partitions
- ✓ Create a shared private link resource

Occasionally, questions are asked about tasks *not* on the above list.

You can't change the name or region of a service programmatically or in the Azure portal. Dedicated resources are allocated when a service is created, so changing the underlying hardware (location or node type) requires a new service.

⚠ Note

The [Search Management REST APIs](#) and [Azure portal](#) support changing your pricing tier. Currently, you can only switch between Basic and Standard (S1, S2, and S3) tiers.

You can't use tools or APIs to transfer content, such as an index, from one service to another. Within a service, programmatic creation of content is through [Search Service REST API](#) or an SDK such as [Azure SDK for .NET](#). While there are no dedicated commands for content migration, you can write script that calls REST API or a client library to create and load indexes on a new service.

Preview administration features are typically not available in the [az search module](#). If you want to use a preview feature, [use the Management REST API](#) and a preview API version.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Get started with Azure Cloud Shell](#).

 [Launch Cloud Shell](#) 

- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Authenticate to Azure using Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use and manage extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run `az upgrade`.

Azure CLI versions are [listed on GitHub](#).

The `az search` module extends the [Azure CLI](#) with full parity to the stable versions of the [Search Management REST APIs](#).

List services in a subscription

The following commands are from [az resource](#), returning information about existing resources and services already provisioned in your subscription. If you don't know how many search services are already created, these commands return that information, saving you a trip to the Azure portal.

The first command returns all search services.

Azure CLI

```
az resource list --resource-type Microsoft.Search/searchServices --output table
```

From the list of services, return information about a specific resource.

Azure CLI

```
az resource list --name <search-service-name>
```

List all az search commands

You can view information on the subgroups and commands available in `az search` from within the CLI. Alternatively, you can review the [documentation](#).

To view the subgroups available within `az search`, run the following command.

```
Azure CLI
```

```
az search --help
```

The response should look similar to the following output.

```
Bash
```

Group

```
az search : Manage Azure Search services, admin keys and query keys.
```

```
WARNING: This command group is in preview and under development. Reference and support
```

```
levels: https://aka.ms/CLI\_refstatus
```

Subgroups:

```
admin-key : Manage Azure Search admin keys.
```

```
private-endpoint-connection : Manage Azure Search private endpoint connections.
```

```
private-link-resource : Manage Azure Search private link resources.
```

```
query-key : Manage Azure Search query keys.
```

```
service : Manage Azure Search services.
```

```
shared-private-link-resource : Manage Azure Search shared private link resources.
```

```
For more specific examples, use: az find "az search"
```

Within each subgroup, multiple commands are available. You can see the available commands for the `service` subgroup by running the following line.

```
Azure CLI
```

```
az search service --help
```

You can also see the arguments available for a particular command.

```
Azure CLI
```

```
az search service create --help
```

Get search service information

If you know the resource group containing your search service, run [az search service show](#) to return the service definition, including name, region, tier, and replica and partition counts. For this command, provide the resource group that contains the search service.

Azure CLI

```
az search service show --name <service-name> --resource-group <search-service-resource-group-name>
```

Create or delete a service

To [create a new search service](#), use the [az search service create](#) command.

Azure CLI

```
az search service create \
  --name <service-name> \
  --resource-group <search-service-resource-group-name> \
  --sku Standard \
  --partition-count 1 \
  --replica-count 1
```

Results should look similar to the following output:

```
{
  "hostingMode": "default",
  "id": "/subscriptions/<alphanumeric-subscription-ID>/resourceGroups/demo-westus/providers/Microsoft.Search/searchServices/my-demo-searchapp",
  "identity": null,
  "location": "West US",
  "name": "my-demo-searchapp",
  "networkRuleSet": {
    "bypass": "None",
    "ipRules": []
  },
  "partitionCount": 1,
  "privateEndpointConnections": [],
  "provisioningState": "succeeded",
  "publicNetworkAccess": "Enabled",
  "replicaCount": 1,
  "resourceGroup": "demo-westus",
  "sharedPrivateLinkResources": [],
  "sku": {
    "name": "standard"
  }
}
```

```
},
  "status": "running",
  "statusDetails": "",
  "tags": null,
  "type": "Microsoft.Search/searchServices"
}
```

az search service delete removes the service and its data.

Azure CLI

```
az search service delete --name <service-name> \
                        --resource-group <search-service-resource-group-name> \
```

Create a service with IP rules

Depending on your security requirements, you might want to create a search service with an [IP firewall configured](#). To do so, pass the Public IP (v4) addresses or CIDR ranges to the `ip-rules` argument as shown below. Rules should be separated by a comma (,) or semicolon (;).

Azure CLI

```
az search service create \
    --name <search-service-name> \
    --resource-group <search-service-resource-group-name> \
    --sku Standard \
    --partition-count 1 \
    --replica-count 1 \
    --ip-rules "55.5.63.73;52.228.215.197;101.37.221.205"
```

Create a service with a system assigned managed identity

In some cases, such as when [using managed identity to connect to a data source](#), you need to turn on [system assigned managed identity](#). This is done by adding `--identity-type SystemAssigned` to the command.

Azure CLI

```
az search service create \
    --name <search-service-name> \
    --resource-group <search-service-resource-group-name> \
    --sku Standard \
    --partition-count 1 \
    --replica-count 1 \
    --identity-type SystemAssigned
```

Create a service with a private endpoint

Private Endpoints for Azure AI Search allow a client on a virtual network to securely access data in a search index over a [Private Link](#). The private endpoint uses an IP address from the [virtual network address space](#) for your search service. Network traffic between the client and the search service traverses over the virtual network and a private link on the Microsoft backbone network, eliminating exposure from the public internet. For more information, please refer to the documentation on [creating a private endpoint for Azure AI Search](#).

The following example shows how to create a search service with a private endpoint.

First, deploy a search service with `PublicNetworkAccess` set to `Disabled`.

Azure CLI

```
az search service create \
  --name <search-service-name> \
  --resource-group <search-service-resource-group-name> \
  --sku Standard \
  --partition-count 1 \
  --replica-count 1 \
  --public-access Disabled
```

Next, create a virtual network and the private endpoint.

Azure CLI

```
# Create the virtual network
az network vnet create \
  --resource-group <vnet-resource-group-name> \
  --location "West US" \
  --name <virtual-network-name> \
  --address-prefixes 10.1.0.0/16 \
  --subnet-name <subnet-name> \
  --subnet-prefixes 10.1.0.0/24

# Update the subnet to disable private endpoint network policies
az network vnet subnet update \
  --name <subnet-name> \
  --resource-group <vnet-resource-group-name> \
  --vnet-name <virtual-network-name> \
  --disable-private-endpoint-network-policies true

# Get the id of the search service
id=$(az search service show \
  --resource-group <search-service-resource-group-name> \
  --name <search-service-name> \
  --query [id] \
  --output tsv)
```

```
# Create the private endpoint
az network private-endpoint create \
    --name <private-endpoint-name> \
    --resource-group <private-endpoint-resource-group-name> \
    --vnet-name <virtual-network-name> \
    --subnet <subnet-name> \
    --private-connection-resource-id $id \
    --group-id searchService \
    --connection-name <private-link-connection-name>
```

Finally, create a private DNS Zone.

Azure CLI

```
## Create private DNS zone
az network private-dns zone create \
    --resource-group <private-dns-resource-group-name> \
    --name "privatelink.search.windows.net"

## Create DNS network link
az network private-dns link vnet create \
    --resource-group <private-dns-resource-group-name> \
    --zone-name "privatelink.search.windows.net" \
    --name "myLink" \
    --virtual-network <virtual-network-name> \
    --registration-enabled false

## Create DNS zone group
az network private-endpoint dns-zone-group create \
    --resource-group <private-endpoint-resource-group-name> \
    --endpoint-name <private-endpoint-name> \
    --name "myZoneGroup" \
    --private-dns-zone "privatelink.search.windows.net" \
    --zone-name "searchServiceZone"
```

For more information on creating private endpoints in Azure CLI, see this [Private Link Quickstart](#).

Manage private endpoint connections

In addition to creating a private endpoint connection, you can also `show`, `update`, and `delete` the connection.

To retrieve a private endpoint connection and to see its status, use `az search private-endpoint-connection show`.

Azure CLI

```
az search private-endpoint-connection show \
--name <pe-connection-name> \
--service-name <search-service-name> \
--resource-group <search-service-resource-group-name>
```

To update the connection, use **az search private-endpoint-connection update**. The following example sets a private endpoint connection to rejected:

Azure CLI

```
az search private-endpoint-connection update \
--name <pe-connection-name> \
--service-name <search-service-name> \
--resource-group <search-service-resource-group-name>
--status Rejected \
--description "Rejected" \
--actions-required "Please fix XYZ"
```

To delete the private endpoint connection, use **az search private-endpoint-connection delete**.

Azure CLI

```
az search private-endpoint-connection delete \
--name <pe-connection-name> \
--service-name <search-service-name> \
--resource-group <search-service-resource-group-name>
```

Create a service with confidential computing

[Confidential computing](#) is an optional compute type for data-in-use protection. When configured, your search service is deployed on confidential VMs (DCasv5 or DCesv5) instead of standard VMs. This compute type also incurs a 10% surcharge for billable tiers. For more information, see the [pricing page](#).

For daily usage, confidential computing isn't necessary. We only recommend this compute type for stringent regulatory, compliance, or security requirements. For more information, see [Confidential computing use cases](#).

The compute type is fixed for the lifetime of your search service. To permanently configure confidential computing, set the `compute-type` property to `confidential` on a new service.

Azure CLI

```
az search service create \
--name <search-service-name> \
```

```
--resource-group <search-service-resource-group-name> \
--location <search-service-region> \
--sku basic \
--compute-type confidential
```

Regenerate admin keys

To roll over admin [API keys](#), use `az search admin-key renew`. Two admin keys are created with each service for authenticated access. Keys are required on every request. Both admin keys are functionally equivalent, granting full write access to a search service with the ability to retrieve any information, or create and delete any object. Two keys exist so that you can use one while replacing the other.

You can only regenerate one at a time, specified as either the `primary` or `secondary` key. For uninterrupted service, remember to update all client code to use a secondary key while rolling over the primary key. Avoid changing the keys while operations are in flight.

As you might expect, if you regenerate keys without updating client code, requests using the old key will fail. Regenerating all new keys doesn't permanently lock you out of your service, and you can still access the service through the Azure portal. After you regenerate primary and secondary keys, you can update client code to use the new keys and operations will resume accordingly.

Values for the API keys are generated by the service. You can't provide a custom key for Azure AI Search to use. Similarly, there's no user-defined name for admin API-keys. References to the key are fixed strings, either `primary` or `secondary`.

Azure CLI

```
az search admin-key renew \
--resource-group <search-service-resource-group-name> \
--service-name <search-service-name> \
--key-kind primary
```

Results should look similar to the following output. Both keys are returned even though you only change one at a time.

```
{
  "primaryKey": <alphanumeric-guid>,
  "secondaryKey": <alphanumeric-guid>
}
```

Create or delete query keys

To create query [API keys](#) for read-only access from client apps to an Azure AI Search index, use [az search query-key create](#). Query keys are used to authenticate to a specific index for retrieving search results. Query keys don't grant read-only access to other items on the service, such as an index, data source, or indexer.

You can't provide a key for Azure AI Search to use. API keys are generated by the service.

Azure CLI

```
az search query-key create \
  --name myQueryKey \
  --resource-group <search-service-resource-group-name> \
  --service-name <search-service-name>
```

Scale replicas and partitions

To [increase or decrease replicas and partitions](#) use [az search service update](#). Increasing replicas or partitions adds to your bill, which has both fixed and variable charges. If you have a temporary need for more processing power, you can increase replicas and partitions to handle the workload. The monitoring area in the Overview portal page has tiles on query latency, queries per second, and throttling, indicating whether current capacity is adequate.

It can take a while to add or remove resourcing. Adjustments to capacity occur in the background, allowing existing workloads to continue. Extra capacity is used for incoming requests as soon as it's ready, with no extra configuration required.

Removing capacity can be disruptive. Stopping all indexing and indexer jobs prior to reducing capacity is recommended to avoid dropped requests. If that isn't feasible, you might consider reducing capacity incrementally, one replica and partition at a time, until your new target levels are reached.

Once you submit the command, there's no way to terminate it midway through. You have to wait until the command is finished before revising the counts.

Azure CLI

```
az search service update \
  --name <search-service-name> \
  --resource-group <search-service-resource-group-name> \
  --partition-count 6 \
  --replica-count 6
```

In addition to updating replica and partition counts, you can also update `ip-rules`, `public-access`, and `identity-type`.

Create a shared private link resource

Private endpoints of secured resources that are created through Azure AI Search APIs are referred to as *shared private link resources*. This is because you're "sharing" access to a resource, such as a storage account that has been integrated with the [Azure Private Link service](#).

If you're using an indexer to index data in Azure AI Search, and your data source is on a private network, you can create an outbound [private endpoint connection](#) to reach the data.

A full list of the Azure Resources for which you can create outbound private endpoints from Azure AI Search can be found [here](#) along with the related **Group ID** values.

To create the shared private link resource, use [`az search shared-private-link-resource create`](#). Keep in mind that some configuration might be required for the data source before running this command.

```
Azure CLI  
  
az search shared-private-link-resource create \  
  --name <spl-name> \  
  --service-name <search-service-name> \  
  --resource-group <search-service-resource-group-name> \  
  --group-id blob \  
  --resource-id "/subscriptions/<alphanumeric-subscription-  
ID>/resourceGroups/<resource-group-  
name>/providers/Microsoft.Storage/storageAccounts/myBlobStorage" \  
  --request-message "Please approve"
```

To retrieve the shared private link resources and view their status, use [`az search shared-private-link-resource list`](#).

```
Azure CLI  
  
az search shared-private-link-resource list \  
  --service-name <search-service-name> \  
  --resource-group <search-service-resource-group-name>
```

You need to approve the connection with the following command before it can be used. The ID of the private endpoint connection must be retrieved from the child resource. In this case, we get the connection ID from `az storage`.

Azure CLI

```
id = (az storage account show -n myBlobStorage --query  
"privateEndpointConnections[0].id")  
  
az network private-endpoint-connection approve --id $id
```

To delete the shared private link resource, use [az search shared-private-link-resource delete](#).

Azure CLI

```
az search shared-private-link-resource delete \  
--name <spl-name> \  
--service-name <search-service-name> \  
--resource-group <search-service-resource-group-name>
```

For more information on setting up shared private link resources, see [making indexer connections through a private endpoint](#).

Next steps

Build an [index](#), [query an index](#) using the Azure portal, REST APIs, or the .NET SDK.

- [Create an Azure AI Search index in the Azure portal](#)
- [Set up an indexer to load data from other services](#)
- [Query an Azure AI Search index using Search explorer in the Azure portal](#)
- [How to use Azure AI Search in .NET](#)

Manage your Azure AI Search service using REST APIs

Learn how to create and configure an Azure AI Search service using the [Management REST APIs](#). Only the Management REST APIs are guaranteed to provide early access to [preview features](#).

The Management REST API is available in stable and preview versions. Be sure to set a preview API version if you're accessing preview features.

- ✓ [Create or update a service](#)
- ✓ [Upgrade a service](#)
- ✓ [Change pricing tiers](#)
- ✓ [Configure role-based access control for data plane](#)
- ✓ [Configure confidential computing](#)
- ✓ [Enable Azure role-based access control for data plane](#)
- ✓ [Enforce a customer-managed key policy](#)
- ✓ [Disable semantic ranker](#)
- ✓ [Disable workloads that push data to external resources](#)
- ✓ [Create a query key](#)
- ✓ [Regenerate an admin key](#)
- ✓ [List private endpoint connections](#)
- ✓ [List search operations](#)
- ✓ [Delete a search service](#)

All of the Management REST APIs have examples. If a task isn't covered in this article, see the [API reference](#) instead.

💡 Tip

If you use CURL to call the Management REST API, make sure you set a content type header to application/json: `-H "Content-Type: application/json"`. Alternatively, you can use the `--JSON` flag if you want to embed the JSON.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Visual Studio Code](#) with a [REST client](#).

- Azure CLI to get an access token, as described in the following steps. You must be an owner or administrator in your Azure subscription.

Management REST API calls are authenticated through Microsoft Entra ID. You must provide an access token on the request and permissions to create and configure a resource. In addition to the Azure CLI, you can use [Azure PowerShell to create an access token](#).

1. Open a command shell for Azure CLI.
2. Sign in to your Azure subscription. If you have multiple tenants or subscriptions, make sure you select the correct one.

```
Azure CLI
```

```
az login
```

3. Get the tenant ID and subscription ID.

```
Azure CLI
```

```
az account show
```

4. Get an access token.

```
Azure CLI
```

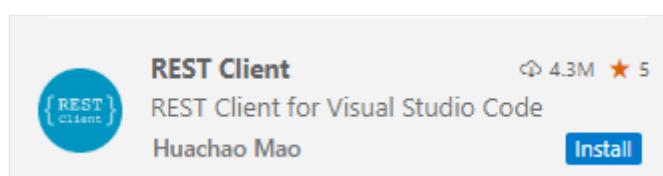

```
az account get-access-token --query accessToken --output tsv
```

You should have a tenant ID, subscription ID, and bearer token. You'll paste these values into the `.rest` or `.http` file that you create in the next step.

Set up Visual Studio Code

If you're not familiar with the REST client for Visual Studio Code, this section includes setup so that you can complete the tasks in this article.

1. Start Visual Studio Code and select the **Extensions** tile.
2. Search for the REST client and select **Install**.

3. Open or create new file named with either a `.rest` or `.http` file extension.

4. Provide variables for the values you retrieved in the previous step.

HTTP

```
@tenant-id = PUT-YOUR-TENANT-ID-HERE  
@subscription-id = PUT-YOUR-SUBSCRIPTION-ID-HERE  
@token = PUT-YOUR-TOKEN-HERE
```

5. Verify the session is operational by listing search services in your subscription.

HTTP

```
### List search services  
GET https://management.azure.com/subscriptions/{{subscription-  
id}}/providers/Microsoft.Search/searchServices?api-version=2025-05-01 HTTP/1.1  
Content-type: application/json  
Authorization: Bearer {{token}}
```

6. Select **Send request**. A response should appear in an adjacent pane. If you have existing search services, they're listed. Otherwise, the list is empty, but as long as the HTTP code is 200 OK, you're ready for the next steps.

HTTP

```
HTTP/1.1 200 OK  
Cache-Control: no-cache  
Pragma: no-cache  
Content-Length: 22068  
Content-Type: application/json; charset=utf-8  
Expires: -1

{  
    "value": [ . . . ]  
}
```

Create or update a service

Creates or updates a search service under the current subscription. This example uses variables for the search service name and region, which haven't been defined yet. Either provide the names directly or add new variables to the collection.

HTTP

```
### Create a search service (provide an existing resource group)
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PUT https://management.azure.com/subscriptions/{{subscription-
id}}/resourceGroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}

{
    "location": "North Central US",
    "sku": {
        "name": "basic"
    },
    "properties": {
        "replicaCount": 1,
        "partitionCount": 1,
        "hostingMode": "default"
    }
}
```

Upgrade a service

Some Azure AI Search capabilities are only available to new services. To avoid service recreation and bring these capabilities to an existing service, you might be able to [upgrade your service](#).

HTTP

```
### Upgrade a search service
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

POST https://management.azure.com/subscriptions/{{subscription-
id}}/resourceGroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}/upgrade?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}
```

Change pricing tiers

If you need more or less capacity, you can [switch to a different pricing tier](#). Currently, you can only switch between Basic and Standard (S1, S2, and S3) tiers. Use the `sku` property to specify the new tier.

HTTP

```
### Change pricing tiers
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PATCH https://management.azure.com/subscriptions/{{subscription-
id}}/resourceGroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {token}

{
    "sku": {
        "name": "standard2"
    }
}
```

Create an S3HD service

To create an [S3HD](#) service, use a combination of `sku` and `hostingMode` properties. Set `sku` to `standard3` and "hostingMode" to `HighDensity`.

HTTP

```
### Create an S3HD service
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PUT https://management.azure.com/subscriptions/{{subscription-
id}}/resourceGroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {token}

{
    "location": "{{region}}",
    "sku": {
        "name": "standard3"
    },
    "properties": {
```

```
        "replicaCount": 1,  
        "partitionCount": 1,  
        "hostingMode": "HighDensity"  
    }  
}
```

Configure role-based access for data plane

Applies to: Search Index Data Contributor, Search Index Data Reader, Search Service Contributor

Configure your search service to recognize an **authorization** header on data requests that provide an OAuth2 access token.

To use role-based access control for data plane operations, set `authOptions` to `aadOrApiKey` and then send the request.

To use role-based access control exclusively, [turn off API key authentication](#) by following up with a second request, this time setting `disableLocalAuth` to true.

HTTP

```
### Configure role-based access  
@resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE  
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE  
  
PATCH https://management.azure.com/subscriptions/{{subscription-  
id}}/resourcegroups/{{resource-  
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-  
version=2025-05-01 HTTP/1.1  
Content-type: application/json  
Authorization: Bearer {{token}}  
  
{  
    "properties": {  
        "disableLocalAuth": false,  
        "authOptions": {  
            "aadOrApiKey": {  
                "aadAuthFailureMode": "http401WithBearerChallenge"  
            }  
        }  
    }  
}
```

Configure confidential computing

Confidential computing is an optional compute type for data-in-use protection. When configured, your search service is deployed on confidential VMs (DCasv5 or DCesv5) instead of standard VMs. This compute type also incurs a 10% surcharge for billable tiers. For more information, see the [pricing page](#).

For daily usage, confidential computing isn't necessary. We only recommend this compute type for stringent regulatory, compliance, or security requirements. For more information, see [Confidential computing use cases](#).

The compute type is fixed for the lifetime of your search service. To permanently configure confidential computing, set the `computeType` property to `confidential` on a new service.

HTTP

```
### Configure confidential computing
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE
PUT https://management.azure.com/subscriptions/{{subscription-id}}/resourcegroups/{{resource-group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-version=2025-05-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}
{
    "location": "{{region}}",
    "sku": {
        "name": "basic"
    },
    "properties": {
        "computeType": "confidential"
    }
}
```

Enforce a customer-managed key policy

If you're using [customer-managed encryption](#), you can enable "encryptionWithCMK" with "enforcement" set to "Enabled" if you want the search service to report its compliance status.

When you enable this policy, any REST calls that create objects containing sensitive data, such as the connection string within a data source, will fail if an encryption key isn't provided: "Error creating Data Source: "CannotCreateNonEncryptedResource: The creation of non-encrypted DataSources is not allowed when encryption policy is enforced."

HTTP

```
### Enforce a customer-managed key policy
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
```

```
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PATCH https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}

{
    "properties": {
        "encryptionWithCmk": {
            "enforcement": "Enabled"
        }
    }
}
```

Disable semantic ranker

Semantic ranker is enabled by default at the free plan that allows up to 1,000 requests per month at no charge. You can lock down the feature at the service level to prevent usage.

HTTP

```
### Disable semantic ranker
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PATCH https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}

{
    "properties": {
        "semanticSearch": "Disabled"
    }
}
```

Disable workloads that push data to external resources

Azure AI Search writes to external data sources when updating a knowledge store, saving debug session state, or caching enrichments. The following example disables these workloads at the service level.

HTTP

```
### Disable external access
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

PATCH https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}

{
    "properties": {
        "publicNetworkAccess": "Disabled"
    }
}
```

Delete a search service

HTTP

```
### Delete a search service
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

DELETE https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}?api-
version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}
```

List admin API keys

HTTP

```
### List admin keys
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

POST https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-service}}/listAdminKeys?
api-version=2025-05-01 HTTP/1.1
    Content-type: application/json
    Authorization: Bearer {{token}}
```

Regenerate admin API keys

You can only regenerate one admin API key at a time.

HTTP

```
### Regnerate admin keys
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

POST https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-
service}}/regenerateAdminKey/primary?api-version=2025-05-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}
```

Create query API keys

HTTP

```
### Create a query key
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE
@query-key = PUT-YOUR-QUERY-KEY-NAME-HERE

POST https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-
service}}/createQueryKey/{query-key}?api-version=2025-05-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}
```

List private endpoint connections

HTTP

```
### List private endpoint connections
@Resource-group = PUT-YOUR-RESOURCE-GROUP-NAME-HERE
@search-service = PUT-YOUR-SEARCH-SERVICE-NAME-HERE

GET https://management.azure.com/subscriptions/{{subscription-
id}}/resourcegroups/{{resource-
group}}/providers/Microsoft.Search/searchServices/{{search-
service}}/privateEndpointConnections?api-version=2025-05-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}
```

List search operations

HTTP

```
### List search operations
GET https://management.azure.com/subscriptions/{{subscription-id}}/resourcegroups?
api-version=2021-04-01 HTTP/1.1
Content-type: application/json
Authorization: Bearer {{token}}
```

Next steps

After a search service is configured, your next steps include [creating an index](#) or [querying an index](#) using the Azure portal, REST APIs, or an Azure SDK.

- [Create an Azure AI Search index in the Azure portal](#)
- [Set up an indexer to load data from other services](#)
- [Query an Azure AI Search index using Search explorer in the Azure portal](#)
- [How to use Azure AI Search in .NET](#)

Last updated on 12/04/2025

Move your Azure AI Search service to another Azure region

Occasionally, customers ask about moving a search service to another region. Currently, there's no built-in mechanism or tooling to help with that task, but this article can help you understand the manual steps for recreating indexes and other objects on a new search service in a different region.

(!) Note

In the Azure portal, all services have an **Export template** command. In the case of Azure AI Search, this command produces a basic definition of a service (name, location, tier, replica, and partition count), but does not recognize the content of your service, nor does it carry over keys, roles, or logs. Although the command exists, we don't recommend using it for moving a search service.

Prerequisites

- Ensure that the services and features that your account uses are supported in the target region.
- For preview features, ensure that your subscription is approved for the target region.

Prepare and move

1. Identify dependencies and related services to understand the full impact of relocating a service, in case you need to move more than just Azure AI Search.

Azure Storage is used for logging, creating a knowledge store, and is a commonly used external data source for AI enrichment and indexing. Foundry Tools are used to power built-in skills during AI enrichment. Both Foundry Tools and your search service are required to be in the same region if you're using AI enrichment.

2. Create an inventory of all objects on the service so that you know what to move: indexes, synonym maps, indexers, data sources, skillsets. If you enabled logging, create and archive any reports you might need for a historical record.
3. Check pricing and availability in the new region to ensure availability of Azure AI Search plus any related services in the new region. Most features are available in all regions, but some preview features have restricted availability.

4. Create a service in the new region and republish from source code any existing indexes, synonym maps, indexers, data sources, and skillsets. Remember that service names must be unique so you can't reuse the existing name. Check each skillset to see if connections to Foundry Tools are still valid in terms of the same-region requirement. Also, if knowledge stores are created, check the connection strings for Azure Storage if you're using a different service.
5. Reload indexes and knowledge stores, if applicable. You'll either use application code to push JSON data into an index, or rerun indexers to pull documents in from external sources.
6. Enable logging, and if you're using them, re-create security roles.
7. Update client applications and test suites to use the new service name and API keys, and test all applications.

Discard or clean up

Delete the old service once the new service is fully tested and operational. Deleting the service automatically deletes all content associated with the service.

Next steps

The following links can help you locate more information when completing the steps outlined above.

- [Azure AI Search pricing and regions ↗](#)
- [Choose a tier](#)
- [Create a search service](#)
- [Load search documents](#)
- [Enable logging](#)

Create an index in Azure AI Search

08/27/2025

In this article, learn the steps for defining a schema for a [search index](#) and pushing it to a search service. Creating an index establishes the physical data structures on your search service. Once the index exists, [load the index](#) as a separate task.

Prerequisites

- Write permissions as a [Search Service Contributor](#) or an [admin API key](#) for key-based authentication.
- An understanding of the data you want to index. A search index is based on external content that you want to make searchable. Searchable content is stored as fields in an index. You should have a clear idea of which source fields you want to make searchable, retrievable, filterable, facetable, and sortable on Azure AI Search. See the [schema checklist](#) for guidance.
- You must also have a unique field in source data that can be used as the [document key \(or ID\)](#) in the index.
- A stable index location. Moving an existing index to a different search service isn't supported out-of-the-box. Revisit application requirements and make sure that your existing search service (capacity and region), are sufficient for your needs. If you're taking a dependency on Azure AI services or Azure OpenAI, [choose a region](#) that provides all of the necessary resources.
- Finally, all service tiers have [index limits](#) on the number of objects that you can create. For example, if you're experimenting on the Free tier, you can only have three indexes at any given time. Within the index itself, there are [limits on vectors](#) and [index limits](#) on the number of simple and complex fields.

Document keys

Search index creation has two requirements: an index must have a unique name on the search service, and it must have a document key. The boolean `key` attribute on a field can be set to true to indicate which field provides the document key.

A document key is the unique identifier of a search document, and a search document is a collection of fields that completely describes something. For example, if you're indexing a [movies data set](#), a search document contains the title, genre, and duration of a single movie.

Movie names are unique in this dataset, so you might use the movie name as the document key.

In Azure AI Search, a document key is a string, and it must originate from unique values in the data source that's providing the content to be indexed. As a general rule, a search service doesn't generate key values, but in some scenarios (such as the [Azure table indexer](#)) it synthesizes existing values to create a unique key for the documents being indexed. Another scenario is one-to-many indexing for chunked or partitioned data, in which case document keys are generated for each chunk.

During incremental indexing, where new and updated content is indexed, incoming documents with new keys are added, while incoming documents with existing keys are either merged or overwritten, depending on whether index fields are null or populated.

Important points about document keys include:

- The maximum length of values in a key field is 1,024 characters.
- Exactly one top-level field in each index must be chosen as the key field and it must be of type `Edm.String`.
- The default of the `key` attribute is false for simple fields and null for complex fields.

Key fields can be used to look up documents directly and update or delete specific documents. The values of key fields are handled in a case-sensitive manner when looking up or indexing documents. See [GET Document \(REST\)](#) and [Index Documents \(REST\)](#) for details.

Schema checklist

Use this checklist to assist the design decisions for your search index.

1. Review [naming conventions](#) so that index and field names conform to the naming rules.
2. Review [supported data types](#). The data type affects how the field is used. For example, numeric content is filterable but not full text searchable. The most common data type is `Edm.String` for searchable text, which is tokenized and queried using the full text search engine. The most common data type for a vector field is `Edm.Single` but you can use other types as well.
3. Provide a description of the index, 4,000 character maximum. This human-readable text is invaluable when a system must access several indexes and make a decision based on the description. Consider a Model Context Protocol (MCP) server that must pick the correct index at run time. The decision can be based on the description rather than on index name alone.

4. Identify a [document key](#). A document key is an index requirement. It's a single string field populated from a source data field that contains unique values. For example, if you're indexing from Blob Storage, the metadata storage path is often used as the document key because it uniquely identifies each blob in the container.

5. Identify the fields in your data source that contribute searchable content in the index.

Searchable nonvector content includes short or long strings that are queried using the full text search engine. If the content is verbose (small phrases or bigger chunks), experiment with different analyzers to see how the text is tokenized.

Searchable vector content can be images or text (in any language) that exists as a mathematical representation. You can use narrow data types or vector compression to make vector fields smaller.

[Attributes set on fields](#), such as `retrievable` or `filterable`, determine both search behaviors and the physical representation of your index on the search service. Determining how fields should be attributed is an iterative process for many developers. To speed up iterations, start with sample data so that you can drop and rebuild easily.

6. Identify which source fields can be used as filters. Numeric content and short text fields, particularly those with repeating values, are good choices. When working with filters, remember:

- Filters can be used in vector and nonvector queries, but the filter itself is applied to human-readable (nonvector) fields in your index.
- Filterable fields can optionally be used in faceted navigation.
- Filterable fields are returned in arbitrary order and don't undergo relevance scoring, so consider making them sortable as well.

7. For vector fields, specify a vector search configuration and the algorithms used for creating navigation paths and filling the embedding space. For more information, see [Add vector fields](#).

Vector fields have extra properties that nonvector fields don't have, such as which algorithms to use and vector compression.

Vector fields omit attributes that aren't useful on vector data, such as sorting, filtering, and facetting.

8. For nonvector fields, determine whether to use the default analyzer (`"analyzer": null`) or a different analyzer. [Analyzers](#) are used to tokenize text fields during indexing and query execution.

For multi-lingual strings, consider a [language analyzer](#).

For hyphenated strings or special characters, consider [specialized analyzers](#). One example is [keyword](#) that treats the entire contents of a field as a single token. This behavior is useful for data like zip codes, IDs, and some product names. For more information, see [Partial term search and patterns with special characters](#).

Note

Full text search is conducted over terms that are tokenized during indexing. If your queries fail to return the results you expect, [test for tokenization](#) to verify the string you're searching for actually exists. You can try different analyzers on strings to see how tokens are produced for various analyzers.

Configure field definitions

The fields collection defines the structure of a search document. All fields have a name, data type, and attributes.

Setting a field as searchable, filterable, sortable, or facetable has an effect on index size and query performance. Don't set those attributes on fields that aren't meant to be referenced in query expressions.

If a field isn't set to be searchable, filterable, sortable, or facetable, the field can't be referenced in any query expression. This is desirable for fields that aren't used in queries, but are needed in search results.

The REST APIs have default attribution based on [data types](#), which is also used by the [import wizards](#) in the Azure portal. The Azure SDKs don't have defaults, but they have field subclasses that incorporate properties and behaviors, such as [SearchableField](#) for strings and [SimpleField](#) for primitives.

Default field attributions for the REST APIs are summarized in the following table.

 Expand table

Data type	Searchable	Retrievable	Filterable	Facetable	Sortable	Stored
Edm.String						
Collection(Edm.String)						
Edm.Boolean						

Data type	Searchable	Retrievable	Filterable	Facetable	Sortable	Stored
<code>Edm.Int32</code> , <code>Edm.Int64</code> , <code>Edm.Double</code>	✗	✓	✓	✓	✓	✓
<code>Edm.DateTimeOffset</code>	✗	✓	✓	✓	✓	✓
<code>Edm.GeographyPoint</code>	✓	✓	✓	✗	✓	✓
<code>Edm.ComplexType</code>	✓	✓	✓	✓	✓	✓
<code>Collection(Edm.Single)</code> and all other vector field types	✓	✓ or ✗	✗	✗	✗	✓

String fields can also be optionally associated with [analyzers](#) and [synonym maps](#). Fields of type `Edm.String` that are filterable, sortable, or facetable can be at most 32 kilobytes in length. This is because values of such fields are treated as a single search term, and the maximum length of a term in Azure AI Search is 32 kilobytes. If you need to store more text than this in a single string field, you should explicitly set filterable, sortable, and facetable to `false` in your index definition.

Vector fields must be associated with [dimensions](#) and [vector profiles](#). Retrievable is true by default if you add the vector field using the [Import data \(new\) wizard](#) in the Azure portal. If you use the REST API, it's false.

Field attributes are described in the following table.

[] Expand table

Attribute	Description
<code>name</code>	Required. Sets the name of the field, which must be unique within the fields collection of the index or parent field.
<code>type</code>	Required. Sets the data type for the field. Fields can be simple or complex. Simple fields are of primitive types, like <code>Edm.String</code> for text or <code>Edm.Int32</code> for integers. Complex fields can have sub-fields that are themselves either simple or complex. This allows you to model objects and arrays of objects, which in turn enables you to upload most JSON object structures to your index. See Supported data types for the complete list of supported types.
<code>key</code>	Required. Set this attribute to true to designate that a field's values uniquely identify documents in the index. See Document keys in this article for details.
<code>retrievable</code>	Indicates whether the field can be returned in a search result. Set this attribute to <code>false</code> if you want to use a field as a filter, sorting, or scoring mechanism but don't want the field to be visible to the end user. This attribute must be <code>true</code> for key fields, and it must be <code>null</code> for complex fields. This attribute can be changed on existing fields. Setting

Attribute	Description
	retrievable to <code>true</code> doesn't cause any increase in index storage requirements. Default is <code>true</code> for simple fields and <code>null</code> for complex fields.
searchable	<p>Indicates whether the field is full-text searchable and can be referenced in search queries. This means it undergoes lexical analysis such as word-breaking during indexing. If you set a searchable field to a value like "Sunny day", internally it's normalized into the individual tokens "sunny" and "day". This enables full-text searches for these terms. Fields of type <code>Edm.String</code> or <code>Collection(Edm.String)</code> are searchable by default. This attribute must be <code>false</code> for simple fields of other nonstring data types, and it must be <code>null</code> for complex fields.</p>
	<p>A searchable field consumes extra space in your index since Azure AI Search processes the contents of those fields and organize them in auxiliary data structures for performant searching. If you want to save space in your index and you don't need a field to be included in searches, set searchable to <code>false</code>. See How full-text search works in Azure AI Search for details.</p>
filterable	<p>Indicates whether to enable the field to be referenced in <code>\$filter</code> queries. Filterable differs from searchable in how strings are handled. Fields of type <code>Edm.String</code> or <code>Collection(Edm.String)</code> that are filterable don't undergo lexical analysis, so comparisons are for exact matches only. For example, if you set such a field <code>f</code> to "Sunny day", <code>\$filter=f eq 'sunny'</code> finds no matches, but <code>\$filter=f eq 'Sunny day'</code> will. This attribute must be <code>null</code> for complex fields. Default is <code>true</code> for simple fields and <code>null</code> for complex fields. To reduce index size, set this attribute to <code>false</code> on fields that you won't be filtering on.</p>
sortable	<p>Indicates whether to enable the field to be referenced in <code>\$orderby</code> expressions. By default Azure AI Search sorts results by score, but in many experiences users want to sort by fields in the documents. A simple field can be sortable only if it's single-valued (it has a single value in the scope of the parent document).</p> <p>Simple collection fields can't be sortable, since they're multi-valued. Simple subfields of complex collections are also multi-valued, and therefore can't be sortable. This is true whether it's an immediate parent field, or an ancestor field, that's the complex collection. Complex fields can't be sortable and the sortable attribute must be <code>null</code> for such fields. The default for sortable is <code>true</code> for single-valued simple fields, <code>false</code> for multi-valued simple fields, and <code>null</code> for complex fields.</p>
facetable	<p>Indicates whether to enable the field to be referenced in facet queries. Typically used in a presentation of search results that includes hit count by category (for example, search for digital cameras and see hits by brand, by megapixels, by price, and so on). This attribute must be <code>null</code> for complex fields. Fields of type <code>Edm.GeographyPoint</code> or <code>Collection(Edm.GeographyPoint)</code> can't be facetable. Default is <code>true</code> for all other simple fields. To reduce index size, set this attribute to <code>false</code> on fields that you won't be faceting on.</p>
analyzer	<p>Sets the lexical analyzer for tokenizing strings during indexing and query operations. Valid values for this property include language analyzers, built-in analyzers, and custom</p>

Attribute	Description
	<code>analyzers</code> . The default is <code>standard.lucene</code> . This attribute can only be used with searchable string fields, and it can't be set together with either <code>searchAnalyzer</code> or <code>indexAnalyzer</code> . Once the analyzer is chosen and the field is created in the index, it can't be changed for the field. Must be <code>null</code> for complex fields .
<code>searchAnalyzer</code>	Set this property together with <code>indexAnalyzer</code> to specify different lexical analyzers for indexing and queries. If you use this property, set <code>analyzer</code> to <code>null</code> and make sure <code>indexAnalyzer</code> is set to an allowed value. Valid values for this property include built-in analyzers and custom analyzers. This attribute can be used only with searchable fields. The search analyzer can be updated on an existing field since it's only used at query-time. Must be <code>null</code> for complex fields].
<code>indexAnalyzer</code>	Set this property together with <code>searchAnalyzer</code> to specify different lexical analyzers for indexing and queries. If you use this property, set <code>analyzer</code> to <code>null</code> and make sure <code>searchAnalyzer</code> is set to an allowed value. Valid values for this property include built-in analyzers and custom analyzers. This attribute can be used only with searchable fields. Once the index analyzer is chosen, it can't be changed for the field. Must be <code>null</code> for complex fields.
<code>synonymMaps</code>	A list of the names of synonym maps to associate with this field. This attribute can be used only with searchable fields. Currently only one synonym map per field is supported. Assigning a synonym map to a field ensures that query terms targeting that field are expanded at query-time using the rules in the synonym map. This attribute can be changed on existing fields. Must be <code>null</code> or an empty collection for complex fields.
<code>fields</code>	A list of subfields if this is a field of type <code>Edm.ComplexType</code> or <code>Collection(Edm.ComplexType)</code> . Must be <code>null</code> or empty for simple fields. See How to model complex data types in Azure AI Search for more information on how and when to use subfields.

Create an index

When you're ready to create the index, use a search client that can send the request. You can use the Azure portal or REST APIs for early development and proof-of-concept testing, otherwise it's common to use the Azure SDKs.

During development, plan on frequent rebuilds. Because physical structures are created in the service, [dropping and re-creating indexes](#) is necessary for many modifications. You might consider working with a subset of your data to make rebuilds go faster.

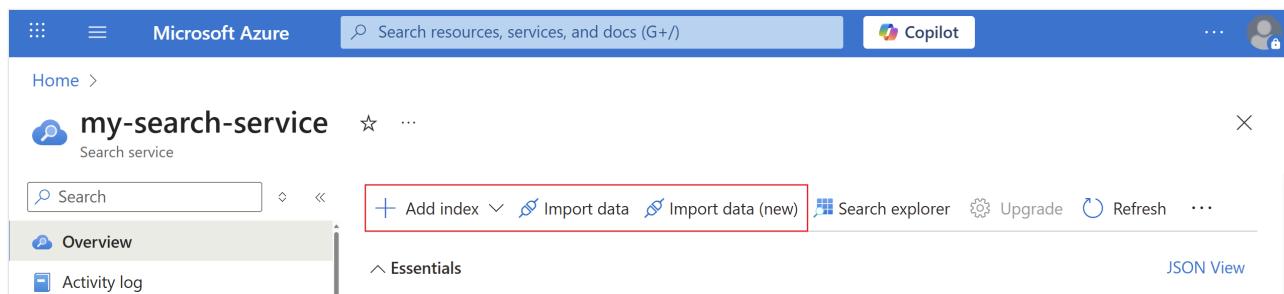

Azure portal

Index design through the Azure portal enforces requirements and schema rules for specific data types, such as disallowing full text search capabilities on numeric fields.

1. Sign in to the [Azure portal](#).
2. Check for space. Search services are subject to [maximum number of indexes](#), varying by service tier. Make sure you have room for a second index.
3. In the search service **Overview** page, choose either option for creating a search index:
 - **Add index**, an embedded editor for specifying an index schema
 - [Import wizards](#)

The wizard is an end-to-end workflow that creates an indexer, a data source, and a finished index. It also loads the data. If this is more than what you want, use **Add index** instead.

The following screenshot highlights where the **Add index**, **Import data**, and **Import data (new)** wizards appear on the command bar.

After an index is created, you can find it again on the **Indexes** page from the left pane.

Tip

After creating an index in the Azure portal, you can copy the JSON representation and add it to your application code.

Set `corsOptions` for cross-origin queries

Index schemas include a section for setting `corsOptions`. By default, client-side JavaScript can't call any APIs because browsers prevent all cross-origin requests. To allow cross-origin queries through to your index, enable CORS (Cross-Origin Resource Sharing) by setting the `corsOptions` attribute. For security reasons, only [query APIs](#) support CORS.

JSON

```
"corsOptions": {  
  "allowedOrigins": [
```

```
  ],
  "maxAgeInSeconds": 300
```

The following properties can be set for CORS:

- **allowedOrigins** (required): This is a list of origins that are allowed access to your index. JavaScript code served from these origins is allowed to query your index (assuming the caller provides a valid key or has permissions). Each origin is typically of the form `protocol://<fully-qualified-domain-name>:<port>` although `<port>` is often omitted. For more information, see [Cross-origin resource sharing \(Wikipedia\)](#).

If you want to allow access to all origins, include `*` as a single item in the **allowedOrigins** array. *This isn't a recommended practice for production search services* but it's often useful for development and debugging.

- **maxAgeInSeconds** (optional): Browsers use this value to determine the duration (in seconds) to cache CORS preflight responses. This must be a non-negative integer. A longer cache period delivers better performance, but it extends the amount of time a CORS policy needs to take effect. If this value isn't set, a default duration of five minutes is used.

Allowed updates on existing indexes

[Create Index](#) creates the physical data structures (files and inverted indexes) on your search service. Once the index is created, your ability to effect changes using [Create or Update Index](#) is contingent upon whether your modifications invalidate those physical structures. Most field attributes can't be changed once the field is created in your index.

To minimize churn in application code, you can [create an index alias](#) that serves as a stable reference to the search index. Instead of updating your code with index names, you can update an index alias to point to newer index versions.

To minimize churn in the design process, the following table describes which elements are fixed and flexible in the schema. Changing a fixed element requires an index rebuild, whereas flexible elements can be changed at any time without impacting the physical implementation. For more information, see [Update or rebuild an index](#).

[] [Expand table](#)

Element	Can be updated?
Name	No

Element	Can be updated?
Key	No
Field names and types	No
Field attributes (searchable, filterable, facetable, sortable)	No
Field attribute (retrievable)	Yes
Stored (applies to vectors)	No
Analyzer	You can add and modify custom analyzers in the index. Regarding analyzer assignments on string fields, you can only modify <code>searchAnalyzer</code> . All other assignments and modifications require a rebuild.
Scoring profiles	Yes, you can create and edit scoring profiles with no rebuild.
Suggesters	No
cross-origin resource sharing (CORS)	Yes
Encryption	Yes, you can update all parts of an <i>existing</i> encryption definition.
Synonym maps	Yes, you can create and edit synonym maps with no rebuild.
Semantic configuration	Yes, you can create and edit semantic configurations with no rebuild.

Next steps

Use the following links to learn about specialized features that can be added to an index:

- [Add vector fields and vector profiles](#)
- [Add scoring profiles](#)
- [Add semantic ranking](#)
- [Add suggesters](#)
- [Add synonym maps](#)
- [Add analyzers](#)
- [Add encryption](#)

Use these links for loading or updating an index:

- [Data import overview](#)
- [Load documents](#)
- [Update or rebuild an index](#)

Load data into a search index in Azure AI Search

10/03/2025

This article explains how to import documents into a predefined search index. In Azure AI Search, a [search index is created first](#) with [data import](#) following as a second step. The exception is [Import wizards](#) in the Azure portal and [indexer pipelines](#), which create and load an index in one workflow.

How data import works

A search service accepts JSON documents that conform to the index schema. A search service can import and index plain text content and vector content in JSON documents.

- Plain text content is retrieved from fields in the external data source, from metadata properties, or from enriched content that's generated by a [skillset](#). Skills can extract or infer textual descriptions from images and unstructured content.
- Vector content is retrieved from a data source that provides it, or it's created by a skillset that implements [integrated vectorization](#) in an Azure AI Search indexer workload.

You can prepare these documents yourself, but if content resides in a [supported data source](#), running an [indexer](#) or using an Import wizard can automate document retrieval, JSON serialization, and indexing.

Once data is indexed, the physical data structures of the index are locked in. For guidance on what can and can't be changed, see [Update and rebuild an index](#).

Indexing isn't a background process. A search service balances indexing and query workloads, but if [query latency is too high](#), you can either [add capacity](#) or identify periods of low query activity for loading an index.

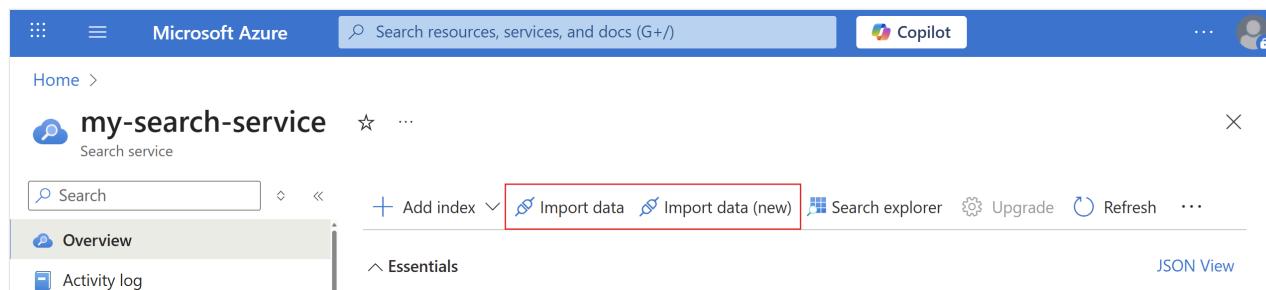

For more information, see [Data import strategies](#).

Use the Azure portal

In the Azure portal, use an [import wizard](#) to create and load indexes in a seamless workflow. If you want to load an existing index, choose an alternative approach.

1. Sign in to the [Azure portal](#) with your Azure account and [find your search service](#).

2. On the **Overview** page, select **Import data** or **Import data (new)** on the command bar to create and populate a search index.

The screenshot shows the Microsoft Azure portal interface. At the top, there's a blue header bar with the Microsoft Azure logo, a search bar containing 'Search resources, services, and docs (G+)', and a 'Copilot' button. Below the header, the URL 'Home > my-search-service' is visible. The main content area shows a 'my-search-service' search service card with a 'Search service' icon. Below the card, there are two buttons: '+ Add index' and 'Import data'. The 'Import data' button is highlighted with a red box. Other buttons in the row include 'Import data (new)', 'Search explorer', 'Upgrade', 'Refresh', and three dots. A sidebar on the left has 'Overview' selected, and a bottom right corner has a 'JSON View' link.

You can follow these links to review the workflow: [Quickstart: Create an Azure AI Search index](#) and [Quickstart: Integrated vectorization](#).

3. After the wizard is finished, use [Search Explorer](#) to check for results.

💡 Tip

The import wizards create and run indexers. If indexers are already defined, you can [reset and run an indexer](#) from the Azure portal, which is useful if you're adding fields incrementally. Reset forces the indexer to start over, picking up all fields from all source documents.

Use the REST APIs

[Documents - Index](#) is the REST API for importing data into a search index.

The body of the request contains one or more documents to be indexed. Documents are uniquely identified through a case-sensitive key. Each document is associated with an action: "upload", "delete", "merge", or "mergeOrUpload". Upload requests must include the document data as a set of key/value pairs.

REST APIs are useful for initial proof-of-concept testing, where you can test indexing workflows without having to write much code. The `@search.action` parameter determines whether documents are added in full, or partially in terms of new or replacement values for specific fields.

[Quickstart: Full-text search using REST](#) explains the steps. The following example is a modified version of the example. The value is trimmed for brevity and the first HotelId value is altered to avoid overwriting an existing document.

1. Formulate a POST call specifying the index name, the "docs/index" endpoint, and a request body that includes the `@search.action` parameter.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/index?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]
{
  "value": [
    {
      "@search.action": "upload",
      "HotelId": "1111",
      "HotelName": "Stay-Kay City Hotel",
      "Description": "The hotel is ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Time's Square and the historic centre of the city, as well as other places of interest that make New York one of America's most attractive and cosmopolitan cities.",
      "Category": "Boutique",
      "Tags": [ "pool", "air conditioning", "concierge" ]
    },
    {
      "@search.action": "mergeOrUpload",
      "HotelId": "2",
      "HotelName": "Old Century Hotel",
      "Description": "This is description is replacing the original one for this hotel. New and changed values overwrite the previous ones. In a comma-delimited list like Tags, be sure to provide the full list because there is no merging of values within the field itself.",
      "Category": "Boutique",
      "Tags": [ "pool", "free wifi", "concierge", "my first new tag", "my second new tag" ]
    }
  ]
}
```

2. Set the `@search.action` parameter to `upload` to create or overwrite a document. Set it to `merge` or `uploadOrMerge` if you're targeting updates to specific fields within the document. The previous example shows both actions.

 [Expand table](#)

Action	Effect
upload	Similar to an "upsert" where the document is inserted if it's new, and updated or replaced if it exists. If the document is missing values that the index requires, the document field's value is set to null.
merge	Updates a document that already exists, and fails a document that can't be found. Merge replaces existing values. For this reason, be sure to check for collection fields that contain multiple values, such as fields of type <code>Collection(Edm.String)</code> . For example, if a <code>tags</code> field starts with a value of

Action	Effect
	<code>["budget"]</code> and you execute a merge with <code>["economy", "pool"]</code> , the final value of the <code>tags</code> field is <code>["economy", "pool"]</code> . It isn't <code>["budget", "economy", "pool"]</code> .
mergeOrUpload	Behaves like merge if the document exists, and upload if the document is new. This is the most common action for incremental updates.
delete	Delete removes the specified document from the index. Any field you specify in a delete operation, other than the key field, is ignored. If you want to remove an individual field from a document, use merge instead and set the field explicitly to null.

There are no ordering guarantees for which action in the request body is executed first. It's not recommended to have multiple "merge" actions associated with the same document in a single request body. If there are multiple "merge" actions required for the same document, perform the merging client-side before updating the document in the search index.

In primitive collections, if the document contains a Tags field of type `Collection(Edm.String)` with a value of `["budget"]`, and you execute a merge with a value of `["economy", "pool"]` for Tag, the final value of the Tags field will be `["economy", "pool"]`. It isn't `["budget", "economy", "pool"]`.

In complex collections, if the document contains a complex collection field named Rooms with a value of `[{ "Type": "Budget Room", "BaseRate": 75.0 }]`, and you execute a merge with a value of `[{ "Type": "Standard Room" }, { "Type": "Budget Room", "BaseRate": 60.5 }]`, the final value of the Rooms field will be `[{ "Type": "Standard Room" }, { "Type": "Budget Room", "BaseRate": 60.5 }]`. It won't be either of the following:

- `[{ "Type": "Budget Room", "BaseRate": 75.0 }, { "Type": "Standard Room" }, { "Type": "Budget Room", "BaseRate": 60.5 }]` (append elements)
- `[{ "Type": "Standard Room", "BaseRate": 75.0 }, { "Type": "Budget Room", "BaseRate": 60.5 }]` (merge elements in order, then append any extras)

ⓘ Note

When you upload `DateTimeOffset` values with time zone information to your index, Azure AI Search normalizes these values to UTC. For example, `2025-01-13T14:03:00-08:00` will be stored as `2025-01-13T22:03:00Z`. If you need to store time zone information, add an extra column to your index.

3. Send the request.

The following table explains the various per-document [status codes](#) that can be returned in the response. Some status codes indicate problems with the request itself, while others indicate temporary error conditions. The latter you should retry after a delay.

 [Expand table](#)

Status code	Meaning	Retryable	Notes
200	Document was successfully modified or deleted.	n/a	Delete operations are idempotent . That is, even if a document key doesn't exist in the index, attempting a delete operation with that key results in a 200 status code.
201	Document was successfully created.	n/a	
400	There was an error in the document that prevented it from being indexed.	No	The error message in the response indicates what is wrong with the document.
404	The document couldn't be merged because the given key doesn't exist in the index.	No	This error doesn't occur for uploads since they create new documents, and it doesn't occur for deletes because they're idempotent .
409	A version conflict was detected when attempting to index a document.	Yes	This can happen when you're trying to index the same document more than once concurrently.
422	The index is temporarily unavailable because it was updated with the 'allowIndexDowntime' flag set to 'true'.	Yes	
429	Indicates that you have exceeded your quota on the number of documents per index.	No	You must either create a new index or upgrade for higher capacity limits.
503	Your search service is temporarily unavailable, possibly due to heavy load.	Yes	Your code should wait before retrying in this case or you risk prolonging the service unavailability.

 **Note**

If your client code frequently encounters a 207 response, one possible reason is that the system is under load. You can confirm this by checking the `statusCode` property for 503. If this is the case, we recommend throttling indexing requests. Otherwise, if

indexing traffic doesn't subside, the system could start rejecting all requests with 503 errors.

4. Look up the documents you just added as a validation step:

HTTP

```
GET https://[service name].search.windows.net/indexes/hotel-sample-index/docs/1111?api-version=2025-09-01
```

When the document key or ID is new, **null** becomes the value for any field that's unspecified in the document. For actions on an existing document, updated values replace the previous values. Any fields that weren't specified in a "merge" or "mergeUpload" are left intact in the search index.

Use the Azure SDKs

Programmability is provided in the following Azure SDKs.

.NET

The Azure SDK for .NET provides the following APIs for simple and bulk document uploads into an index:

- [IndexDocumentsAsync](#)
- [SearchIndexingBufferedSender](#)

There are several samples that illustrate indexing in context of simple and large-scale indexing:

- "[Load an index](#)" explains basic steps.
- [Azure.Search.Documents Samples - Indexing Documents](#) ↗ from the Azure SDK team adds [SearchIndexingBufferedSender](#).
- [Tutorial: Index any data](#) couples batch indexing with testing strategies for determining an optimum size.
- Be sure to check the [azure-search-vector-samples](#) ↗ repo for code examples showing how to index vector fields.

- [Import data wizard overview](#)
- [Indexers overview](#)

Update or rebuild an index in Azure AI Search

09/28/2025

This article explains how to update an existing index in Azure AI Search with schema changes or content changes through incremental indexing. It explains the circumstances under which rebuilds are required, and provides recommendations for mitigating the effects of rebuilds on ongoing query requests.

During active development, it's common to drop and rebuild indexes when you're iterating over index design. Most developers work with a small representative sample of their data so that reindexing goes faster.

For schema changes on applications already in production, we recommend creating and testing a new index that runs side by side an existing index. Use an [index alias](#) to swap in the new index so that you can avoid changes your application code.

Update content

Incremental indexing and synchronizing an index against changes in source data is fundamental to most search applications. This section explains the workflow for adding, removing, or overwriting the content of a search index through the REST API, but the Azure SDKs provide equivalent functionality.

The body of the request contains one or more documents to be indexed. Within the request, each document in the index is:

- Identified by a unique case-sensitive key.
- Associated with an action: "upload", "delete", "merge", or "mergeOrUpload".
- Populated with a set of name/value pairs for each field that you're adding or updating.

JSON

```
{  
  "value": [  
    {  
      "@search.action": "upload (default) | merge | mergeOrUpload | delete",  
      "key_field_name": "unique_key_of_document", (key/value pair for key field  
from index schema)  
      "field_name": field_value (name/value pairs matching index schema)  
      ...  
    },  
    ...  
  ]  
}
```

```
]  
}
```

- First, use the APIs for loading documents, such as [Documents - Index \(REST\)](#) or an equivalent API in the Azure SDKs. For more information about indexing techniques, see [Load documents](#).
- For a large update, batching (up to 1,000 documents per batch, or about 16 MB per batch, whichever limit comes first) is recommended and significantly improves indexing performance.
- Set the `@search.action` parameter on the API to determine the effect on existing documents.

 [Expand table](#)

Action	Effect
delete	Removes the entire document from the index. If you want to remove an individual field, use merge instead, setting the field in question to null. Deleted documents and fields don't immediately free up space in the index. Every few minutes, a background process performs the physical deletion. Whether you use the Azure portal or an API to return index statistics, you can expect a small delay before the deletion is reflected in the Azure portal and through APIs.
merge	Updates a document that already exists, and fails a document that can't be found. Merge replaces existing values. For this reason, be sure to check for collection fields that contain multiple values, such as fields of type <code>Collection(Edm.String)</code> . For example, if a <code>tags</code> field starts with a value of <code>["budget"]</code> and you execute a merge with <code>["economy", "pool"]</code> , the final value of the <code>tags</code> field is <code>["economy", "pool"]</code> . It won't be <code>["budget", "economy", "pool"]</code> . The same behavior applies to complex collections. If the document contains a complex collection field named <code>Rooms</code> with a value of <code>[{ "Type": "Budget Room", "BaseRate": 75.0 }]</code> , and you execute a merge with a value of <code>[{ "Type": "Standard Room" }, { "Type": "Budget Room", "BaseRate": 60.5 }]</code> , the final value of the <code>Rooms</code> field will be <code>[{ "Type": "Standard Room" }, { "Type": "Budget Room", "BaseRate": 60.5 }]</code> . It won't append or merge new and existing values.
mergeOrUpload	Behaves like merge if the document exists, and upload if the document is new. This is the most common action for incremental updates.
upload	Similar to an "upsert" where the document is inserted if it's new, and updated or replaced if it exists. If the document is missing values that the index requires, the document field's value is set to null.

Queries continue to run during indexing, but if you're updating or removing existing fields, you can expect mixed results and a higher incidence of throttling.

! Note

There are no ordering guarantees for which action in the request body is executed first. It's not recommended to have multiple "merge" actions associated with the same document in a single request body. If there are multiple "merge" actions required for the same document, perform the merging client-side before updating the document in the search index.

Responses

Status code 200 is returned for a successful response, meaning that all items have been stored durably and will start to be indexed. Indexing runs in the background and makes new documents available (that is, queryable and searchable) a few seconds after the indexing operation completed. The specific delay depends on the load on the service.

Successful indexing is indicated by the `status` property being set to true for all items, as well as the `statusCode` property being set to either 201 (for newly uploaded documents) or 200 (for merged or deleted documents):

JSON

```
{
  "value": [
    {
      "key": "unique_key_of_new_document",
      "status": true,
      "errorMessage": null,
      "statusCode": 201
    },
    {
      "key": "unique_key_of_merged_document",
      "status": true,
      "errorMessage": null,
      "statusCode": 200
    },
    {
      "key": "unique_key_of_deleted_document",
      "status": true,
      "errorMessage": null,
      "statusCode": 200
    }
  ]
}
```

Status code 207 is returned when at least one item wasn't successfully indexed. Items that haven't been indexed have the status field set to false. The `errorMessage` and `statusCode` properties indicate the reason for the indexing error:

JSON

```
{  
  "value": [  
    {  
      "key": "unique_key_of_document_1",  
      "status": false,  
      "errorMessage": "The search service is too busy to process this document.  
Please try again later.",  
      "statusCode": 503  
    },  
    {  
      "key": "unique_key_of_document_2",  
      "status": false,  
      "errorMessage": "Document not found.",  
      "statusCode": 404  
    },  
    {  
      "key": "unique_key_of_document_3",  
      "status": false,  
      "errorMessage": "Index is temporarily unavailable because it was updated  
with the 'allowIndexDowntime' flag set to 'true'. Please try again later.",  
      "statusCode": 422  
    }  
  ]  
}
```

The `errorMessage` property indicates the reason for the indexing error if possible.

The following table explains the various per-document status codes that can be returned in the response. Some status codes indicate problems with the request itself, while others indicate temporary error conditions. The latter you should retry after a delay.

[] Expand table

Status code	Meaning	Retryable	Notes
200	Document was successfully modified or deleted.	n/a	Delete operations are idempotent. That is, even if a document key doesn't exist in the index, attempting a delete operation with that key results in a 200 status code.
201	Document was successfully created.	n/a	

Status code	Meaning	Retryable	Notes
400	There was an error in the document that prevented it from being indexed.	No	The error message in the response indicates what is wrong with the document.
404	The document couldn't be merged because the given key doesn't exist in the index.	No	This error doesn't occur for uploads since they create new documents, and it doesn't occur for deletes because they're idempotent.
409	A version conflict was detected when attempting to index a document.	Yes	This can happen when you're trying to index the same document more than once concurrently.
422	The index is temporarily unavailable because it was updated with the 'allowIndexDowntime' flag set to 'true'.	Yes	
429	Too Many Requests	Yes	If you get this error code during indexing, it usually means that you're running low on storage. As you near storage limits , the service can enter a state where you can't add or update until you delete some documents. For more information, see Plan and manage capacity if you want more storage, or free up space by deleting documents.
503	Your search service is temporarily unavailable, possibly due to heavy load.	Yes	Your code should wait before retrying in this case or you risk prolonging the service unavailability.

If your client code frequently encounters a 207 response, one possible reason is that the system is under load. You can confirm this by checking the statusCode property for 503. If the statusCode is 503, we recommend throttling indexing requests. Otherwise, if indexing traffic doesn't subside, the system could start rejecting all requests with 503 errors.

Status code 429 indicates that you've exceeded your quota on the number of documents per index. You must either [upgrade for higher capacity limits](#) or create a new index.

(!) Note

When you upload `DateTimeOffset` values with time zone information to your index, Azure AI Search normalizes these values to UTC. For example, 2024-01-13T14:03:00-08:00 is

stored as 2024-01-13T22:03:00Z. If you need to store time zone information, add an extra column to your index for this data point.

Tips for incremental indexing

- [Indexers automate incremental indexing](#). If you can use an indexer, and if the data source supports change tracking, you can run the indexer on a recurring schedule to add, update, or overwrite searchable content so that it's synchronized to your external data.
- If you're making index calls directly through the [push API](#), use `mergeOrUpload` as the search action.
- The payload must include the keys or identifiers of every document you want to add, update, or delete.
- If your index includes vector fields and you set the [stored property to false](#), make sure you provide the vector in your partial document update, even if the value is unchanged. A side effect of setting `stored` to false is that vectors are dropped on a reindexing operation. Providing the vector in the documents payload prevents this from happening.
- To update the contents of simple fields and subfields in complex types, list only the fields you want to change. For example, if you only need to update a description field, the payload should consist of the document key and the modified description. Omitting other fields retains their existing values.
- To merge inline changes into string collection, provide the entire value. Recall the `tags` field example from the previous section. New values overwrite the old values for an entire field, and there's no merging within the content of a field.

Here's a [REST API example](#) demonstrating these tips:

```
rest
```

```
### Get Stay-Kay City Hotel by ID
GET {{baseUrl}}/indexes/hotels-vector-quickstart/docs('1')?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

### Change the description, city, and tags for Stay-Kay City Hotel
POST {{baseUrl}}/indexes/hotels-vector-quickstart/docs/search.index?api-
version=2025-09-01 HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

{
```

```

    "value": [
      {
        "@search.action": "mergeOrUpload",
        "HotelId": "1",
        "Description": "I'm overwriting the description for Stay-Kay City
Hotel.",
        "Tags": ["my old item", "my new item"],
        "Address": {
          "City": "Gotham City"
        }
      }
    ]
}

### Retrieve the same document, confirm the overwrites and retention of all other
values
GET {{baseUrl}}/indexes/hotels-vector-quickstart/docs('1')?api-version=2025-09-01
HTTP/1.1
Content-Type: application/json
api-key: {{apiKey}}

```

Update an index schema

The index schema defines the physical data structures created on the search service, so there aren't many schema changes that you can make without incurring a full rebuild.

Updates with no rebuild

The following list enumerates the schema changes that can be introduced seamlessly into an existing index. Generally, the list includes new fields and functionality used during query execution.

- Add an [index description \(preview\)](#)
- Add a new field
- Set the `retrievable` attribute on an existing field
- Update `searchAnalyzer` on a field having an existing `indexAnalyzer`
- Add a new [analyzer definition](#) in an index (which can be applied to new fields)
- Add, update, or delete [scoring profiles](#)
- Add, update, or delete [synonymMaps](#)
- Add, update, or delete [semantic configurations](#)
- Add, update, or delete CORS settings

The order of operations is:

1. [Get the index definition.](#)

2. Revise the schema with updates from the previous list.

3. [Update index schema](#) on the search service.

4. [Update index content](#) to match your revised schema if you added a new field. For all other changes, the existing indexed content is used as-is.

When you update an index schema to include a new field, existing documents in the index are given a null value for that field. On the next indexing job, values from external source data replace the nulls added by Azure AI Search.

There should be no query disruptions during the updates, but query results will vary as the updates take effect.

Updates requiring a rebuild

Some modifications require an index drop and rebuild, replacing a current index with a new one.

[+] [Expand table](#)

Action	Description
Delete a field	To physically remove all traces of a field, you have to rebuild the index. When an immediate rebuild isn't practical, you can modify application code to redirect access away from an obsolete field or use the searchFields and select query parameters to choose which fields are searched and returned. Physically, the field definition and contents remain in the index until the next rebuild, when you apply a schema that omits the field in question.
Change a field definition	Revisions to a field name, data type, or specific index attributes (searchable, filterable, sortable, facetable) require a full rebuild.
Assign an analyzer to a field	Analyzers are defined in an index, assigned to fields, and then invoked during indexing to inform how tokens are created. You can add a new analyzer definition to an index at any time, but you can only <i>assign</i> an analyzer when the field is created. This is true for both the analyzer and indexAnalyzer properties. The searchAnalyzer property is an exception (you can assign this property to an existing field).
Update or delete an analyzer definition in an index	You can't delete or change an existing analyzer configuration (analyzer, tokenizer, token filter, or char filter) in the index unless you rebuild the entire index.
Add a field to a suggester	If a field already exists and you want to add it to a Suggesters construct, rebuild the index.

Action	Description
Upgrade your service or tier	If you need more capacity, check if you can upgrade your service or switch to a higher pricing tier . If not, you must create a new service and rebuild your indexes from scratch. To help automate this process, you can use a code sample that backs up your index to a series of JSON files. You can then recreate the index in a search service you specify.

The order of operations is:

1. [Get an index definition](#) in case you need it for future reference, or to use as the basis for a new version.
2. Consider using a backup and restore solution to preserve a copy of index content. There are solutions in [C#](#) and in [Python](#). We recommend the Python version because it's more up to date.
If you have capacity on your search service, keep the existing index while creating and testing the new one.
3. [Drop the existing index](#). Queries targeting the index are immediately dropped. Remember that deleting an index is irreversible, destroying physical storage for the fields collection and other constructs.
4. [Post a revised index](#), where the body of the request includes changed or modified field definitions and configurations.
5. [Load the index with documents](#) from an external source. Documents are indexed using the field definitions and configurations of the new schema.

When you create the index, physical storage is allocated for each field in the index schema, with an inverted index created for each searchable field and a vector index created for each vector field. Fields that aren't searchable can be used in filters or expressions, but don't have inverted indexes and aren't full-text or fuzzy searchable. On an index rebuild, these inverted indexes and vector indexes are deleted and recreated based on the index schema you provide.

To minimize disruption to application code, consider [creating an index alias](#). Application code references the alias, but you can update the name of the index that the alias points to.

Add an index description

An index has a `description` property that you can specify and use when a system must access several indexes and make a decision based on the description. Consider a Model Context

Protocol (MCP) server that must pick the correct index at run time. The decision can be based on the description rather than on the index name alone.

An index description is a schema update, and you can add it without having to rebuild the entire index.

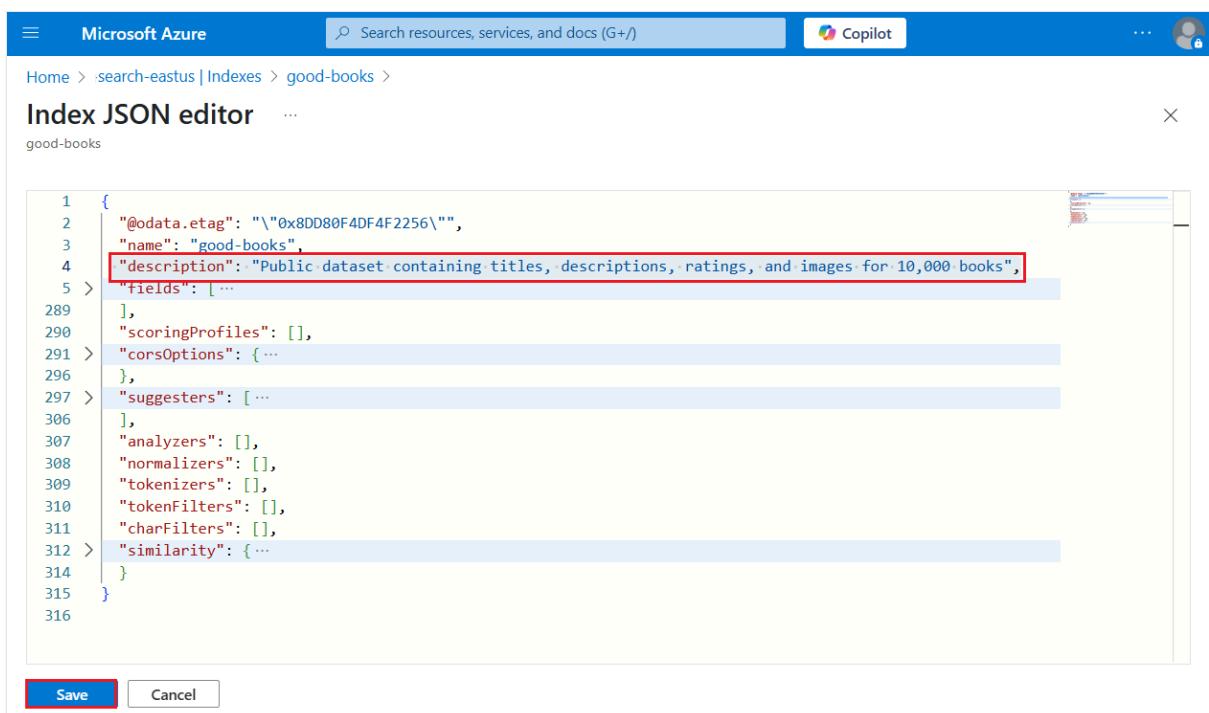

- String length is 4,000 characters maximum.
- Content must be human-readable, in Unicode. Your use-case should determine which language to use.

Support for an index description is provided in the preview REST API, the Azure portal, or in a prerelease Azure SDK package that provides the feature.

Azure portal

The Azure portal supports the latest preview API.

1. Sign in to the Azure portal and find your search service.
2. Under **Search management > Indexes**, select an index.
3. Select **Edit JSON**.
4. Insert `"description"`, followed by the description. The value must be less than 4,000 characters and in Unicode.

The screenshot shows the Microsoft Azure portal interface. At the top, there's a blue header bar with the Microsoft Azure logo, a search bar, and a Copilot button. Below the header, the URL shows the user is in the 'search-eastus | Indexes' section, specifically viewing the 'good-books' index. The main area is titled 'Index JSON editor' with the index name 'good-books' below it. The JSON code for the index is displayed in a code editor. A specific line of code, '4 > "description": "Public dataset containing titles, descriptions, ratings, and images for 10,000 books",', is highlighted with a red rectangular box. At the bottom of the code editor, there are two buttons: a blue 'Save' button and a white 'Cancel' button.

```
1  {
2    "@odata.etag": "\"0x8DD80F4DF4F2256\"",
3    "name": "good-books",
4    "description": "Public dataset containing titles, descriptions, ratings, and images for 10,000 books",
5    "fields": [
289    ],
290    "scoringProfiles": [],
291    "corsOptions": {...},
296    },
297    "suggesters": [...],
306    ],
307    "analyzers": [],
308    "normalizers": [],
309    "tokenizers": [],
310    "tokenFilters": [],
311    "charFilters": [],
312    "similarity": {...}
314  }
315}
316
```

5. Save the index.

Balancing workloads

Indexing doesn't run in the background, but the search service will balance any indexing jobs against ongoing queries. During indexing, you can [monitor query requests](#) in the Azure portal to ensure queries are completing in a timely manner.

If indexing workloads introduce unacceptable levels of query latency, conduct [performance analysis](#) and review these [performance tips](#) for potential mitigation.

Check for updates

You can begin querying an index as soon as the first document is loaded. If you know a document's ID, the [Lookup Document REST API](#) returns the specific document. For broader testing, you should wait until the index is fully loaded, and then use queries to verify the context you expect to see.

You can use [Search Explorer](#) or a [REST client](#) to check for updated content.

If you added or renamed a field, use `select` to return that field:

JSON

```
"search": "*",
"select": "document-id, my-new-field, some-old-field",
"count": true
```

The Azure portal provides index size and vector index size. You can check these values after updating an index, but remember to expect a small delay as the service processes the change and to account for portal refresh rates, which can be a few minutes.

Delete orphan documents

Azure AI Search supports document-level operations so that you can look up, update, and delete a specific document in isolation. The following example shows how to delete a document.

Deleting a document doesn't immediately free up space in the index. Every few minutes, a background process performs the physical deletion. Whether you use the Azure portal or an API to return index statistics, you can expect a small delay before the deletion is reflected in the Azure portal and API metrics.

1. Identify which field is the document key. In the Azure portal, you can view the fields of each index. Document keys are string fields and are denoted with a key icon to make

them easier to spot.

2. Check the values of the document key field: `search=*&$select=HotelId`. A simple string is straightforward, but if the index uses a base-64 encoded field, or if search documents were generated from a `parsingMode` setting, you might be working with values that you aren't familiar with.
3. [Look up the document](#) to verify the value of the document ID and to review its content before deleting it. Specify the key or document ID in the request. The following examples illustrate a simple string for the [Hotels sample index](#) and a base-64 encoded string for the `metadata_storage_path` key of the [cog-search-demo index](#).

HTTP

```
GET https://[service name].search.windows.net/indexes/hotel-sample-index/docs/1111?api-version=2025-09-01
```

HTTP

```
GET https://[service name].search.windows.net/indexes/cog-search-demo/docs/aHR0cHM6Ly9oZWlkaWJsb2JzdG9yYWdlMi5ibG9iLmNvcnUud2luZG93cy5uZXQvY29nLXN1YXJjaC1kZW1vL2d1dGhyawUuanBn0?api-version=2025-09-01
```

4. [Delete the document](#) using a delete `@search.action` to remove it from the search index.

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/index?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]
{
  "value": [
    {
      "@search.action": "delete",
      "id": "1111"
    }
  ]
}
```

Manage an index in Azure AI Search

07/03/2025

After you [create an index](#), you can use the [Azure portal](#) to access its statistics and definition or remove it from your search service.

This article describes how to manage an index without affecting its content. For guidance on modifying an index definition, see [Update or rebuild an index in Azure AI Search](#).

Limitations

The pricing tier of your search service determines the maximum number and size of your indexes, fields, and documents. For more information, see [Service limits in Azure AI Search](#).

Otherwise, the following limitations apply to index management:

- You can't take an index offline for maintenance. Indexes are always available for search operations.
- You can't directly copy or duplicate an index within or across search services. However, you can use the backup and restore sample for [.NET](#) or [Python](#) to achieve similar functionality.

View all indexes

To view all your indexes:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Search management > Indexes**.

Name	Document count	Vector index quota usage	Total storage size
index-1	50	0 Bytes	578.66 KB
index-2	7	122.58 KB	454.76 KB
index-3	100	408.11 KB	1.73 MB
index-4	100	408.26 KB	1.73 MB
index-5	105	1.24 MB	4.5 MB
index-6	20	242.36 KB	919.33 KB

By default, the indexes are sorted by name in ascending order. You can sort by **Name**, **Document count**, **Vector index quota usage**, or **Total storage size** by selecting the corresponding column header.

View an index's statistics

On the index page, the portal provides the following statistics:

- Number of documents in the index.
- Storage space used by the index.
- Vector storage space used by the index.
- Maximum storage space for each index on your search service, which [depends on your pricing tier](#). This value doesn't represent the total storage currently available to the index.

Documents	50	Total storage	578.66 KB	Vector index quota usage	0 Bytes	Max storage	15 GB
-----------	----	---------------	-----------	--------------------------	---------	-------------	-------

View an index's definition

Each index is defined by fields and optional components that enhance search capabilities, such as analyzers, normalizers, tokenizers, and synonym maps. This definition determines the index's structure and behavior during indexing and querying.

On the index page, select **Edit JSON** to view its complete definition.

The screenshot shows the Azure portal interface for managing an index named 'my-index'. At the top, there are navigation links: 'Home > my-search-service | Indexes > my-index ...'. Below this is a toolbar with icons for 'Save', 'Discard', 'Refresh', 'Create demo app', 'Edit JSON' (which is highlighted with a red box), 'Delete', and 'Encryption'. Key statistics are displayed: 'Documents 50', 'Total storage 578.66 KB', 'Vector index quota usage 0 Bytes', and 'Max storage 15 GB'. A horizontal menu bar includes 'Search explorer' (underlined), 'Fields', 'CORS', 'Scoring profiles', 'Semantic configurations', and 'Vector profiles'. Below the menu is a search bar with a 'Search' button and a magnifying glass icon. The 'Results' section shows a single item with the number '1'.

Delete an index

⚠ Warning

You can't undo an index deletion. Before you proceed, make sure that you want to permanently remove the index and its documents from your search service.

On the index page, select **Delete** to initiate the deletion process.

This screenshot is identical to the one above, showing the 'my-index' index details page. However, the 'Delete' button in the toolbar is now highlighted with a red box, indicating it is the selected action.

The portal prompts you to confirm the deletion. After you select **Delete**, check your notifications to confirm that the deletion was successful.

Delete confirmation

This action will permanently delete index 'my-index' and all its data.

Delete

Cancel

Create an index alias in Azure AI Search

10/03/2025

ⓘ Important

Index aliases are currently in public preview and available under [supplemental terms of use](#).

In Azure AI Search, an index alias is a secondary name for a search index. You can create an alias that maps to a search index and substitute the alias name in places where you would otherwise reference an index name. This gives you flexibility if you ever need to change which index your application is pointing to. Instead of updating the references to the index name in your production code, you can just update the mapping for your alias.

You can create and manage aliases in Azure AI Search service via HTTP requests (POST, GET, PUT, DELETE) against a given alias resource. Aliases are service level resources and maintained independently from search indexes. Once a search index is created, you can create an alias that maps to that search index.

Before using an alias, your application sends requests directly to `hotel-samples-index`.

HTTP

```
POST /indexes/hotel-samples-index/docs/search?api-version=2025-08-01-preview
{
  "search": "pool spa +airport",
  "select": "HotelId, HotelName, Category, Description",
  "count": true
}
```

After using an alias, your application sends requests to `my-alias`, which maps to `hotel-samples-index`.

HTTP

```
POST /indexes/my-alias/docs/search?api-version=2025-08-01-preview
{
  "search": "pool spa +airport",
  "select": "HotelId, HotelName, Category, Description",
  "count": true
}
```

Supported scenarios

You can only use an alias with document operations or to get and update an index definition.

Aliases can't be used to [delete an index](#), or [test text tokenization](#), or be referenced as the `targetIndexName` on an [indexer](#) or [knowledge source](#).

Create an index alias

Creating an alias establishes a mapping between an alias name and an index name. If the request is successful, the alias can be used for indexing, querying, and other operations.

Updating an alias allows you to map that alias to a different search index. When you update an existing alias, the entire definition is replaced with the contents of the request body. In general, the best pattern to use for updates is to retrieve the alias definition with a GET, modify it, and then update it with PUT.

You can create an alias using the preview REST API, the preview SDKs, or through the [Azure portal](#). An alias consists of the `name` of the alias and the name of the search index that the alias is mapped to. Only one index name can be specified in the `indexes` array.

The maximum number of aliases that you can create varies by pricing tier. For more information, see [Service limits](#).

REST API

You can use the [Create or Update Alias \(REST preview\)](#) to create an index alias.

HTTP

```
POST /aliases?api-version=2025-08-01-preview
{
    "name": "my-alias",
    "indexes": ["hotel-samples-index"]
}
```

Send requests to an index alias

Aliases can be used for all document operations including querying, indexing, suggestions, and autocomplete.

This query sends the request to `my-alias`, which is mapped to an actual index on your search service.

HTTP

```
POST /indexes/my-alias/docs/search?api-version=2025-08-01-preview
{
    "search": "pool spa +airport",
    "searchMode": any,
    "queryType": "simple",
    "select": "HotelId, HotelName, Category, Description",
    "count": true
}
```

Get an alias definition

This request returns a list of existing alias objects by name.

HTTP

```
GET https://[service name].search.windows.net/aliases?api-version=[api-
version]&$select=name
api-key: [admin key]
```

This request returns an alias definition

HTTP

```
GET https://[service name].search.windows.net/aliases/my-alias?api-version=[api-
version]
api-key: [admin key]
```

Update an alias

The most common update to an alias is changing the index name when the underlying index is replaced with a newer version.

PUT is required for alias updates as described in [Create or Update Alias \(REST preview\)](#).

HTTP

```
PUT /aliases/my-alias?api-version=2025-08-01-preview
{
    "name": "my-alias",
```

```
    "indexes": ["hotel-samples-index2"]  
}
```

An update to an alias may take up to 10 seconds to propagate through the system so you should wait at least 10 seconds before deleting the index that the alias was previously mapped to.

If you attempt to delete an index that is currently mapped to an alias, the operation will fail with 400 (Bad Request) and an error message stating that the alias(es) that's mapped to that index must be deleted or mapped to a different index before the index can be deleted.

Index large data sets in Azure AI Search

10/06/2025

If you need to index large or complex data sets in your search solution, this article explores strategies to accommodate long-running processes on Azure AI Search.

These strategies assume familiarity with the [two basic approaches for importing data](#): *pushing* data into an index, or *pulling* in data from a supported data source using a [search indexer](#). If your scenario involves computationally intensive [AI enrichment](#), then indexers are required, given the skillset dependency on indexers.

This article complements [Tips for better performance](#), which offers best practices on index and query design. A well-designed index that includes only the fields and attributes you need is an important prerequisite for large-scale indexing.

We recommend using a search service created after April 3, 2024 for [higher storage per partition](#). Older services can also be [upgraded to benefit from higher partition storage](#).

(!) Note

The strategies described in this article assume a single large data source. If your solution requires indexing from multiple data sources, see [Index multiple data sources in Azure AI Search](#) for a recommended approach.

Index data using the push APIs

Push APIs, such as the [Documents Index REST API](#) or the [IndexDocuments method \(Azure SDK for .NET\)](#), are the most prevalent form of indexing in Azure AI Search. For solutions that use a push API, the strategy for long-running indexing has one or both of the following components:

- Batching documents
- Managing threads

Batch multiple documents per request

A simple mechanism for indexing a large quantity of data is to submit multiple documents or records in a single request. As long as the entire payload is under 16 MB, a request can handle up to 1,000 documents in a bulk upload operation. These limits apply whether you're using the [Documents Index REST API](#) or the [IndexDocuments method](#) in the .NET SDK. Using either API, you can package 1,000 documents in the body of each request.

Batching documents significantly shortens the amount of time it takes to work through a large data volume. Determining the optimal batch size for your data is a key component of optimizing indexing speeds. The two primary factors influencing the optimal batch size are:

- The schema of your index
- The size of your data

Because the optimal batch size depends on your index and your data, the best approach is to test different batch sizes to determine which one results in the fastest indexing speeds for your scenario. For sample code to test batch sizes using the .NET SDK, see [Tutorial: Optimize indexing with the push API](#).

Manage threads and a retry strategy

Indexers have built-in thread management, but when you're using the push APIs, your application code needs to manage threads. Make sure there are sufficient threads to make full use of the available capacity, especially if you recently [upgraded your service](#), [switched to a higher pricing tier](#), or [increased partitions](#).

1. [Increase the number of concurrent threads](#) in your client code.
2. As you ramp up the requests hitting the search service, you might encounter [HTTP status codes](#) indicating the request didn't fully succeed. During indexing, two common HTTP status codes are:
 - **503 Service Unavailable:** This error means that the system is under heavy load and your request can't be processed at this time.
 - **207 Multi-Status:** This error means that some documents succeeded, but at least one failed.
3. To handle failures, requests should be retried using an [exponential backoff retry strategy](#).

The Azure .NET SDK automatically retries 503s and other failed requests, but you need to implement your own logic to retry 207s. Open-source tools such as [Polly](#) can also be used to implement a retry strategy.

Use indexers and the pull APIs

[Indexers](#) have several capabilities that are useful for long-running processes:

- Batching documents
- Parallel indexing over partitioned data

- Scheduling and change detection for indexing only new and changed documents over time

Indexer schedules can resume processing at the last known stopping point. If data isn't fully indexed within the processing window, the indexer picks up wherever it left off on the next run, assuming you're using a data source that provides change detection.

Partitioning data into smaller individual data sources enables parallel processing. You can break up source data, such as into multiple containers in Azure Blob Storage, [create a data source](#) for each partition, and then [run the indexers in parallel](#), subject to the number of search units of your search service.

Check indexer batch size

As with the push API, indexers allow you to configure the number of items per batch. For indexers based on the [Create Indexer REST API](#), you can set the `batchSize` argument to customize this setting to better match the characteristics of your data.

Default batch sizes are data-source specific. Azure SQL Database and Azure Cosmos DB have a default batch size of 1,000. In contrast, Azure Blob and SharePoint Online (Preview) indexing sets batch size at 10 documents in recognition of the larger average document size.

Schedule indexers for long-running processes

Indexer scheduling is an important mechanism for processing large data sets and for accommodating slow-running processes like image analysis in an enrichment pipeline.

Typically, indexer processing runs within a two-hour window. If the indexing workload takes days rather than hours to complete, you can put the indexer on a consecutive, recurring schedule that starts every two hours. Assuming the data source has [change tracking enabled](#), the indexer resumes processing where it last left off. At this cadence, an indexer can work its way through a document backlog over a series of days until all unprocessed documents are processed. This pattern is especially important during the initial run or when indexing large blob containers, where the blob listing phase alone can take multiple hours or days. During this time, the indexer would show no blobs being processed, but unless an error is reported, it is likely still iterating through the blob list. Document processing and enrichment begin only after this phase completes, and this behavior is expected.

JSON

```
{  
  "dataSourceName" : "hotels-ds",  
  "targetIndexName" : "hotels-idx",
```

```
        "schedule" : { "interval" : "PT2H", "startTime" : "2024-01-01T00:00:00Z" }  
    }
```

When there are no longer any new or updated documents in the data source, indexer execution history reports 0/0 documents processed, and no processing occurs.

For more information about setting schedules, see [Create Indexer REST API](#) or see [Schedule indexers for Azure AI Search](#).

ⓘ Note

Some indexers that run on an older runtime architecture have a 24-hour rather than 2-hour maximum processing window. The two-hour limit is for newer content processors that run in an [internally managed multitenant environment](#). Whenever possible, Azure AI Search tries to offload indexer and skillset processing to the multitenant environment. If the indexer can't be migrated, it runs in the private environment and it can run for as long as 24 hours. If you're scheduling an indexer that exhibits these characteristics, assume a 24-hour processing window.

Run indexers in parallel

If you partition your data, you can create multiple indexer-data-source combinations that pull from each data source and write to the same search index. Because each indexer is distinct, you can run them at the same time, populating a search index more quickly than if you ran them sequentially.

Make sure you have sufficient capacity. One search unit in your service can run one indexer at any given time. Creating multiple indexers is only useful if they can run in parallel.

The number of indexing jobs that can run simultaneously varies for text-based and skills-based indexing. For more information, see [Indexer execution](#).

If your data source is an [Azure Blob Storage container](#) or [Azure Data Lake Storage Gen 2](#), enumerating a large number of blobs can take a long time (even hours) until this operation is completed. As a result, your indexer's *documents succeeded* count doesn't appear to increase during that time and it might seem it's not making any progress, when it is. If you would like document processing to go faster for a large number of blobs, consider partitioning your data into multiple containers and create parallel indexers pointing to a single index.

1. Sign in to the [Azure portal](#) and check the number of search units used by your search service. Select **Settings > Scale** to view the number at the top of the page. The number of indexers that run in parallel is approximately equal to the number of search units.

2. Partition source data among multiple containers or multiple virtual folders inside the same container.
3. Create multiple [data sources](#), one for each partition, paired to its own [indexer](#).
4. Specify the same target search index in each indexer.
5. Schedule the indexers.
6. Review indexer status and execution history for confirmation.

There are some risks associated with parallel indexing. First, recall that indexing doesn't run in the background, increasing the likelihood that queries are throttled or dropped.

Second, Azure AI Search doesn't lock the index for updates. Concurrent writes are managed, invoking a retry if a particular write doesn't succeed on first attempt, but you might notice an increase in indexing failures.

Although multiple indexer-data-source sets can target the same index, be careful of indexer runs that can overwrite existing values in the index. If a second indexer-data-source targets the same documents and fields, any values from the first run are overwritten. Field values are replaced in full; an indexer can't merge values from multiple runs into the same field.

Index big data on Spark

If you have a big data architecture and your data is on a Spark cluster, we recommend [SynapseML for loading and indexing data](#). The tutorial includes steps for calling Azure AI services for AI enrichment, but you can also use the `AzureSearchWriter` API for text indexing.

Add synonyms in Azure AI Search

Article • 04/14/2025

On a search service, a synonym map associates equivalent terms, expanding the scope of a query without the user having to actually provide the term. For example, assuming *dog*, *canine*, and *puppy* are mapped synonyms, a query on *canine* matches on a document containing *dog*. You might create multiple synonym maps for different languages, such as English and French versions, or lexicons if your content includes technical jargon, slang, or obscure terminology.

Some key points about synonym maps:

- A synonym map is a top-level resource that can be created once and used by many indexes.
- A synonym map applies to string fields.
- You can create and assign a synonym map at any time with no disruption to indexing or queries.
- Your [service tier](#) sets the limits on how many synonym maps you can create.
- Your search service can have multiple synonym maps, but within an index, a field definition can only have one synonym map assignment.

Create a synonym map

A synonym map consists of name, format, and rules that function as synonym map entries. The only format that's supported is `solr`, and the `solr` format determines rule construction.

To create a synonym map, do so programmatically. the Azure portal doesn't support synonym map definitions.

REST

Use the [Create Synonym Map \(REST API\)](#) to create a synonym map.

HTTP

```
POST /synonymmaps?api-version=2024-07-01
{
    "name": "geo-synonyms",
    "format": "solr",
    "synonyms": "
        USA, United States, United States of America\n
        Washington, Wash., WA => WA\n"
}
```

Define rules

Mapping rules adhere to the open-source synonym filter specification of Apache Solr, described in this document: [SynonymGraphFilter](#). The `solr` format supports two kinds of rules:

- equivalency (where terms are equal substitutes in the query)
- explicit mappings (where terms are mapped to one explicit term)

Each rule is delimited by the new line character (`\n`). You can define up to 5,000 rules per synonym map in a free service and 20,000 rules per map in other tiers. Each rule can have up to 20 expansions, or items in a rule. For more information, see [Synonym limits](#).

Query parsers automatically lower-case any upper or mixed case terms. To preserve special characters in the string, such as a comma or dash, add the appropriate escape characters when creating the synonym map.

Equivalency rules

Rules for equivalent terms are comma-delimited within the same rule. In the first example, a query on *USA* expands to *USA* OR *"United States"* OR *"United States of America."* Notice that if you want to match on a phrase, the query itself must be a quote-enclosed phrase query.

In the equivalence case, a query for *dog* expands the query to also include *puppy* and *canine*.

JSON

```
{  
  "format": "solr",  
  "synonyms": "  
    USA, United States, United States of America\n    dog, puppy, canine\n    coffee, latte, cup of joe, java\n"}  
}
```

Explicit mapping

Rules for an explicit mapping are denoted by an arrow `=>`. When specified, a term sequence of a search query that matches the left-hand side of `=>` is replaced with the alternatives on the right-hand side at query time.

In the explicit case, a query for *Washington*, *Wash.* or *WA* is rewritten as *WA*, and the query engine only looks for matches on the term *WA*. Explicit mapping only applies in the direction

specified, and doesn't rewrite the query *WA* to *Washington* in this case.

JSON

```
{  
  "format": "solr",  
  "synonyms": "  
    Washington, Wash., WA => WA\\n  
    California, Calif., CA => CA\\n"  
}
```

Escaping special characters

Synonyms are analyzed during query processing just like any other query term, which means that rules for reserved and special characters apply to the terms in your synonym map. The list of characters that require escaping varies between the simple syntax and full syntax:

- **simple syntax** + | " () ' \
- **full syntax** + - & | ! () { } [] ^ " ~ * ? : \ /

To preserve characters that the default analyzer discards, substitute an analyzer that preserves them. Some choices include Microsoft natural [language analyzers](#), which preserves hyphenated words, or a custom analyzer for more complex patterns. For more information, see [Partial terms, patterns, and special characters](#).

The following example shows an example of how to escape a character with a backslash:

JSON

```
{  
  "format": "solr",  
  "synonyms": "WA\\, USA, WA, Washington\\n"  
}
```

Since the backslash is itself a special character in other languages like JSON and C#, you probably need to double-escape it. Here's an example in JSON:

JSON

```
{  
  "format": "solr",  
  "synonyms": "WA\\\\, USA, WA, Washington"  
}
```

Manage synonym maps

You can update a synonym map without disrupting query and indexing workloads. However, once you add a synonym map to a field, if you then delete a synonym map, any query that includes the fields in question fails with a 404 error.

Creating, updating, and deleting a synonym map is always a whole-document operation. You can't update or delete parts of the synonym map incrementally. Updating even a single rule requires a reload.

Assign synonyms to fields

After you create the synonym map, assign it to a field in your index. To assign synonym maps, do so programmatically. the Azure portal doesn't support synonym map field associations.

- A field must be of type `Edm.String` or `Collection(Edm.String)`
- A field must have `"searchable":true`
- A field can have only one synonym map

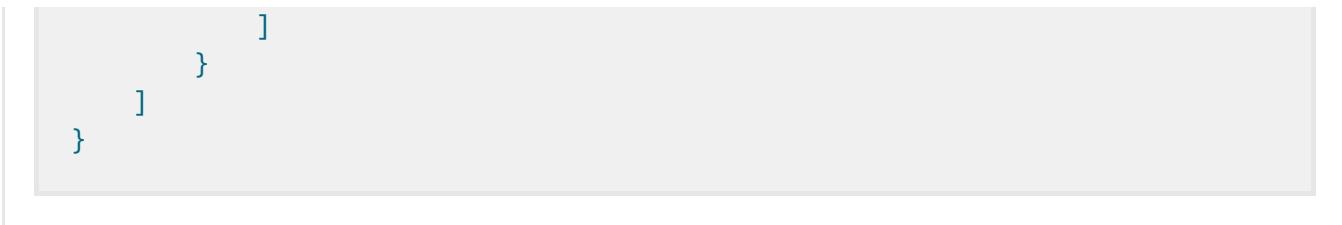

If the synonym map exists on the search service, it's used on the next query, with no reindexing or rebuild required.

REST

Use the [Create or Update Index \(REST API\)](#) to modify a field definition.

HTTP

```
PUT /indexes?api-version=2024-07-01
{
    "name": "hotels-sample-index",
    "fields": [
        {
            "name": "description",
            "type": "Edm.String",
            "searchable": true,
            "synonymMaps": [
                "en-synonyms"
            ]
        },
        {
            "name": "description_fr",
            "type": "Edm.String",
            "searchable": true,
            "analyzer": "fr.microsoft",
            "synonymMaps": [
                "fr-synonyms"
            ]
        }
    ]
}
```

Query on equivalent or mapped fields

A synonym field assignment doesn't change how you write queries. After the synonym map assignment, the only difference is that if a query term exists in the synonym map, the search engine either expands or rewrites the term or phrase, depending on the rule.

How synonyms are used during query execution

Synonyms are a query expansion technique that supplements the contents of an index with equivalent terms, but only for fields that have a synonym assignment. If a field-scoped query *excludes* a synonym-enabled field, you don't see matches from the synonym map.

For synonym-enabled fields, synonyms are subject to the same text analysis as the associated field. For example, if a field is analyzed using the standard Lucene analyzer, synonym terms are also subject to the standard Lucene analyzer at query time. If you want to preserve punctuation, such as periods or dashes, in the synonym term, apply a content-preserving analyzer on the field.

Internally, the synonyms feature rewrites the original query with synonyms by using the OR operator. For this reason, hit highlighting and scoring profiles treat the original term and synonyms as equivalent.

Synonyms apply to free-form text queries only and aren't supported for filters, facets, autocomplete, or suggestions. Autocomplete and suggestions are based only on the original term; synonym matches don't appear in the response.

If you have an existing index in a development (nonproduction) environment, experiment with a small dictionary to see how the addition of synonyms changes the search experience, including impact on scoring profiles, hit highlighting, and suggestions.

Wildcard searches

Synonym expansions don't apply to wildcard search terms; prefix, fuzzy, and regex terms aren't expanded.

If you need to do a single query that applies synonym expansion and wildcard, regex, or fuzzy searches, you can combine the queries using the OR syntax. For example, to combine synonyms with wildcards for simple query syntax, the term would be `<query> | <query>*`.

Next step

[Create a synonym map \(REST API\)](#)

Configure a suggester for autocomplete and suggestions in a query

09/11/2025

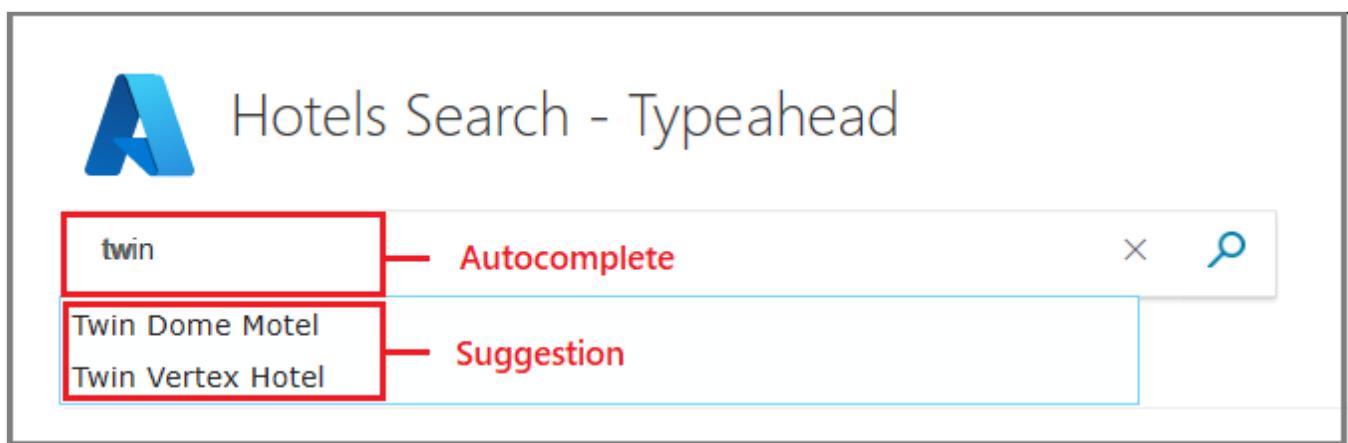

In Azure AI Search, typeahead or "search-as-you-type" is enabled by using a *suggester*. A suggester is a configuration in an index that specifies which fields should be used to populate autocomplete and suggested matches. These fields undergo extra tokenization, generating prefix sequences to support matches on partial terms. For example, a suggester that includes a `city` field with a value for *Seattle* has prefix combinations of *sea*, *seat*, *seatt*, and *seattl* to support typeahead.

Matches on partial terms can be either an autocompleted query or a suggested match. The same suggester supports both experiences.

Typeahead experiences

Typeahead in Azure AI Search can be either *autocomplete*, which completes a partial input for a whole term query, or *suggestions* that invite click through to a particular match. Autocomplete produces a query. Suggestions produce a matching document.

The following screenshot illustrates both. Autocomplete anticipates a potential term, finishing *tw* with *in*. Suggestions are mini search results, where a field like `hotel name` represents a matching hotel search document from the index. For suggestions, you can surface any field that provides descriptive information.

You can use these features separately or together. To implement these behaviors in Azure AI Search, there's an index and query component.

- Add a suggester to a search index definition. The remainder of this article focuses on creating a suggester.

- Call a suggester-enabled query, in the form of a suggestion request or autocomplete request, by using one of the APIs listed in [Use a suggester](#).

Search-as-you-type is enabled on a per-field basis for string fields. You can implement both typeahead behaviors within the same search solution if you want an experience similar to the one indicated in the screenshot. Both requests target the *documents* collection of a specific index, and responses are returned after a user provides at least a three-character input string.

How to create a suggester

To create a suggester, add one to an [index definition](#). A suggester takes a name and a collection of fields over which the typeahead experience is enabled. The best time to create a suggester is when you're also defining the field that uses it.

- Use string fields only.
- If the string field is part of a complex type (for example, a City field within Address), include the parent in the field path: `"Address/City"` (REST, C#, and Python), or `["Address"]["City"]` (JavaScript).
- Use the default standard Lucene analyzer (`"analyzer": null`) or a [language analyzer](#) (for example, `"analyzer": "fr.microsoft"`) on the field.

If you try to create a suggester using preexisting fields, the API disallows it. Prefixes are generated during indexing, when partial terms in two or more character combinations are tokenized alongside whole terms. Given that existing fields are already tokenized, you have to rebuild the index if you want to add them to a suggester. For more information, see [Update or rebuild an index in Azure AI Search](#).

Choose fields

Although a suggester has several properties, it's primarily a collection of string fields for which you're enabling a search-as-you-type experience. There's one suggester for each index, so the suggester list must include all fields that contribute content for both suggestions and autocomplete.

Autocomplete benefits from a larger pool of fields to draw from because the extra content has more term completion potential.

Suggestions, on the other hand, produce better results when your field choice is selective. Remember that the suggestion is a proxy for a search document so pick fields that best represent a single result. Names, titles, or other unique fields that distinguish among multiple

matches work best. If fields consist of repetitive values, the suggestions consist of identical results and a user won't know which one to choose.

To satisfy both search-as-you-type experiences, add all of the fields that you need for autocomplete, but then use `select`, `top`, `filter`, and `searchFields` to control results for suggestions.

Choose analyzers

Your choice of an analyzer determines how fields are tokenized and prefixed. For example, for a hyphenated string like *context-sensitive*, using a language analyzer results in these token combinations: *context*, *sensitive*, *context-sensitive*. Had you used the standard Lucene analyzer, the hyphenated string wouldn't exist.

When evaluating analyzers, consider using the [Analyze Text API](#) for insight into how terms are processed. Once you build an index, you can try various analyzers on a string to view token output.

Fields that use [custom analyzers](#) or [built-in analyzers](#), (except for standard Lucene) are explicitly disallowed to prevent poor outcomes.

! Note

If you need to work around the analyzer constraint, for example if you need a keyword or ngram analyzer for certain query scenarios, you should use two separate fields for the same content. This allows one of the fields to have a suggester, while the other can be set up with a custom analyzer configuration. If you're using an indexer, you can map a source field to two different index fields to support multiple configurations.

Create using the Azure portal

In the Azure portal, you can specify a suggester when you select **Add index**.

1. Select **Add index** and add a string field.
2. Set field attribution to **Searchable**.
3. Select an analyzer.
4. Once fields are defined, select **Autocomplete settings**.
5. Select the searchable string fields for which you want to enable an autocomplete experience.

Create using REST

In the REST API, add suggesters by using [Create Index](#).

JSON

```
{  
  "name": "hotels-sample-index",  
  "fields": [  
    . . .  
    {  
      "name": "HotelName",  
      "type": "Edm.String",  
      "facetable": false,  
      "filterable": false,  
      "key": false,  
      " retrievable": true,  
      "searchable": true,  
      "sortable": false,  
      "analyzer": "en.microsoft",  
      "indexAnalyzer": null,  
      "searchAnalyzer": null,  
      "synonymMaps": [],  
      "fields": []  
    },  
  ],  
  "suggesters": [  
    {  
      "name": "sg",  
      "searchMode": "analyzingInfixMatching",  
      "sourceFields": ["HotelName"]  
    }  
  ],  
  "scoringProfiles": [  
    . . .  
  ]  
}
```

Create using .NET

In C#, define a [SearchSuggester](#) object. `Suggesters` is a collection on a `SearchIndex` object, but it can only take one item. Add a suggester to the index definition.

C#

```
private static void CreateIndex(string indexName, SearchIndexClient indexClient)  
{  
    FieldBuilder fieldBuilder = new FieldBuilder();  
    var searchFields = fieldBuilder.Build(typeof(Hotel));
```

```

var definition = new SearchIndex(indexName, searchFields);

var suggester = new SearchSuggester("sg", new[] { "HotelName", "Category",
"Address/City", "Address/StateProvince" });
definition.Suggesters.Add(suggester);

indexClient.CreateOrUpdateIndex(definition);
}

```

Property reference

[] [Expand table](#)

Property	Description
name	Specified in the suggester definition, but also called on an Autocomplete or Suggestions request.
sourceFields	<p>Specified in the suggester definition. It's a list of one or more fields in the index that are the source of the content for suggestions. Fields must be of type <code>Edm.String</code>. If an analyzer is specified on the field, it must be a named lexical analyzer listed on LexicalAnalyzerName Struct (not a custom analyzer).</p> <p>As a best practice, specify only those fields that lend themselves to an expected and appropriate response, whether it's a completed string in a search bar or a dropdown list.</p> <p>A hotel name is a good candidate because it has precision. Verbose fields like descriptions and comments are too dense. Similarly, repetitive fields, such as categories and tags, are less effective. In the examples, we include <i>category</i> anyway to demonstrate that you can include multiple fields.</p>
searchMode	REST-only parameter, but also visible in the Azure portal. This parameter isn't available in the .NET SDK. It indicates the strategy used to search for candidate phrases. The only mode currently supported is <code>analyzingInfixMatching</code> , which currently matches on the beginning of a term.

Use a suggester

A suggester is used in a query. After a suggester is created, call one of the following APIs for a search-as-you-type experience:

- [Suggest REST API](#)
- [Autocomplete REST API](#)
- [SuggestAsync method](#)
- [AutocompleteAsync method](#)

In a search application, client code should use a library like [jQuery UI Autocomplete](#) to collect the partial query and provide the match. For more information about this task, see [Add autocomplete or suggested results to client code](#).

API usage is illustrated in the following call to the Autocomplete REST API. There are two takeaways from this example. First, as with all queries, the operation is against the documents collection of an index and the query includes a `search` parameter, which in this case provides the partial query. Second, you must add `suggesterName` to the request. If a suggester isn't defined in the index, calls to autocomplete or suggestions fail.

HTTP

```
POST /indexes/myxboxgames/docs/autocomplete?search&api-version=2025-09-01
{
  "search": "minecraf",
  "suggesterName": "sg"
}
```

Sample code

To learn how to use an open source Suggestions package for partial term completion in the client app, see [Explore the .NET search code](#).

Next step

Learn more about request formulation.

[Add autocomplete and search suggestions in client apps](#)

Create an index for multiple languages in Azure AI Search

05/29/2025

If you have strings in multiple languages, you can use [vector search](#) to represent multilingual content mathematically, which is the more modern approach. Alternatively, if you aren't using vectors, you can attach [language analyzers](#) that analyze strings using linguistic rules of a specific language during indexing and query execution. With a language analyzer, you get better handling of diacritics, character variants, punctuation, and word root forms.

Azure AI Search supports Microsoft and Lucene analyzers. By default, the search engine uses Standard Lucene, which is language agnostic. If testing indicates that the default analyzer is insufficient, replace it with a language analyzer.

In Azure AI Search, the two patterns for supporting multiple languages include:

- Create language-specific indexes where all of the human readable content is in the same language, and all searchable string fields are attributed to use the same [language analyzer](#).
- Create a blended index with language-specific versions of each field (for example, `description_en`, `description_fr`, `description_ko`), and then constrain full text search to just those fields at query time. This approach is useful for scenarios where language variants are only needed on a few fields, like a description.

This article focuses on steps and best practices for configuring and querying language-specific fields in a blended index:

- ✓ Define a string field for each language variant.
- ✓ Set a language analyzer on each field.
- ✓ On the query request, set the `searchFields` parameter to specific fields, and then use `select` to return just those fields that have compatible content.

ⓘ Note

If you're using large language models in a retrieval augmented generated (RAG) pattern, you can engineer the prompt to return translated strings. That scenario is out of scope for this article.

Prerequisites

Language analysis applies to fields of type `Edm.String` that are `searchable`, and that contain localized text. If you also need text translation, review the next section to see if AI enrichment meets your needs.

Non-string fields and non-searchable string fields don't undergo lexical analysis and aren't tokenized. Instead, they're stored and returned verbatim.

Add text translation

This article assumes translated strings already exist. If that's not the case, you can attach Azure AI services to an [enrichment pipeline](#), invoking text translation during indexing. Text translation takes a dependency on the indexer feature and Azure AI services, but all setup is done within Azure AI Search.

To add text translation, follow these steps:

1. Verify your content is in a [supported data source](#).
2. [Create a data source](#) that points to your content.
3. [Create a skillset](#) that includes the [Text Translation skill](#).

The Text Translation skill takes a single string as input. If you have multiple fields, can create a skillset that calls Text Translation multiple times, once for each field. Alternatively, you can use the [Text Merger skill](#) to consolidate the content of multiple fields into one long string.

4. Create an index that includes fields for translated strings. Most of this article covers index design and field definitions for indexing and querying multi-language content.
5. [Attach a multi-region Azure AI services resource](#) to your skillset.
6. [Create and run the indexer](#), and then apply the guidance in this article to query just the fields of interest.

💡 Tip

Text translation is built into the [Import data wizard](#). If you have a [supported data source](#) with text you'd like to translate, you can step through the wizard to try out the language detection and translation functionality before writing any code.

Define fields for content in different languages

In Azure AI Search, queries target a single index. Developers who want to provide language-specific strings in a single search experience typically define dedicated fields to store the values: one field for English strings, one for French, and so on.

The `analyzer` property on a field definition is used to set the [language analyzer](#). It's used for both indexing and query execution.

```
JSON

{
  "name": "hotels-sample-index",
  "fields": [
    {
      "name": "Description",
      "type": "Edm.String",
      "retrievable": true,
      "searchable": true,
      "analyzer": "en.microsoft"
    },
    {
      "name": "Description_fr",
      "type": "Edm.String",
      "retrievable": true,
      "searchable": true,
      "analyzer": "fr.microsoft"
    }
  ]
}
```

Build and load an index

An intermediate step is [building and populating the index](#) before formulating a query. We mention this step here for completeness. One way to determine index availability is by checking the indexes list in the [portal](#).

Constrain the query and trim results

Parameters on the query are used to limit search to specific fields and then trim the results of any fields not helpful to your scenario.

[] [Expand table](#)

Parameters	Purpose
<code>searchFields</code>	Limits full text search to the list of named fields.

Parameters	Purpose
<code>select</code>	Trims the response to include only the fields you specify. By default, all retrievable fields are returned. The <code>select</code> parameter lets you choose which ones to return.

Given a goal of constraining search to fields containing French strings, you would use `searchFields` to target the query at fields containing strings in that language.

Specifying the analyzer on a query request isn't necessary. A language analyzer on the field definition determines text analysis during query execution. For queries that specify multiple fields, each invoking different language analyzers, the terms or phrases are processed concurrently by the assigned analyzers for each field.

By default, a search returns all fields that are marked as retrievable. As such, you might want to exclude fields that don't conform to the language-specific search experience you want to provide. Specifically, if you limited search to a field with French strings, you probably want to exclude fields with English strings from your results. Using the `select` query parameter gives you control over which fields are returned to the calling application.

Example in REST

HTTP

```
POST https://[service name].search.windows.net/indexes/hotels-sample-index/docs/search?api-version=2024-07-01
{
    "search": "animaux acceptés",
    "searchFields": "Tags, Description_fr",
    "select": "HotelName, Description_fr, Address/City, Address/StateProvince,
    Tags",
    "count": "true"
}
```

Example in C#

C#

```
private static void RunQueries(SearchClient srchclient)
{
    SearchOptions options;
    SearchResults<Hotel> response;

    options = new SearchOptions()
    {
        IncludeTotalCount = true,
        Filter = "",
    }
```

```

        OrderBy = { "" }  

    };  
  

    options.Select.Add("HotelId");  

    options.Select.Add("HotelName");  

    options.Select.Add("Description_fr");  

    options.SearchFields.Add("Tags");  

    options.SearchFields.Add("Description_fr");  
  

    response = srchclient.Search<Hotel>("*", options);  

    WriteDocuments(response);
}

```

Boost language-specific fields

Sometimes the language of the agent issuing a query isn't known, in which case the query can be issued against all fields simultaneously. IA preference for results in a certain language can be defined using [scoring profiles](#). In the example below, matches found in the description in French are scored higher relative to matches in other languages:

JSON

```

"scoringProfiles": [  

  {  

    "name": "frenchFirst",  

    "text": {  

      "weights": { "description_fr": 2 }
    }
  }
]

```

You would then include the scoring profile in the search request:

HTTP

```

POST /indexes/hotels/docs/search?api-version=2024-07-01  

{  

  "search": "pets allowed",  

  "searchFields": "Tags, Description_fr",  

  "select": "HotelName, Tags, Description_fr",  

  "scoringProfile": "frenchFirst",  

  "count": "true"
}

```

Model complex data types in Azure AI Search

Article • 04/14/2025

External datasets used to populate an Azure AI Search index can come in many shapes. Sometimes they include hierarchical or nested substructures. Examples might include multiple addresses for a single customer, multiple colors and sizes for a single product, multiple authors of a single book, and so on. In modeling terms, you might see these structures referred to as *complex*, *compound*, *composite*, or *aggregate* data types. The term Azure AI Search uses for this concept is **complex type**. In Azure AI Search, complex types are modeled using **complex fields**. A complex field is a field that contains children (subfields) which can be of any data type, including other complex types. This works in a similar way as structured data types in a programming language.

Complex fields represent either a single object in the document, or an array of objects, depending on the data type. Fields of type `Edm.ComplexType` represent single objects, while fields of type `collection(Edm.ComplexType)` represent arrays of objects.

Azure AI Search natively supports complex types and collections. These types allow you to model almost any JSON structure in an Azure AI Search index. In previous versions of Azure AI Search APIs, only flattened row sets could be imported. In the newest version, your index can now more closely correspond to source data. In other words, if your source data has complex types, your index can have complex types also.

To get started, we recommend the [Hotels data set](#), which you can load in the **Import data** wizard in the Azure portal. The wizard detects complex types in the source and suggests an index schema based on the detected structures.

ⓘ Note

Support for complex types became generally available starting in `api-version=2019-05-06`.

If your search solution is built on earlier workarounds of flattened datasets in a collection, you should change your index to include complex types as supported in the newest API version. For more information about upgrading API versions, see [Upgrade to the newest REST API version](#) or [Upgrade to the newest .NET SDK version](#).

Example of a complex structure

The following JSON document is composed of simple fields and complex fields. Complex fields, such as `Address` and `Rooms`, have subfields. `Address` has a single set of values for those subfields, since it's a single object in the document. In contrast, `Rooms` has multiple sets of values for its subfields, one for each object in the collection.

JSON

```
{  
    "HotelId": "1",  
    "HotelName": "Stay-Kay City Hotel",  
    "Description": "Ideally located on the main commercial artery of the city in the heart of New York.",  
    "Tags": ["Free wifi", "on-site parking", "indoor pool", "continental breakfast"],  
    "Address": {  
        "StreetAddress": "677 5th Ave",  
        "City": "New York",  
        "StateProvince": "NY"  
    },  
    "Rooms": [  
        {  
            "Description": "Budget Room, 1 Queen Bed (Cityside)",  
            "RoomNumber": 1105,  
            "BaseRate": 96.99,  
        },  
        {  
            "Description": "Deluxe Room, 2 Double Beds (City View)",  
            "Type": "Deluxe Room",  
            "BaseRate": 150.99,  
        }  
        . . .  
    ]  
}
```

Create complex fields

As with any index definition, you can use the Azure portal, [REST API](#), or [.NET SDK](#) to create a schema that includes complex types.

Other Azure SDKs provide samples in [Python](#), [Java](#), and [JavaScript](#).

Azure portal

1. Sign in to the [Azure portal](#).
2. On the search service **Overview** page, select the **Indexes** tab.

3. Open an existing index or create a new index.
4. Select the **Fields** tab, and then select **Add field**. An empty field is added. If you're working with an existing fields collection, scroll down to set up the field.
5. Give the field a name and set the type to either `Edm.ComplexType` or `Collection(Edm.ComplexType)`.
6. Select the ellipses on the far right, and then select either **Add field** or **Add subfield**, and then assign attributes.

Complex collection limits

During indexing, you can have a maximum of 3,000 elements across all complex collections within a single document. An element of a complex collection is a member of that collection. For Rooms (the only complex collection in the Hotel example), each room is an element. In the example above, if the "Stay-Kay City Hotel" had 500 rooms, the hotel document would have 500 room elements. For nested complex collections, each nested element is also counted, in addition to the outer (parent) element.

This limit applies only to complex collections, and not complex types (like Address) or string collections (like Tags).

Update complex fields

All of the [reindexing rules](#) that apply to fields in general still apply to complex fields. Adding a new field to a complex type doesn't require an index rebuild, but most other modifications do require a rebuild.

Structural updates to the definition

You can add new subfields to a complex field at any time without the need for an index rebuild. For example, adding "ZipCode" to `Address` or "Amenities" to `Rooms` is allowed, just like adding a top-level field to an index. Existing documents have a null value for new fields until you explicitly populate those fields by updating your data.

Notice that within a complex type, each subfield has a type and can have attributes, just as top-level fields do

Data updates

Updating existing documents in an index with the `upload` action works the same way for complex and simple fields: all fields are replaced. However, `merge` (or `mergeOrUpload` when applied to an existing document) doesn't work the same across all fields. Specifically, `merge` doesn't support merging elements within a collection. This limitation exists for collections of primitive types and complex collections. To update a collection, you need to retrieve the full collection value, make changes, and then include the new collection in the Index API request.

Search complex fields in text queries

Free-form search expressions work as expected with complex types. If any searchable field or subfield anywhere in a document matches, then the document itself is a match.

Queries get more nuanced when you have multiple terms and operators, and some terms have field names specified, as is possible with the [Lucene syntax](#). For example, this query attempts to match two terms, "Portland" and "OR", against two subfields of the Address field:

```
search=Address/City:Portland AND Address/State:OR
```

Queries like this are *uncorrelated* for full-text search, unlike filters. In filters, queries over subfields of a complex collection are correlated using range variables in [any or all](#). The Lucene query above returns documents containing both "Portland, Maine" and "Portland, Oregon", along with other cities in Oregon. This happens because each clause applies to all values of its field in the entire document, so there's no concept of a "current subdocument". For more information on this, see [Understanding OData collection filters in Azure AI Search](#).

Search complex fields in RAG queries

A RAG pattern passes search results to a chat model for generative AI and conversational search. By default, search results passed to an LLM are a flattened rowset. However, if your index has complex types, your query can provide those fields if you first convert the search results to JSON, and then pass the JSON to the LLM.

A partial example illustrates the technique:

- Indicate the fields you want in the prompt or in the query
- Make sure the fields are searchable and retrievable in the index
- Select the fields for the search results
- Format the results as JSON
- Send the request for chat completion to the model provider

```

import json

# Query is the question being asked. It's sent to the search engine and the LLM.
query="Can you recommend a few hotels that offer complimentary breakfast? Tell me
their description, address, tags, and the rate for one room they have which sleep
4 people."

# Set up the search results and the chat thread.
# Retrieve the selected fields from the search index related to the question.
selected_fields = ["HotelName", "Description", "Address", "Rooms", "Tags"]
search_results = search_client.search(
    search_text=query,
    top=5,
    select=selected_fields,
    query_type="semantic"
)
sources_filtered = [{field: result[field] for field in selected_fields} for result
in search_results]
sources_formatted = "\n".join([json.dumps(source) for source in sources_filtered])

response = openai_client.chat.completions.create(
    messages=[
        {
            "role": "user",
            "content": GROUNDED_PROMPT.format(query=query,
sources=sources_formatted)
        }
    ],
    model=AZURE_DEPLOYMENT_MODEL
)

print(response.choices[0].message.content)

```

For the end-to-end example, see [Quickstart: Generative search \(RAG\) with grounding data from Azure AI Search](#).

Select complex fields

The `$select` parameter is used to choose which fields are returned in search results. To use this parameter to select specific subfields of a complex field, include the parent field and subfield separated by a slash (/).

```
$select=HotelName, Address/City, Rooms/BaseRate
```

Fields must be marked as Retrievable in the index if you want them in search results. Only fields marked as Retrievable can be used in a `$select` statement.

Filter, facet, and sort complex fields

The same [OData path syntax](#) used for filtering and fielded searches can also be used for faceting, sorting, and selecting fields in a search request. For complex types, rules apply that govern which subfields can be marked as sortable or facetable. For more information on these rules, see the [Create Index API reference](#).

Faceting subfields

Any subfield can be marked as facetable unless it is of type `Edm.GeographyPoint` or `Collection(Edm.GeographyPoint)`.

The document counts returned in the facet results are calculated for the parent document (a hotel), not the subdocuments in a complex collection (rooms). For example, suppose a hotel has 20 rooms of type "suite". Given this facet parameter `facet=Rooms/Type`, the facet count is one for the hotel, not 20 for the rooms.

Sorting complex fields

Sort operations apply to documents (Hotels) and not subdocuments (Rooms). When you have a complex type collection, such as Rooms, it's important to realize that you can't sort on Rooms at all. In fact, you can't sort on any collection.

Sort operations work when fields have a single value per document, whether the field is a simple field, or a subfield in a complex type. For example, `Address/City` is allowed to be sortable because there's only one address per hotel, so `$orderby=Address/City` sorts hotels by city.

Filtering on complex fields

You can refer to subfields of a complex field in a filter expression. Just use the same [OData path syntax](#) that's used for faceting, sorting, and selecting fields. For example, the following filter returns all hotels in Canada:

```
$filter=Address/Country eq 'Canada'
```

To filter on a complex collection field, you can use a **lambda expression** with the [any and all operators](#). In that case, the **range variable** of the lambda expression is an object with subfields. You can refer to those subfields with the standard OData path syntax. For example, the following filter returns all hotels with at least one deluxe room and all nonsmoking rooms:

```
$filter=Rooms/any(room: room/Type eq 'Deluxe Room') and Rooms/all(room: not room/SmokingAllowed)
```

As with top-level simple fields, simple subfields of complex fields can only be included in filters if they have the **filterable** attribute set to `true` in the index definition. For more information, see the [Create Index API reference](#).

Workaround for the complex collection limit

Recall that Azure AI Search limits complex objects in a collection to 3,000 objects per document. Exceeding this limit results in the following message:

```
A collection in your document exceeds the maximum elements across all complex collections limit.  
The document with key '1052' has '4303' objects in collections (JSON arrays).  
At most '3000' objects are allowed to be in collections across the entire document.  
Remove objects from collections and try indexing the document again."
```

If you need more than 3,000 items, you can pipe (`|`) or use any form of delimiter to delimit the values, concatenate them, and store them as a delimited string. There's no limitation on the number of strings stored in an array. Storing complex values as strings bypasses the complex collection limitation.

To illustrate, assume you have a `"searchScope"` array with more than 3,000 elements:

JSON

```
"searchScope": [  
  {  
    "countryCode": "FRA",  
    "productCode": 1234,  
    "categoryCode": "C100"  
  },  
  {  
    "countryCode": "USA",  
    "productCode": 1235,  
    "categoryCode": "C200"  
  }  
  . . .  
]
```

The workaround for storing the values as a delimited string might look like this:

JSON

```
"searchScope": [
    "|FRA|1234|C100|",
    "|FRA|*|*|",
    "|*|1234|*|",
    "|*|*|C100|",
    "|FRA|*|C100|",
    "|*|1234|C100|"
]
```

Storing all of the search variants in the delimited string is helpful in search scenarios where you want to search for items that have just "FRA" or "1234" or another combination within the array.

Here's a filter formatting snippet in C# that converts inputs into searchable strings:

C#

```
foreach (var filterItem in filterCombinations)
{
    var formattedCondition = $"searchScope/any(s: s eq '{filterItem}')";
    combFilter.Append(combFilter.Length > 0 ? " or (" + formattedCondition
+ ")" : "(" + formattedCondition + ")");
}
```

The following list provides inputs and search strings (outputs) side by side:

- For "FRA" county code and the "1234" product code, the formatted output is `|FRA|1234|*|`.
- For "1234" product code, the formatted output is `|*|1234|*|`.
- For "C100" category code, the formatted output is `|*|*|C100|`.

Only provide the wildcard (*) if you're implementing the string array workaround. Otherwise, if you're using a complex type, your filter might look like this example:

C#

```
var countryFilter = $"searchScope/any(ss: search.in(countryCode , 'FRA'))";
var catgFilter = $"searchScope/any(ss: search.in(categoryCode , 'C100'))";
var combinedCountryCategoryFilter = "(" + countryFilter + " and " + catgFilter +
")";
```

If you implement the workaround, be sure to test extensively.

Next steps

Try the [Hotels data set](#) in the **Import data** wizard. You need the Azure Cosmos DB connection information provided in the readme to access the data.

With that information in hand, your first step in the wizard is to create a new Azure Cosmos DB data source. Further on in the wizard, when you get to the target index page, you see an index with complex types. Create and load this index, and then execute queries to understand the new structure.

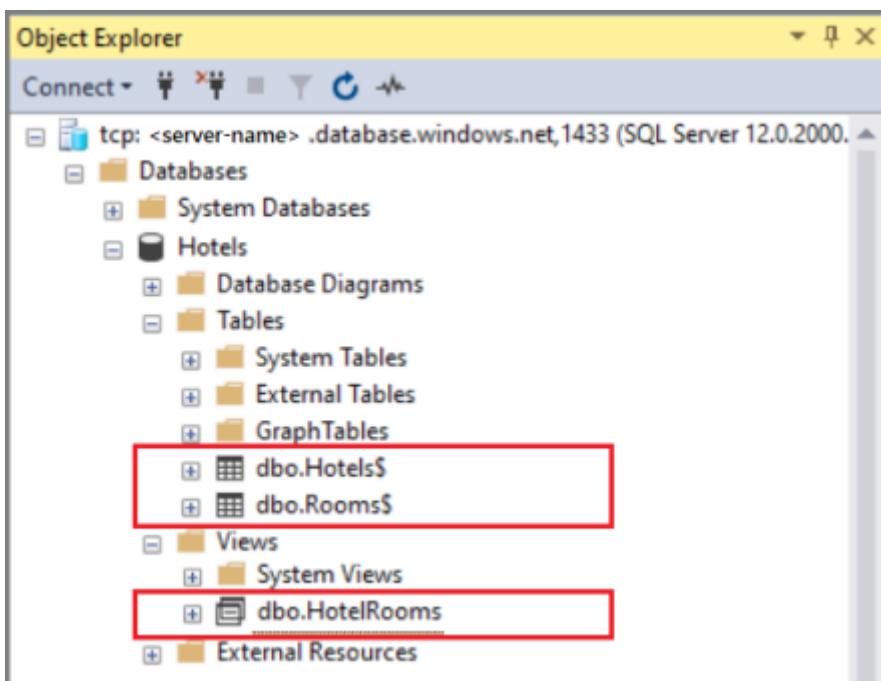

[Quickstart: portal wizard for import, indexing, and queries](#)

How to model relational SQL data for import and indexing in Azure AI Search

07/25/2025

Azure AI Search accepts a flat rowset as input to the [indexing pipeline](#). If your source data originates from joined tables in a SQL Server relational database, this article explains how to construct the rowset, and how to model a parent-child relationship in an Azure AI Search index.

As an illustration, we refer to a hypothetical hotels database, based on [demo data](#). Assume the database consists of a `Hotels$` table with 50 hotels, and a `Rooms$` table with rooms of varying types, rates, and amenities, for a total of 750 rooms. There's a one-to-many relationship between the tables. In our approach, a view provides the query that returns 50 rows, one row per hotel, with associated room detail embedded into each row.

The problem of denormalized data

One of the challenges in working with one-to-many relationships is that standard queries built on joined tables return denormalized data, which doesn't work well in an Azure AI Search scenario. Consider the following example that joins hotels and rooms.

SQL

```
SELECT * FROM Hotels$  
INNER JOIN Rooms$  
ON Rooms$.HotelID = Hotels$.HotelID
```

Results from this query return all of the Hotel fields, followed by all Room fields, with preliminary hotel information repeating for each room value.

Fields from Hotels\$				Fields from Rooms\$				
HotelID	HotelName	Description	State	HotelID	Description	Type	BaseRate	
181	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Standard Room, 1 Queen Bed (City View)	Standard Room	121.99
182	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Budget Room, 1 King Bed (Waterfront View)	Budget Room	88.99
183	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Standard Room, 2 Double Beds (Ctryside)	Standard Room	127.99
184	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Budget Room, 2 Double Beds (Ctryside)	Budget Room	96.99
185	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Budget Room, 1 Queen Bed (Mountain View)	Budget Room	63.99
186	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Standard Room, 1 Queen Bed (Mountain View)	Standard Room	124.99
187	2	Twin Dome Motel	The hotel is situated in a nineteenth century plaza...	FL	2	Standard Room, 1 Queen Bed (Ctryside)	Standard Room	117.99

While this query succeeds on the surface (providing all of the data in a flat rowset), it fails in delivering the right document structure for the expected search experience. During indexing, Azure AI Search creates one search document for each row ingested. If your search documents looked like the above results, you would have perceived duplicates - seven separate documents for the Old Century Hotel alone. A query on "hotels in Florida" would return seven results for just the Old Century Hotel, pushing other relevant hotels deep into the search results.

To get the expected experience of one document per hotel, you should provide a rowset at the right granularity, but with complete information. This article explains how.

Define a query that returns embedded JSON

To deliver the expected search experience, your data set should consist of one row for each search document in Azure AI Search. In our example, we want one row for each hotel, but we also want our users to be able to search on other room-related fields they care about, such as the nightly rate, size and number of beds, or a view of the beach, all of which are part of a room detail.

The solution is to capture the room detail as nested JSON, and then insert the JSON structure into a field in a view, as shown in the second step.

1. Assume you have two joined tables, `Hotels$` and `Rooms$`, that contain details for 50 hotels and 750 rooms and are joined on the `HotelID` field. Individually, these tables contain 50 hotels and 750 related rooms.

SQL

```
CREATE TABLE [dbo].[Hotels$](
    [HotelID] [nchar](10) NOT NULL,
    [HotelName] [nvarchar](255) NULL,
    [Description] [nvarchar](max) NULL,
    [Description_fr] [nvarchar](max) NULL,
    [Category] [nvarchar](255) NULL,
    [Tags] [nvarchar](255) NULL,
    [ParkingIncluded] [float] NULL,
```

```

[SmokingAllowed] [float] NULL,
[LastRenovationDate] [smalldatetime] NULL,
[Rating] [float] NULL,
[StreetAddress] [nvarchar](255) NULL,
[City] [nvarchar](255) NULL,
[State] [nvarchar](255) NULL,
[ZipCode] [nvarchar](255) NULL,
[GeoCoordinates] [nvarchar](255) NULL
) ON [PRIMARY] TEXTIMAGE_ON [PRIMARY]
GO

CREATE TABLE [dbo].[Rooms$](
[HotelID] [nchar](10) NULL,
[Description] [nvarchar](255) NULL,
[Description_fr] [nvarchar](255) NULL,
[Type] [nvarchar](255) NULL,
[BaseRate] [float] NULL,
[BedOptions] [nvarchar](255) NULL,
[SleepsCount] [float] NULL,
[SmokingAllowed] [float] NULL,
[Tags] [nvarchar](255) NULL
) ON [PRIMARY]
GO

```

2. Create a view composed of all fields in the parent table (`SELECT * from dbo.Hotels$`), with the addition of a new *Rooms* field that contains the output of a nested query. A **FOR JSON AUTO** clause on `SELECT * from dbo.Rooms$` structures the output as JSON.

SQL

```

CREATE VIEW [dbo].[HotelRooms]
AS
SELECT *, (SELECT *
            FROM dbo.Rooms$
           WHERE dbo.Rooms$.HotelID = dbo.Hotels$.HotelID FOR JSON AUTO) AS
Rooms
FROM dbo.Hotels$
GO

```

The following screenshot shows the resulting view, with the *Rooms* nvarchar field at the bottom. The *Rooms* field exists only in the HotelRooms view.

The screenshot shows the SQL Server Object Explorer with the following hierarchy:

- Views
- + System Views
- + dbo.HotelRooms
- + Columns
- + HotelID (nchar(10), not null)
- + HotelName (nvarchar(255), null)
- + Description (nvarchar(max), null)
- + Description_fr (nvarchar(max), null)
- + Category (nvarchar(255), null)
- + Tags (nvarchar(255), null)
- + ParkingIncluded (float, null)
- + SmokingAllowed (float, null)
- + LastRenovationDate (smalldatetime, null)
- + Rating (float, null)
- + StreetAddress (nvarchar(255), null)
- + City (nvarchar(255), null)
- + State (nvarchar(255), null)
- + ZipCode (nvarchar(255), null)
- + GeoCoordinates (nvarchar(255), null)
- + Rooms (nvarchar(max), null) Rooms

3. Run `SELECT * FROM dbo.HotelRooms` to retrieve the row set. This query returns 50 rows, one per hotel, with associated room information as a JSON collection.

The screenshot shows the SQL Server Management Studio Results pane with the following data:

Query executed successfully. tcp:azs-playground.database... findable (111) | Hotels | 00:00:00 | 50 rows

This rowset is now ready for import into Azure AI Search.

! Note

This approach assumes that embedded JSON is under the [maximum column size limits of SQL Server](#).

Use a complex collection for the "many" side of a one-to-many relationship

On the Azure AI Search side, create an index schema that models the one-to-many relationship using nested JSON. The result set you created in the previous section generally corresponds to the index schema provided next (we cut some fields for brevity).

The following example is similar to the example in [How to model complex data types](#). The *Rooms* structure, which has been the focus of this article, is in the fields collection of an index named *hotels*. This example also shows a complex type for *Address*, which differs from *Rooms* in that it's composed of a fixed set of items, as opposed to the multiple, arbitrary number of items allowed in a collection.

JSON

```
{  
    "name": "hotels",  
    "fields": [  
        { "name": "HotelId", "type": "Edm.String", "key": true, "filterable": true },  
        { "name": "HotelName", "type": "Edm.String", "searchable": true, "filterable":  
false },  
        { "name": "Description", "type": "Edm.String", "searchable": true, "analyzer":  
"en.lucene" },  
        { "name": "Description_fr", "type": "Edm.String", "searchable": true,  
"analyzer": "fr.lucene" },  
        { "name": "Category", "type": "Edm.String", "searchable": true, "filterable":  
true, "facetable": true },  
        { "name": "ParkingIncluded", "type": "Edm.Boolean", "filterable": true,  
"facetable": true },  
        { "name": "Tags", "type": "Collection(Edm.String)", "searchable": true,  
"filterable": true, "facetable": true },  
        { "name": "Address", "type": "Edm.ComplexType",  
            "fields": [  
                { "name": "StreetAddress", "type": "Edm.String", "filterable": false,  
"sortable": false, "facetable": false, "searchable": true },  
                { "name": "City", "type": "Edm.String", "searchable": true, "filterable":  
true, "sortable": true, "facetable": true },  
                { "name": "StateProvince", "type": "Edm.String", "searchable": true,  
"filterable": true, "sortable": true, "facetable": true }  
            ]  
        },  
        { "name": "Rooms", "type": "Collection(Edm.ComplexType)",  
            "fields": [  
                { "name": "Description", "type": "Edm.String", "searchable": true,

"facetable": true },  
                { "name": "BedOptions", "type": "Edm.String", "searchable": true,  
"filterable": true, "facetable": false },  
                { "name": "SleepsCount", "type": "Edm.Int32", "filterable": true,  
"facetable": true },  
                { "name": "SmokingAllowed", "type": "Edm.Boolean", "filterable": true,  
"facetable": false},  
                { "name": "Tags", "type": "Edm.Collection", "searchable": true }  
            ]  
        }  
    ]  
}
```

```
]  
}
```

Given the previous result set and the above index schema, you have all the required components for a successful indexing operation. The flattened data set meets indexing requirements yet preserves detail information. In the Azure AI Search index, search results fall easily into hotel-based entities, while preserving the context of individual rooms and their attributes.

Facet behavior on complex type subfields

Fields that have a parent, such as the fields under Address and Rooms, are called *subfields*. Although you can assign a "facetable" attribute to a subfield, the count of the facet is always for the main document.

For complex types like Address, where there's just one "Address/City" or "Address/stateProvince" in the document, the facet behavior works as expected. However, in the case of Rooms, where there are multiple subdocuments for each main document, the facet counts can be misleading.

As noted in [Model complex types](#): "the document counts returned in the facet results are calculated for the parent document (a hotel), not the subdocuments in a complex collection (rooms). For example, suppose a hotel has 20 rooms of type "suite". Given this facet parameter facet=Rooms/Type, the facet count is one for the hotel, not 20 for the rooms."

Next steps

Using your own data set, you can use the [Import data wizard](#) to create and load the index. The wizard detects the embedded JSON collection, such as the one contained in *Rooms*, and infers an index schema that includes a complex type collection.

Analyzers for text processing in Azure AI Search

07/11/2025

An *analyzer* is a component of the [full text search engine](#) that's responsible for processing strings during indexing and query execution. Text processing (also known as lexical analysis) is transformative, modifying a string through actions such as these:

- Remove non-essential words ([stopwords](#)) and punctuation
- Split up phrases and hyphenated words into component parts
- Lower-case any upper-case words
- Reduce words into primitive root forms for storage efficiency and so that matches can be found regardless of tense

The output of a lexical analyzer is a sequence of [tokens](#).

Lexical analysis applies to `Edm.String` fields that are marked as "searchable", which indicates full text search. For fields of this configuration, analysis occurs during indexing when tokens are created, and then again during query execution when queries are parsed and the engine scans for matching tokens. A match is more likely to occur when the same analyzer is used for both indexing and queries, but you can set the analyzer for each workload independently, depending on your requirements.

Query types that are *not* full text search, such as filters or fuzzy search, don't go through the analysis phase on the query side. Instead, the parser sends those strings directly to the search engine, using the pattern that you provide as the basis for the match. Typically, these query forms require whole-string tokens to make pattern matching work. To ensure whole term tokens are preserved during indexing, you might need [custom analyzers](#). For more information about when and why query terms are analyzed, see [Full text search in Azure AI Search](#).

For more background on lexical analysis, listen to the following video clip for a brief explanation.

https://www.youtube-nocookie.com/embed/Y_X6USgvB1g?version=3&start=132&end=189

Default analyzer

In Azure AI Search, an analyzer is automatically invoked on all string fields marked as searchable.

By default, Azure AI Search uses the [Apache Lucene Standard analyzer \(standard lucene\)](#), which breaks text into elements following the "Unicode Text Segmentation" rules. The standard analyzer converts all characters to their lower case form. Both indexed documents and search terms go through the analysis during indexing and query processing.

You can override the default on a field-by-field basis. Alternative analyzers are:

- [language analyzer](#) for linguistic processing
- [custom analyzer](#) for custom configurations
- [built-in analyzers](#) for as-is usage

Types of analyzers

The following list describes which analyzers are available in Azure AI Search.

[] [Expand table](#)

Category	Description
Standard Lucene analyzer	Default. No specification or configuration is required. This general-purpose analyzer performs well for many languages and scenarios.
Built-in analyzers	Consumed as-is and referenced by name. There are two types: language and language-agnostic. Specialized (language-agnostic) analyzers are used when text inputs require specialized processing or minimal processing. Examples of analyzers in this category include Asciifolding , Keyword , Pattern , Simple , Stop , Whitespace . Language analyzers are used when you need rich linguistic support for individual languages. Azure AI Search supports 35 Lucene language analyzers and 50 Microsoft natural language processing analyzers.
Custom analyzers	Refers to a user-defined configuration of a combination of existing elements, consisting of one tokenizer (required) and optional filters (char or token).

A few built-in analyzers, such as [Pattern](#) or [Stop](#), support a limited set of configuration options. To set these options, create a custom analyzer, consisting of the built-in analyzer and one of the alternative options documented in [Built-in analyzers](#). As with any custom configuration, provide your new configuration with a name, such as `myPatternAnalyzer` to distinguish it from the Lucene Pattern analyzer.

Specifying analyzers

Setting an analyzer is optional. As a general rule, try using the default standard Lucene analyzer first to see how it performs. If queries fail to return the expected results, switching to a different analyzer is often the right solution.

1. If you're using a custom analyzer, add it to the search index under the "analyzer" section.

For more information, see [Create Index](#) and also [Add custom analyzers](#).

2. When defining a field, set its "analyzer" property to one of the following: a [built-in analyzer](#) such as `keyword`, a [language analyzer](#) such as `en.microsoft`, or a custom analyzer (defined in the same index schema).

JSON

```
"fields": [  
  {  
    "name": "Description",  
    "type": "Edm.String",  
    "retrievable": true,  
    "searchable": true,  
    "analyzer": "en.microsoft",  
    "indexAnalyzer": null,  
    "searchAnalyzer": null  
  },
```

3. If you're using a [language analyzer](#), you must use the "analyzer" property to specify it. The "searchAnalyzer" and "indexAnalyzer" properties don't apply to language analyzers.

4. Alternatively, set "indexAnalyzer" and "searchAnalyzer" to vary the analyzer for each workload. These properties work together as a substitute for the "analyzer" property, which must be null. You might use different analyzers for indexing and queries if one of those activities required a specific transformation not needed by the other.

JSON

```
"fields": [  
  {  
    "name": "ProductGroup",  
    "type": "Edm.String",  
    "retrievable": true,  
    "searchable": true,  
    "analyzer": null,  
    "indexAnalyzer": "keyword",  
    "searchAnalyzer": "standard"  
  },
```

When to add analyzers

The best time to add and assign analyzers is during active development, when dropping and recreating indexes is routine.

Because analyzers are used to tokenize terms, you should assign an analyzer when the field is created. In fact, assigning an analyzer or indexAnalyzer to a field that has already been physically created isn't allowed (although you can change the searchAnalyzer property at any time with no impact to the index).

To change the analyzer of an existing field, you'll have to drop and recreate the entire index (you can't rebuild individual fields). For indexes in production, you can defer a rebuild by creating a new field with the new analyzer assignment, and start using it in place of the old one. Use [Update Index](#) to incorporate the new field and [mergeOrUpload](#) to populate it. Later, as part of planned index servicing, you can clean up the index to remove obsolete fields.

To add a new field to an existing index, call [Update Index](#) to add the field, and [mergeOrUpload](#) to populate it.

To add a custom analyzer to an existing index, pass the "allowIndexDowntime" flag in [Update Index](#) if you want to avoid this error:

```
"Index update not allowed because it would cause downtime. In order to add new analyzers, tokenizers, token filters, or character filters to an existing index, set the 'allowIndexDowntime' query parameter to 'true' in the index update request. Note that this operation will put your index offline for at least a few seconds, causing your indexing and query requests to fail. Performance and write availability of the index can be impaired for several minutes after the index is updated, or longer for very large indexes."
```

Recommendations for working with analyzers

This section offers advice on how to work with analyzers.

One analyzer for read-write unless you have specific requirements

Azure AI Search lets you specify different analyzers for indexing and search through the "indexAnalyzer" and "searchAnalyzer" field properties. If unspecified, the analyzer set with the analyzer property is used for both indexing and searching. If the analyzer is unspecified, the default Standard Lucene analyzer is used.

A general rule is to use the same analyzer for both indexing and querying, unless specific requirements dictate otherwise. Be sure to test thoroughly. When text processing differs at

search and indexing time, you run the risk of mismatch between query terms and indexed terms when the search and indexing analyzer configurations aren't aligned.

Test during active development

Overriding the standard analyzer requires an index rebuild. If possible, decide on which analyzers to use during active development, before rolling an index into production.

Inspect tokenized terms

If a search fails to return expected results, the most likely scenario is token discrepancies between term inputs on the query, and tokenized terms in the index. If the tokens aren't the same, matches fail to materialize. To inspect tokenizer output, we recommend using the [Analyze API](#) as an investigation tool. The response consists of tokens, as generated by a specific analyzer.

REST examples

The examples below show analyzer definitions for a few key scenarios.

- [Custom analyzer example](#)
- [Assign analyzers to a field example](#)
- [Mixing analyzers for indexing and search](#)
- [Language analyzer example](#)

Custom analyzer example

This example illustrates an analyzer definition with custom options. Custom options for char filters, tokenizers, and token filters are specified separately as named constructs, and then referenced in the analyzer definition. Predefined elements are used as-is and referenced by name.

Walking through this example:

- Analyzers are a property of the field class for a searchable field.
- A custom analyzer is part of an index definition. It might be lightly customized (for example, customizing a single option in one filter) or customized in multiple places.
- In this case, the custom analyzer is "my_analyzer", which in turn uses a customized standard tokenizer "my_standard_tokenizer" and two token filters: lowercase and customized asciifolding filter "my_asciifolding".

- It also defines 2 custom char filters "map_dash" and "remove_whitespace". The first one replaces all dashes with underscores while the second one removes all spaces. Spaces need to be UTF-8 encoded in the mapping rules. The char filters are applied before tokenization and will affect the resulting tokens (the standard tokenizer breaks on dash and spaces but not on underscore).

JSON

```
{
  "name": "myindex",
  "fields": [
    {
      "name": "id",
      "type": "Edm.String",
      "key": true,
      "searchable": false
    },
    {
      "name": "text",
      "type": "Edm.String",
      "searchable": true,
      "analyzer": "my_analyzer"
    }
  ],
  "analyzers": [
    {
      "name": "my_analyzer",
      "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
      "charFilters": [
        "map_dash",
        "remove_whitespace"
      ],
      "tokenizer": "my_standard_tokenizer",
      "tokenFilters": [
        "my_asciifolding",
        "lowercase"
      ]
    }
  ],
  "charFilters": [
    {
      "name": "map_dash",
      "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",
      "mappings": [ "-=>_"]
    },
    {
      "name": "remove_whitespace",
      "@odata.type": "#Microsoft.Azure.Search.MappingCharFilter",
      "mappings": [ "\u0020=>"]
    }
  ],
  "tokenizers": [
  ]}
```

```
        "name": "my_standard_tokenizer",
        "@odata.type": "#Microsoft.Azure.Search.StandardTokenizerV2",
        "maxTokenLength": 20
    },
],
"tokenFilters": [
{
    "name": "my_asciifolding",
    "@odata.type": "#Microsoft.Azure.Search.AsciiFoldingTokenFilter",
    "preserveOriginal": true
}
]
}
```

Per-field analyzer assignment example

The Standard analyzer is the default. Suppose you want to replace the default with a different predefined analyzer, such as the pattern analyzer. If you aren't setting custom options, you only need to specify it by name in the field definition.

The "analyzer" element overrides the Standard analyzer on a field-by-field basis. There is no global override. In this example, `text1` uses the pattern analyzer and `text2`, which doesn't specify an analyzer, uses the default.

JSON

```
{
  "name": "myindex",
  "fields": [
    {
      "name": "id",
      "type": "Edm.String",
      "key": true,
      "searchable": false
    },
    {
      "name": "text1",
      "type": "Edm.String",
      "searchable": true,
      "analyzer": "pattern"
    },
    {
      "name": "text2",
      "type": "Edm.String",
      "searchable": true
    }
  ]
}
```

Mixing analyzers for indexing and search operations

The APIs include index attributes for specifying different analyzers for indexing and search. The searchAnalyzer and indexAnalyzer attributes must be specified as a pair, replacing the single analyzer attribute.

JSON

```
{  
  "name": "myindex",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true,  
      "searchable": false  
    },  
    {  
      "name": "text",  
      "type": "Edm.String",  
      "searchable": true,  
      "indexAnalyzer": "whitespace",  
      "searchAnalyzer": "simple"  
    },  
  ],  
}
```

Language analyzer example

Fields containing strings in different languages can use a language analyzer, while other fields retain the default (or use some other predefined or custom analyzer). If you use a language analyzer, it must be used for both indexing and search operations. Fields that use a language analyzer can't have different analyzers for indexing and search.

JSON

```
{  
  "name": "myindex",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true,  
      "searchable": false  
    },  
    {  
      "name": "text",  
      "type": "Edm.String",  
      "searchable": true,  
      "indexAnalyzer": "language",  
      "searchAnalyzer": "language"  
    },  
  ],  
}
```

```
        "indexAnalyzer": "whitespace",
        "searchAnalyzer": "simple"
    },
{
    "name": "text_fr",
    "type": "Edm.String",
    "searchable": true,
    "analyzer": "fr.lucene"
}
],
}
```

C# examples

If you are using the .NET SDK code samples, you can append these examples to use or configure analyzers.

- [Assign a built-in analyzer](#)
- [Configure an analyzer](#)

Assign a language analyzer

Any analyzer that is used as-is, with no configuration, is specified on a field definition. There is no requirement for creating an entry in the [analyzers] section of the index.

Language analyzers are used as-is. To use them, call [LexicalAnalyzer](#), specifying the [LexicalAnalyzerName](#) type providing a text analyzer supported in Azure AI Search.

Custom analyzers are similarly specified on the field definition, but for this to work you must specify the analyzer in the index definition, as described in the next section.

C#

```
public partial class Hotel
{
    ...
    [SearchableField(AnalyzerName = LexicalAnalyzerName.EnLucene)]
    public string Description { get; set; }

    [SearchableField(AnalyzerName = LexicalAnalyzerName.FrLucene)]
    [JsonPropertyName("Description_fr")]
    public string DescriptionFr { get; set; }

    [SearchableField(AnalyzerName = "url-analyze")]
    public string Url { get; set; }
    ...
}
```

Define a custom analyzer

When customization or configuration is required, add an analyzer construct to an index. Once you define it, you can add it to the field definition as demonstrated in the previous example.

Create a [CustomAnalyzer](#) object. A custom analyzer is a user-defined combination of a known tokenizer, zero or more token filter, and zero or more character filter names:

- [CustomAnalyzer.Tokenizer](#)
- [CustomAnalyzer.TokenFilters](#)
- [CustomAnalyzer.CharFilters](#)

The following example creates a custom analyzer named "url-analyze" that uses the [uax_url_email](#) tokenizer and the [Lowercase](#) token filter.

C#

```
private static void CreateIndex(string indexName, SearchIndexClient adminClient)
{
    FieldBuilder fieldBuilder = new FieldBuilder();
    var searchFields = fieldBuilder.Build(typeof(Hotel));

    var analyzer = new CustomAnalyzer("url-analyze",
LexicalTokenizerName.UaxUrlEmail)
    {
        TokenFilters = { LexicalTokenFilterName.Lowercase }
    };

    var definition = new SearchIndex(indexName, searchFields);

    definition.Analyzers.Add(analyzer);

    adminClient.CreateOrUpdateIndex(definition);
}
```

Next steps

A detailed description of query execution can be found in [Full text search in Azure AI Search](#). The article uses examples to explain behaviors that might seem counter-intuitive on the surface.

To learn more about analyzers, see the following articles:

- [Add a custom analyzer](#)
- [Create a search index](#)

- Create a multi-language index

Add language analyzers to string fields in an Azure AI Search index

06/16/2025

A *language analyzer* is a specific type of [text analyzer](#) that performs lexical analysis using the linguistic rules of the target language. Every searchable string field has an **analyzer** property. If your content consists of translated strings, such as separate fields for English and Chinese text, you could specify language analyzers on each field to access the rich linguistic capabilities of those analyzers.

When to use a language analyzer

You should consider a language analyzer in classic search workflows that don't include large language models and their awareness of linguistic rules and multilingual content.

In class search, you might add a language analyzer when awareness of word or sentence structure adds value to text parsing. A common example is the association of irregular verb forms ("bring" and "brought) or plural nouns ("mice" and "mouse"). Without linguistic awareness, these strings are parsed on physical characteristics alone, which fails to catch the connection. Since large chunks of text are more likely to have this content, fields consisting of descriptions, reviews, or summaries are good candidates for a language analyzer.

You might also consider language analyzers when content consists of non-Western language strings. While the [default analyzer \(Standard Lucene\)](#) is language-agnostic, the concept of using spaces and special characters (hyphens and slashes) to separate strings is more applicable to Western languages than non-Western ones.

For example, in Chinese, Japanese, Korean (CJK), and other Asian languages, a space isn't necessarily a word delimiter. Consider the following Japanese string. Because it has no spaces, a language-agnostic analyzer would likely analyze the entire string as one token, when in fact the string is actually a phrase.

これは私たちの銀河系の中ではもっとも重く明るいクラスの球状星団です。
(This is the heaviest and brightest group of spherical stars in our galaxy.)

For the example above, a successful query would have to include the full token, or a partial token using a suffix wildcard, resulting in an unnatural and limiting search experience.

A better experience is to search for individual words: 明るい (Bright), 私たちの (Our), 銀河系 (Galaxy). Using one of the Japanese analyzers available in Azure AI Search is more likely to unlock this behavior because those analyzers are better equipped at splitting the chunk of text into meaningful words in the target language.

Comparing Lucene and Microsoft Analyzers

Azure AI Search supports 35 language analyzers backed by Lucene, and 50 language analyzers backed by proprietary Microsoft natural language processing technology used in Office and Bing.

Some developers might prefer the open-source solution of Lucene. Lucene language analyzers are faster, but the Microsoft analyzers have advanced capabilities, such as lemmatization, word decompounding (in languages like German, Danish, Dutch, Swedish, Norwegian, Estonian, Finnish, Hungarian, Slovak) and entity recognition (URLs, emails, dates, numbers). If possible, you should run comparisons of both the Microsoft and Lucene analyzers to decide which one is a better fit. You can use [Analyze API](#) to see the tokens generated from a given text using a specific analyzer.

Indexing with Microsoft analyzers is on average two to three times slower than their Lucene equivalents, depending on the language. Search performance shouldn't be significantly affected for average size queries.

English analyzers

The default analyzer is Standard Lucene, which works well for English, but perhaps not as well as Lucene's English analyzer or Microsoft's English analyzer.

- Lucene's English analyzer extends the Standard analyzer. It removes possessives (trailing 's) from words, applies stemming as per Porter Stemming algorithm, and removes English stop words.
- Microsoft's English analyzer performs lemmatization instead of stemming. This means it can handle inflected and irregular word forms much better which results in more relevant search results.

How to specify a language analyzer

Set the analyzer during index creation before it's loaded with data.

1. In the field definition, make sure the field is attributed as "searchable" and is of type Edm.String.

- Set the "analyzer" property to one of the language analyzers from the [supported analyzers list](#).

The "analyzer" property is the only property that will accept a language analyzer, and it's used for both indexing and queries. Other analyzer-related properties ("searchAnalyzer" and "indexAnalyzer") won't accept a language analyzer.

Language analyzers can't be customized. If an analyzer isn't meeting your requirements, create a [custom analyzer](#) with the `microsoft_language_tokenizer` or `microsoft_language_stemming_tokenizer`, and then add filters for pre- and post-tokenization processing.

The following example illustrates a language analyzer specification in an index:

JSON

```
{  
  "name": "hotels-sample-index",  
  "fields": [  
    {  
      "name": "Description",  
      "type": "Edm.String",  
      "retrievable": true,  
      "searchable": true,  
      "analyzer": "en.microsoft",  
      "indexAnalyzer": null,  
      "searchAnalyzer": null  
    },  
    {  
      "name": "Description_fr",  
      "type": "Edm.String",  
      "retrievable": true,  
      "searchable": true,  
      "analyzer": "fr.microsoft",  
      "indexAnalyzer": null,  
      "searchAnalyzer": null  
    },  
  ]}
```

For more information about creating an index and setting field properties, see [Create Index \(REST\)](#). For more information about text analysis, see [Analyzers in Azure AI Search](#).

Supported language analyzers

Below is the list of supported languages, with Lucene and Microsoft analyzer names.

[] Expand table

Language	Microsoft Analyzer Name	Lucene Analyzer Name
Arabic	ar.microsoft	ar.lucene
Armenian		hy.lucene
Bangla	bn.microsoft	
Basque		eu.lucene
Bulgarian	bg.microsoft	bg.lucene
Catalan	ca.microsoft	ca.lucene

Add custom analyzers to string fields in an Azure AI Search index

06/16/2025

A *custom analyzer* is a component of lexical analysis over plain text content. It's a user-defined combination of one tokenizer, one or more token filters, and one or more character filters. A custom analyzer is specified within a search index, and then referenced by name on field definitions that require custom analysis. A custom analyzer is invoked on a per-field basis. Attributes on the field determine whether it's used for indexing, queries, or both.

In a custom analyzer, character filters prepare the input text before it's processed by the tokenizer (for example, removing markup). Next, the tokenizer breaks text into tokens. Finally, token filters modify the tokens emitted by the tokenizer. For concepts and examples, see [Analyzers in Azure AI Search](#) and [Tutorial: Create a custom analyzer for phone numbers](#).

Why use a custom analyzer?

You should consider a custom analyzer in classic search workflows that don't include large language models and their ability to handle content anomalies.

In class search, a custom analyzer gives you control over the process of converting plain text into indexable and searchable tokens by allowing you to choose which types of analysis or filtering to invoke, and the order in which they occur.

Create and assign a custom analyzer if none of default (Standard Lucene), built-in, or language analyzers are sufficient for your needs. You might also create a custom analyzer if you want to use a built-in analyzer with custom options. For example, if you wanted to change the `maxTokenLength` on Standard Lucene, you would create a custom analyzer, with a user-defined name, to set that option.

Scenarios where custom analyzers can be helpful include:

- Using character filters to remove HTML markup before text inputs are tokenized, or replace certain characters or symbols.
- Phonetic search. Add a phonetic filter to enable searching based on how a word sounds, not how it's spelled.
- Disable lexical analysis. Use the Keyword analyzer to create searchable fields that aren't analyzed.

- Fast prefix/suffix search. Add the Edge N-gram token filter to index prefixes of words to enable fast prefix matching. Combine it with the Reverse token filter to do suffix matching.
- Custom tokenization. For example, use the Whitespace tokenizer to break sentences into tokens using whitespace as a delimiter
- ASCII folding. Add the Standard ASCII folding filter to normalize diacritics like ö or ê in search terms.

 **Note**

Custom analyzers aren't exposed in the Azure portal. The only way to add a custom analyzer is through code that [creates an index schema](#).

Create a custom analyzer

To create a custom analyzer, specify it in the `analyzers` section of an index at design time, and then reference it on searchable, `Edm.String` fields using either the `analyzer` property, or the `indexAnalyzer` and `searchAnalyzer` pair.

An analyzer definition includes a name, type, one or more character filters, a maximum of one tokenizer, and one or more token filters for post-tokenization processing. Character filters are applied before tokenization. Token filters and character filters are applied from left to right.

- Names in a custom analyzer must be unique and can't be the same as any of the built-in analyzers, tokenizers, token filters, or characters filters. Names consist of letters, digits, spaces, dashes, or underscores. Names must start and end with plain text characters. Names must be under 128 characters in length.
- Type must be `#Microsoft.Azure.Search.CustomAnalyzer`.
- `charFilters` can be one or more filters from [Character Filters](#), processed before tokenization, in the order provided. Some character filters have options, which can be set in a `charFilters` section. Character filters are optional.
- `tokenizer` is exactly one [Tokenizer](#). A value is required. If you need more than one tokenizer, you can create multiple custom analyzers and assign them on a field-by-field basis in your index schema.
- `tokenFilters` can be one or more filters from [Token Filters](#), processed after tokenization, in the order provided. For token filters that have options, add a `tokenFilter` section to

specify the configuration. Token filters are optional.

Analyzers must not produce tokens longer than 300 characters, or indexing will fail. To trim long token or to exclude them, use the **TruncateTokenFilter** and the **LengthTokenFilter** respectively. See [Token filters](#) for reference.

JSON

```
"analyzers":(optional)[
  {
    "name":"name of analyzer",
    "@odata.type": "#Microsoft.Azure.Search.CustomAnalyzer",
    "charFilters":[
      "char_filter_name_1",
      "char_filter_name_2"
    ],
    "tokenizer":"tokenizer_name",
    "tokenFilters":[
      "token_filter_name_1",
      "token_filter_name_2"
    ]
  },
  {
    "name":"name of analyzer",
    "@odata.type": "#analyzer_type",
    "option1":value1,
    "option2":value2,
    ...
  }
],
"charFilters":(optional)[
  {
    "name":"char_filter_name",
    "@odata.type": "#char_filter_type",
    "option1":value1,
    "option2":value2,
    ...
  }
],
"tokenizers":(optional)[
  {
    "name":"tokenizer_name",
    "@odata.type": "#tokenizer_type",
    "option1":value1,
    "option2":value2,
    ...
  }
],
"tokenFilters":(optional)[
  {
    "name":"token_filter_name",
    "@odata.type": "#token_filter_type",
    "option1":value1,
```

```
        "option2":value2,  
        ...  
    }  
]
```

Within an index definition, you can place this section anywhere in the body of a create index request but usually it goes at the end:

JSON

```
{  
    "name": "name_of_index",  
    "fields": [ ],  
    "suggesters": [ ],  
    "scoringProfiles": [ ],  
    "defaultScoringProfile": (optional) "...",  
    "corsOptions": (optional) { },  
    "analyzers":(optional)[ ],  
    "charFilters":(optional)[ ],  
    "tokenizers":(optional)[ ],  
    "tokenFilters":(optional)[ ]  
}
```

The analyzer definition is a part of the larger index. Definitions for char filters, tokenizers, and token filters are added to the index only if you're setting custom options. To use an existing filter or tokenizer as-is, specify it by name in the analyzer definition. For more information, see [Create Index \(REST\)](#). For more examples, see [Add analyzers in Azure AI Search](#).

Test custom analyzers

You can use the [Test Analyzer \(REST\)](#) to see how an analyzer breaks given text into tokens.

Request

HTTP

```
POST https://[search service name].search.windows.net/indexes/[index  
name]/analyze?api-version=[api-version]  
Content-Type: application/json  
api-key: [admin key]  
  
{  
    "analyzer": "my_analyzer",  
    "text": "Vis-à-vis means Opposite"  
}
```

Response

HTTP

```
{  
  "tokens": [  
    {  
      "token": "vis_a_vis",  
      "startOffset": 0,  
      "endOffset": 9,  
      "position": 0  
    },  
    {  
      "token": "vis_à_vis",  
      "startOffset": 0,  
      "endOffset": 9,  
      "position": 0  
    },  
    {  
      "token": "means",  
      "startOffset": 10,  
      "endOffset": 15,  
      "position": 1  
    },  
    {  
      "token": "opposite",  
      "startOffset": 16,  
      "endOffset": 24,  
      "position": 2  
    }  
  ]  
}
```

Update custom analyzers

Once an analyzer, a tokenizer, a token filter, or a character filter is defined, it can't be modified. New ones can be added to an existing index only if the `allowIndexDowntime` flag is set to true in the index update request:

HTTP

```
PUT https://[search service name].search.windows.net/indexes/[index name]?api-version=[api-version]&allowIndexDowntime=true
```

This operation takes your index offline for at least a few seconds, causing your indexing and query requests to fail. Performance and write availability of the index can be impaired for several minutes after the index is updated, or longer for very large indexes, but these effects are temporary and eventually resolve on their own.

Built-in analyzers

If you want to use a built-in analyzer with custom options, creating a custom analyzer is the mechanism by which you specify those options. In contrast, to use a built-in analyzer as-is, you simply need to [reference it by name](#) in the field definition.

[\[+\] Expand table](#)

analyzer_name	analyzer_type ¹	Description and Options
keyword	(type applies only when options are available)	Treats the entire content of a field as a single token. This is useful for data like zip codes, IDs, and some product names.
pattern	PatternAnalyzer	Flexibly separates text into terms via a regular expression pattern. Options lowercase (type: bool) - Determines whether terms are lowercased. The default is true. pattern (type: string) - A regular expression pattern to match token separators. The default is <code>\W+</code> , which matches non-word characters. flags (type: string) - Regular expression flags. The default is an empty string. Allowed values: CANON_EQ, CASE_INSENSITIVE, COMMENTS, DOTALL, LITERAL, MULTILINE, UNICODE_CASE, UNIX_LINES stopwords (type: string array) - A list of stopwords. The default is an empty list.
simple	(type applies only when options are available)	Divides text at non-letters and converts them to lower case.
standard (Also referred to as standard.lucene)	StandardAnalyzer	Standard Lucene analyzer, composed of the standard tokenizer, lowercase filter, and stop filter. Options maxTokenLength (type: int) - The maximum token length. The default is 255. Tokens longer than the maximum length are split. Maximum token length that can be used is 300 characters.

analyzer_name	analyzer_type ¹	Description and Options
		stopwords (type: string array) - A list of stopwords. The default is an empty list.
standardascifolding.lucene	(type applies only when options are available)	Standard analyzer with Ascii folding filter.
stop ↗	StopAnalyzer	Divides text at non-letters, applies the lowercase and stopword token filters.
		Options
		stopwords (type: string array) - A list of stopwords. The default is a predefined list for English.
whitespace ↗	(type applies only when options are available)	An analyzer that uses the whitespace tokenizer. Tokens that are longer than 255 characters are split.

¹ Analyzer Types are always prefixed in code with `#Microsoft.Azure.Search` such that `PatternAnalyzer` would actually be specified as `#Microsoft.Azure.Search.PatternAnalyzer`. We removed the prefix for brevity, but the prefix is required in your code.

The analyzer_type is only provided for analyzers that can be customized. If there are no options, as is the case with the keyword analyzer, there's no associated `#Microsoft.Azure.Search` type.

Character filters

Character filters add processing before a string reaches the tokenizer.

Azure AI Search supports character filters in the following list. More information about each one can be found in the Lucene API reference.

 [Expand table](#)

char_filter_name	char_filter_type ¹	Description and Options
html_strip ↗	(type applies only when options are available)	A char filter that attempts to strip out HTML constructs.
mapping ↗	MappingCharFilter	A char filter that applies mappings defined with the mappings option. Matching is greedy (longest pattern

char_filter_name	char_filter_type ¹	Description and Options
		<p>matching at a given point wins). Replacement is allowed to be the empty string.</p> <p>Options</p> <p>mappings (type: string array) - A list of mappings of the following format: <code>a=>b</code> (all occurrences of the character <code>a</code> are replaced with character <code>b</code>). Required.</p>
pattern_replace	PatternReplaceCharFilter	<p>A char filter that replaces characters in the input string. It uses a regular expression to identify character sequences to preserve and a replacement pattern to identify characters to replace. For example, input text = <code>aa bb aa bb</code>, pattern= <code>(aa)\\s+(bb)</code> replacement= <code>\$1#\$2</code>, result = <code>aa#bb aa#bb</code>.</p> <p>Options</p> <p>pattern (type: string) - Required.</p> <p>replacement (type: string) - Required.</p>

¹ Char Filter Types are always prefixed in code with `#Microsoft.Azure.Search` such that `MappingCharFilter` would actually be specified as `#Microsoft.Azure.Search.MappingCharFilter`. We removed the prefix to reduce the width of the table, but remember to include it in your code. Notice that `char_filter_type` is only provided for filters that can be customized. If there are no options, as is the case with `html_strip`, there's no associated `#Microsoft.Azure.Search` type.

Tokenizers

A tokenizer divides continuous text into a sequence of tokens, such as breaking a sentence into words, or a word into root forms.

Azure AI Search supports tokenizers in the following list. More information about each one can be found in the Lucene API reference.

[Expand table](#)

tokenizer_name	tokenizer_type ¹	Description and Options
classic	ClassicTokenizer	Grammar based tokenizer that is suitable for

tokenizer_name	tokenizer_type ¹	Description and Options
		<p>processing most European-language documents.</p> <p>Options</p> <p>maxTokenLength (type: int) - The maximum token length. Default: 255, maximum: 300. Tokens longer than the maximum length are split.</p>
edgeNGram	EdgeNGramTokenizer	<p>Tokenizes the input from an edge into n-grams of given sizes.</p> <p>Options</p> <p>minGram (type: int) - Default: 1, maximum: 300.</p> <p>maxGram (type: int) - Default: 2, maximum: 300. Must be greater than minGram.</p> <p>tokenChars (type: string array) - Character classes to keep in the tokens. Allowed values: <code>letter</code>, <code>digit</code>, <code>whitespace</code>, <code>punctuation</code>, <code>symbol</code>. Defaults to an empty array - keeps all characters.</p>
keyword_v2	KeywordTokenizerV2	<p>Emits the entire input as a single token.</p> <p>Options</p>

tokenizer_name	tokenizer_type ¹	Description and Options
		maxTokenLength (type: int) - The maximum token length. Default: 256, maximum: 300. Tokens longer than the maximum length are split.
letter	(type applies only when options are available)	Divides text at non-letters. Tokens that are longer than 255 characters are split.
lowercase	(type applies only when options are available)	Divides text at non-letters and converts them to lower case. Tokens that are longer than 255 characters are split.
microsoft_language_tokenizer	MicrosoftLanguageTokenizer	Divides text using language-specific rules.
		<p>Options</p> <p>maxTokenLength (type: int) - The maximum token length, default: 255, maximum: 300. Tokens longer than the maximum length are split. Tokens longer than 300 characters are first split into tokens of length 300 and then each of those tokens is split based on the maxTokenLength set.</p> <p>isSearchTokenizer (type: bool) - Set to true if used as the</p>

tokenizer_name	tokenizer_type ¹	Description and Options
		<p>search tokenizer, set to false if used as the indexing tokenizer.</p> <p>language (type: string) - Language to use, default <code>english</code>. tokenizer_name	tokenizer_type ¹	Description and Options
	<p>maxTokenLength (type: int) - The maximum token length, default: 255, maximum: 300.</p> <p>Tokens longer than the maximum length are split. Tokens longer than 300 characters are first split into tokens of length 300 and then each of those tokens is split based on the maxTokenLength set.</p> <p>isSearchTokenizer (type: bool) - Set to true if used as the search tokenizer, set to false if used as the indexing tokenizer.</p> <p>language (type: string) - Language to use, default <code>english</code>. Allowed values include:</p> <ul style="list-style-type: none"> <code>arabic</code>, <code>bangla</code>, <code>bulgarian</code>, <code>catalan</code>, <code>croatian</code>, <code>czech</code>, <code>danish</code>, <code>dutch</code>, <code>english</code>, <code>estonian</code>, <code>finnish</code>, <code>french</code>, <code>german</code>, <code>greek</code>, <code>gujarati</code>, <code>hebrew</code>, <code>hindi</code>, <code>hungarian</code>, <code>icelandic</code>, <code>indonesian</code>, <code>italian</code>, <code>kannada</code>, <code>latvian</code>, <code>lithuanian</code>, <code>malay</code>, <code>malayalam</code>, <code>marathi</code>, <code>norwegianBokmaal</code>, <code>polish</code>, <code>portuguese</code>, <code>portugueseBrazilian</code>, <code>punjabi</code>, <code>romanian</code>, 	

tokenizer_name	tokenizer_type ¹	Description and Options
		russian, serbianCyrillic, serbianLatin, slovak, slovenian, spanish, swedish, tamil, telugu, turkish, ukrainian, urdu
nGram ↗	NGramTokenizer	<p>Tokenizes the input into n-grams of the given sizes.</p> <p>Options</p> <p>minGram (type: int) - Default: 1, maximum: 300.</p> <p>maxGram (type: int) - Default: 2, maximum: 300. Must be greater than minGram.</p> <p>tokenChars (type: string array) - Character classes to keep in the tokens. Allowed values: letter, digit, whitespace, punctuation, symbol. Defaults to an empty array - keeps all characters.</p>
path_hierarchy_v2 ↗	PathHierarchyTokenizerV2	<p>Tokenizer for path-like hierarchies.</p> <p>Options</p> <p>delimiter (type: string) - Default: '/.</p> <p>replacement (type: string) - If set, replaces the delimiter character.</p>

tokenizer_name	tokenizer_type ¹	Description and Options
		<p>Default same as the value of delimiter.</p> <p>maxTokenLength (type: int) - The maximum token length. Default: 300, maximum: 300. Paths longer than maxTokenLength are ignored.</p> <p>reverse (type: bool) - If true, generates token in reverse order. Default: false.</p> <p>skip (type: bool) - Initial tokens to skip. The default is 0.</p>
pattern ↴	PatternTokenizer	<p>This tokenizer uses regex pattern matching to construct distinct tokens.</p> <p>Options</p> <p>pattern ↴ (type: string) - Regular expression pattern to match token separators. The default is <code>\W+</code>, which matches non-word characters.</p> <p>flags ↴ (type: string) - Regular expression flags. The default is an empty string. Allowed values: CANON_EQ, CASE_INSENSITIVE, COMMENTS, DOTALL, LITERAL,</p>

tokenizer_name	tokenizer_type ¹	Description and Options
	MULTILINE, UNICODE_CASE, UNIX_LINES	
		group (type: int) - Which group to extract into tokens. The default is -1 (split).
standard_v2 ↗	StandardTokenizerV2	Breaks text following the Unicode Text Segmentation rules ↗ .
		Options
		maxTokenLength (type: int) - The maximum token length. Default: 255, maximum: 300. Tokens longer than the maximum length are split.
uax_url_email ↗	UaxUrlEmailTokenizer	Tokenizes urls and emails as one token.
		Options
		maxTokenLength (type: int) - The maximum token length. Default: 255, maximum: 300. Tokens longer than the maximum length are split.
whitespace ↗	(type applies only when options are available)	Divides text at whitespace. Tokens that are longer than 255 characters are split.

¹ Tokenizer Types are always prefixed in code with `#Microsoft.Azure.Search` such that `ClassicTokenizer` would actually be specified as `#Microsoft.Azure.Search.ClassicTokenizer`. We removed the prefix to reduce the width of the table, but remember to include it in your code. Notice that `tokenizer_type` is only provided for tokenizers that can be customized. If there are no options, as is the case with the letter tokenizer, there's no associated `#Microsoft.Azure.Search` type.

Token filters

A token filter is used to filter out or modify the tokens generated by a tokenizer. For example, you can specify a lowercase filter that converts all characters to lowercase. You can have multiple token filters in a custom analyzer. Token filters run in the order in which they're listed.

In the following table, the token filters that are implemented using Apache Lucene are linked to the Lucene API documentation.

[+] Expand table

token_filter_name	token_filter_type ¹	Description and Options
arabic_normalization ↴	(type applies only when options are available)	A token filter that applies the Arabic normalizer to normalize the orthography.
apostrophe ↴	(type applies only when options are available)	Strips all characters after an apostrophe (including the apostrophe itself).
asciifolding ↴	AsciiFoldingTokenFilter	Converts alphabetic, numeric, and symbolic Unicode characters which aren't in the first 127 ASCII characters (the <code>Basic Latin</code> Unicode block) into their ASCII equivalents, if one exists.
		Options
		preserveOriginal (type: bool) - If true, the original token is kept. The default is false.
cjk_bigram ↴	CjkBigramTokenFilter	Forms bigrams of CJK terms that are generated from StandardTokenizer.

<code>token_filter_name</code>	<code>token_filter_type</code> ¹	Description and Options
		<p>Options</p> <p><code>ignoreScripts</code> (type: string array) - Scripts to ignore. Allowed values include: <code>han</code>, <code>hiragana</code>, <code>katakana</code>, <code>hangul</code>. The default is an empty list.</p> <p><code>outputUnigrams</code> (type: bool) - Set to true if you always want to output both unigrams and bigrams. The default is false.</p>
cjk_width	(type applies only when options are available)	Normalizes CJK width differences. Folds full width ASCII variants into the equivalent basic Latin and half-width Katakana variants into the equivalent kana.
classic	(type applies only when options are available)	Removes the English possessives, and dots from acronyms.
common_grams	CommonGramTokenFilter	<p>Construct bigrams for frequently occurring terms while indexing. Single terms are still indexed too, with bigrams overlaid.</p> <p>Options</p> <p><code>commonWords</code> (type: string array) - The set of common words. The default is an empty list. Required.</p> <p><code>ignoreCase</code> (type: bool) - If true, matching is case insensitive. The default is false.</p> <p><code>queryMode</code> (type: bool) - Generates bigrams then removes common words and single terms followed by a common word. The default is false.</p>

token_filter_name	token_filter_type ¹	Description and Options
dictionary_decompounder	DictionaryDecompounderTokenFilter	<p>Decomposes compound words found in many Germanic languages.</p> <p>Options</p> <p>wordList (type: string array) - The list of words to match against. The default is an empty list. Required.</p> <p>minWordSize (type: int) - Only words longer than this will be processed. The default is 5.</p> <p>minSubwordSize (type: int) - Only subwords longer than this will be outputted. The default is 2.</p> <p>maxSubwordSize (type: int) - Only subwords shorter than this will be outputted. The default is 15.</p> <p>onlyLongestMatch (type: bool) - Add only the longest matching subword to output. The default is false.</p>
edgeNGram_v2	EdgeNGramTokenFilterV2	<p>Generates n-grams of the given sizes from starting from the front or the back of an input token.</p> <p>Options</p> <p>minGram (type: int) - Default: 1, maximum: 300.</p> <p>maxGram (type: int) - Default: 2, maximum 300. Must be greater than minGram.</p> <p>side (type: string) - Specifies which side of the input the n-gram should be generated</p>

<code>token_filter_name</code>	<code>token_filter_type</code> ¹	Description and Options
		from. Allowed values: <code>front</code> , <code>back</code>
elision	ElisionTokenFilter	<p>Removes elisions. For example, <code>l'avion</code> (the plane) is converted to <code>avion</code> (plane).</p> <p>Options</p> <p><code>articles</code> (type: string array) - A set of articles to remove. The default is an empty list. If there's no list of articles set, by default all French articles are removed.</p>
german_normalization	(type applies only when options are available)	Normalizes German characters according to the heuristics of the German2 snowball algorithm .
hindi_normalization	(type applies only when options are available)	Normalizes text in Hindi to remove some differences in spelling variations.
indic_normalization	IndicNormalizationTokenFilter	Normalizes the Unicode representation of text in Indian languages.
keep	KeepTokenFilter	<p>A token filter that only keeps tokens with text contained in specified list of words.</p> <p>Options</p> <p><code>keepWords</code> (type: string array) - A list of words to keep. The default is an empty list. Required.</p> <p><code>keepWordsCase</code> (type: bool) - If true, lower case all words first. The default is false.</p>
keyword_marker	KeywordMarkerTokenFilter	Marks terms as keywords.
		Options
		<code>keywords</code> (type: string array) -

token_filter_name	token_filter_type ¹	Description and Options
		A list of words to mark as keywords. The default is an empty list. Required.
		ignoreCase (type: bool) - If true, lower case all words first. The default is false.
keyword_repeat ↗	(type applies only when options are available)	Emits each incoming token twice once as keyword and once as non-keyword.
kstem ↗	(type applies only when options are available)	A high-performance <code>kstem</code> filter for English.
length ↗	LengthTokenFilter	Removes words that are too long or too short.
		Options
		min (type: int) - The minimum number. Default: 0, maximum: 300.
		max (type: int) - The maximum number. Default: 300, maximum: 300.
limit ↗	Microsoft.Azure.Search.LimitTokenFilter	Limits the number of tokens while indexing.
		Options
		maxTokenCount (type: int) - Max number of tokens to produce. The default is 1.
		consumeAllTokens (type: bool) - Whether all tokens from the input must be consumed even if maxTokenCount is reached. The default is false.
lowercase ↗	(type applies only when options are available)	Normalizes token text to lower case.
nGram_v2 ↗	NGramTokenFilterV2	Generates n-grams of the given sizes.

token_filter_name	token_filter_type ¹	Description and Options
		<p>Options</p> <p>minGram (type: int) - Default: 1, maximum: 300.</p> <p>maxGram (type: int) - Default: 2, maximum 300. Must be greater than minGram.</p>
pattern_capture	PatternCaptureTokenFilter	<p>Uses Java regexes to emit multiple tokens, one for each capture group in one or more patterns.</p> <p>Options</p> <p>patterns (type: string array) - A list of patterns to match against each token. Required.</p> <p>preserveOriginal (type: bool) - Set to true to return the original token even if one of the patterns matches, default: true</p>
pattern_replace	PatternReplaceTokenFilter	<p>A token filter which applies a pattern to each token in the stream, replacing match occurrences with the specified replacement string.</p> <p>Options</p> <p>pattern (type: string) - Required.</p> <p>replacement (type: string) - Required.</p>
persian_normalization	(type applies only when options are available)	Applies normalization for Persian.
phonetic	PhoneticTokenFilter	Create tokens for phonetic matches.
		<p>Options</p>

token_filter_name	token_filter_type ¹	Description and Options
		<p>encoder (type: string) - Phonetic encoder to use. Allowed values include: metaphone, doubleMetaphone, soundex, refinedSoundex, caverphone1, caverphone2, cologne, nysiis, koelnerPhonetik, haasePhonetik, beiderMorse. Default: metaphone. Default is metaphone.</p> <p>See encoder for more information.</p>
		<p>replace (type: bool) - True if encoded tokens should replace original tokens, false if they should be added as synonyms. The default is true.</p>
porter_stem	(type applies only when options are available)	Transforms the token stream as per the Porter stemming algorithm .
reverse	(type applies only when options are available)	Reverses the token string.
scandinavian_normalization	(type applies only when options are available)	Normalizes use of the interchangeable Scandinavian characters.
scandinavian_folding	(type applies only when options are available)	Folds Scandinavian characters åÅääää into a and ööøø into o. It also discriminates against use of double vowels aa, ae, ao, oe and oo, leaving just the first one.
shingle	ShingleTokenFilter	<p>Creates combinations of tokens as a single token.</p> <p>Options</p> <p>maxShingleSize (type: int) - Defaults to 2.</p> <p>minShingleSize (type: int) -</p>

<code>token_filter_name</code>	<code>token_filter_type</code> ¹	Description and Options
		Defaults to 2.
		<p><code>outputUnigrams</code> (type: bool) - if true, the output stream contains the input tokens (unigrams) as well as shingles. The default is true.</p> <p><code>outputUnigramsIfNoShingles</code> (type: bool) - If true, override the behavior of <code>outputUnigrams==false</code> for those times when no shingles are available. The default is false.</p> <p><code>tokenSeparator</code> (type: string) - The string to use when joining adjacent tokens to form a shingle. The default is a single empty space <code> </code>.</p> <p><code>filterToken</code> (type: string) - The string to insert for each position for which there's no token. The default is <code>_</code>.</p>
snowball ↗	SnowballTokenFilter	<p>Snowball Token Filter.</p> <p>Options</p> <p><code>language</code> (type: string) - Allowed values include:</p> <ul style="list-style-type: none"> <code>armenian</code>, <code>basque</code>, <code>catalan</code>, <code>danish</code>, <code>dutch</code>, <code>english</code>, <code>finnish</code>, <code>french</code>, <code>german</code>, <code>german2</code>, <code>hungarian</code>, <code>italian</code>, <code>kp</code>, <code>lovins</code>, <code>norwegian</code>, <code>porter</code>, <code>portuguese</code>, <code>romanian</code>, <code>russian</code>, <code>spanish</code>, <code>swedish</code>, <code>turkish</code>
sorani_normalization ↗	SoraniNormalizationTokenFilter	<p>Normalizes the Unicode representation of <code>Sorani</code> text.</p> <p>Options</p> <p>None.</p>

token_filter_name	token_filter_type ¹	Description and Options
stemmer	StemmerTokenFilter	<p>Language-specific stemming filter.</p> <p>Options</p> <p>language (type: string) - Allowed values include:</p> <ul style="list-style-type: none"> - arabic - armenian - basque - brazilian - bulgarian - catalan - czech - danish - dutch - dutchKp - english - lightEnglish - minimalEnglish - possessiveEnglish - porter2 - lovins - finnish - lightFinnish - french - lightFrench - minimalFrench - galician - minimalGalician - german - german2 - lightGerman - minimalGerman - greek - hindi - hungarian - lightHungarian - indonesian - irish - italian - lightItalian - sorani - latvian - norwegian - lightNorwegian - minimalNorwegian

token_filter_name	token_filter_type ¹	Description and Options
		<ul style="list-style-type: none"> - lightNynorsk - minimalNynorsk - portuguese - lightPortuguese - minimalPortuguese - portugueseRslp - romanian - russian - lightRussian - spanish - lightSpanish - swedish - lightSwedish - turkish
stemmer_override	StemmerOverrideTokenFilter	<p>Any dictionary-Stemmed terms are marked as keywords, which prevents stemming down the chain. Must be placed before any stemming filters.</p> <p>Options</p> <p>rules (type: string array) - Stemming rules in the following format <code>word => stem</code> for example <code>ran => run</code>. The default is an empty list. Required.</p>
stopwords	StopwordsTokenFilter	<p>Removes stop words from a token stream. By default, the filter uses a predefined stop word list for English.</p> <p>Options</p> <p>stopwords (type: string array) - A list of stopwords. Can't be specified if a <code>stopwordsList</code> is specified.</p> <p>stopwordsList (type: string) - A predefined list of stopwords. Can't be specified if <code>stopwords</code> is specified. Allowed values include: <code>arabic</code>, <code>armenian</code>, <code>basque</code>, <code>brazilian</code>, <code>bulgarian</code>,</p>

token_filter_name	token_filter_type ¹	Description and Options
		<p>catalan, czech, danish, dutch, english, finnish, french, galician, german, greek, hindi, hungarian, indonesian, irish, italian, latvian, norwegian, persian, portuguese, romanian, russian, sorani, spanish, swedish, thai, turkish, default: english. Can't be specified if stopwords is specified.</p> <p>ignoreCase (type: bool) - If true, all words are lower cased first. The default is false.</p> <p>removeTrailing (type: bool) - If true, ignore the last search term if it's a stop word. The default is true.</p>
synonym ↗	SynonymTokenFilter	<p>Matches single or multi word synonyms in a token stream.</p> <p>Options</p> <p>synonyms (type: string array) - Required. List of synonyms in one of the following two formats:</p> <ul style="list-style-type: none"> -incredible, unbelievable, fabulous => amazing - all terms on the left side of => symbol are replaced with all terms on its right side. -incredible, unbelievable, fabulous, amazing - A comma-separated list of equivalent words. Set the expand option to change how this list is interpreted. <p>ignoreCase (type: bool) - Case-folds input for matching. The default is false.</p>

token_filter_name	token_filter_type ¹	Description and Options
		<p>expand (type: bool) - If true, all words in the list of synonyms (if => notation isn't used) map to one another.</p> <p>The following list: incredible, unbelievable, fabulous, amazing is equivalent to: incredible, unbelievable, fabulous, amazing => incredible, unbelievable, fabulous, amazing</p> <p>- If false, the following list: incredible, unbelievable, fabulous, amazing are equivalent to: incredible, unbelievable, fabulous, amazing => incredible.</p>
trim ↗	(type applies only when options are available)	Trims leading and trailing whitespace from tokens.
truncate ↗	TruncateTokenFilter	<p>Truncates the terms into a specific length.</p> <p>Options</p> <p>length (type: int) - Default: 300, maximum: 300. Required.</p>
unique ↗	UniqueTokenFilter	<p>Filters out tokens with same text as the previous token.</p> <p>Options</p> <p>onlyOnSamePosition (type: bool) - If set, remove duplicates only at the same position. The default is true.</p>
uppercase ↗	(type applies only when options are available)	Normalizes token text to uppercase.
word_delimiter ↗	WordDelimiterTokenFilter	Splits words into subwords and performs optional transformations on subword groups.

token_filter_name	token_filter_type ¹	Description and Options
		Options
		generateWordParts (type: bool) - Causes parts of words to be generated, for example AzureSearch becomes Azure Search. The default is true.
		generateNumberParts (type: bool) - Causes number subwords to be generated. The default is true.
		catenateWords (type: bool) - Causes maximum runs of word parts to be catenated, for example Azure-Search becomes AzureSearch. The default is false.
		catenateNumbers (type: bool) - Causes maximum runs of number parts to be catenated, for example 1-2 becomes 12. The default is false.
		catenateAll (type: bool) - Causes all subword parts to be catenated, e.g. Azure-Search-1 becomes AzureSearch1. The default is false.
		splitOnCaseChange (type: bool) - If true, splits words on caseChange, for example AzureSearch becomes Azure Search. The default is true.
		preserveOriginal - Causes original words to be preserved and added to the subword list. The default is false.
		splitOnNumerics (type: bool) - If true, splits on numbers, for example Azure1Search becomes Azure 1 Search. The

<code>token_filter_name</code>	<code>token_filter_type</code> ¹	Description and Options
		default is true.
		stemEnglishPossessive (type: bool) - Causes trailing 's to be removed for each subword. The default is true.
		protectedWords (type: string array) - Tokens to protect from being delimited. The default is an empty list.

¹ Token Filter Types are always prefixed in code with `#Microsoft.Azure.Search` such that `ArabicNormalizationTokenFilter` would actually be specified as `#Microsoft.Azure.Search.ArabicNormalizationTokenFilter`. We removed the prefix to reduce the width of the table, but remember to include it in your code.

Create a vector index

09/28/2025

In Azure AI Search, you can use [Create or Update Index \(REST API\)](#) to store vectors in a search index. A vector index is defined by an index schema that has vector fields, nonvector fields, and a vector configuration section.

When you create a vector index, you implicitly create an *embedding space* that serves as the corpus for vector queries. The embedding space consists of all vector fields populated with embeddings from the same embedding model. At query time, the system compares the vector query to the indexed vectors, returning results based on semantic similarity.

To index vectors in Azure AI Search, follow these steps:

- ✓ Start with a basic schema definition.
- ✓ Add vector algorithms and optional compression.
- ✓ Add vector field definitions.
- ✓ Load prevectorized data as a [separate step](#) or use [integrated vectorization](#) for data chunking and embedding during indexing.

This article uses REST for illustration. After you understand the basic workflow, continue with the Azure SDK code samples in the [azure-search-vector-samples](#) repo, which provides guidance on using vectors in test and production code.

Tip

You can also use the Azure portal to [create a vector index](#) and try out integrated data chunking and vectorization.

Prerequisites

- An [Azure AI Search service](#) in any region and on any tier. If you plan to use [integrated vectorization](#) with Azure AI skills and vectorizers, Azure AI Search must be in the same region as the embedding models hosted on Azure AI Vision.
- Your source documents must have [vector embeddings](#) to upload to the index. You can also use [integrated vectorization](#) for this step.
- You should know the dimensions limit of the model that creates the embeddings so that you can assign that limit to the vector field. For `text-embedding-ada-002`, dimensions are

fixed at 1536. For [text-embedding-3-small](#) or [text-embedding-3-large](#), dimensions range from 1 to 1536 and from 1 to 3072, respectively.

- You should know what similarity metric to use. For embedding models on Azure OpenAI, similarity is computed using [cosine](#).
- You should know how to [create an index](#). A schema always includes a field for the document key, fields for search or filters, and other configurations for behaviors needed during indexing and queries.

Limitations

Some search services created before January 2019 can't create a vector index. If this applies to you, create a new service to use vectors.

Prepare documents for indexing

Before indexing, assemble a document payload that includes fields of vector and nonvector data. The document structure must conform to the `fields` collection of index schema.

Make sure your source documents provide the following content:

 Expand table

Content	Description
Unique identifier	A field or a metadata property that uniquely identifies each document. All search indexes require a document key. To satisfy document key requirements, a source document must have one field or property uniquely identifies it in the index. If you're indexing blobs, it might be the <code>metadata_storage_path</code> that uniquely identifies each blob. If you're indexing from a database, it might be primary key. This source field must be mapped to an index field of type <code>Edm.String</code> and <code>key=true</code> in the search index.
Non-vector content	Provide other fields with human-readable content. Human-readable content is useful for the query response and for hybrid queries that include full-text search or semantic ranking in the same request. If you're using a chat completion model, most models like ChatGPT expect human-readable text and don't accept raw vectors as input.
Vector content	A vectorized representation of your nonvector content for use at query time. A vector is an array of single-precision floating point numbers generated by an embedding model. Each vector field contains a model-generated array. There's one embedding per field, where the field is a top-level field (not part of a nested or complex type). For simple integration, we recommend embedding models in Azure OpenAI , such as text-embedding-3 for text documents or the Image Retrieval REST API for images and multimodal embeddings.

If you can use indexers and skillsets, consider [integrated vectorization](#), which encodes

Content	Description
	images and text during indexing. Your field definitions are for vector fields, but incoming source data can be text or images, which are converted to vector arrays during indexing.

Your search index should include fields and content for all of the query scenarios you want to support. Suppose you want to search or filter over product names, versions, metadata, or addresses. In this case, vector similarity search isn't especially helpful. Keyword search, geo-search, or filters that iterate over verbatim content would be a better choice. A search index that's inclusive of both vector and nonvector fields provides maximum flexibility for query construction and response composition.

For a short example of a documents payload that includes vector and nonvector fields, see the [load vector data](#) section of this article.

Start with a basic index

Start with a minimum schema so that you have a definition to work with before adding a vector configuration and vector fields. A simple index might look the following example. For more information about an index schema, see [Create a search index](#).

Notice that the index has a required name, a required document key (`"key": true`), and fields for human-readable content in plain text. It's common to have a human-readable version of whatever content you intend to vectorize. For example, if you have a chunk of text from a PDF file, your index schema should have a field for plain-text chunks and a second field for vectorized chunks.

Here's a basic index with a `"name"`, a `"fields"` collection, and some other constructs for extra configuration:

HTTP

```
POST https://[servicename].search.windows.net/indexes?api-version=[api-version]
{
  "name": "example-index",
  "description": "This is an example index."
  "fields": [
    { "name": "documentId", "type": "Edm.String", "key": true, "retrievable": true, "searchable": true, "filterable": true },
    { "name": "myHumanReadableNameField", "type": "Edm.String", "retrievable": true, "searchable": true, "filterable": false, "sortable": true, "facetable": false },
    { "name": "myHumanReadableContentField", "type": "Edm.String", "retrievable": true, "searchable": true, "filterable": false, "sortable": false, "facetable": false, "analyzer": "en.microsoft" },
  ],
}
```

```
"analyzers": [ ],
"scoringProfiles": [ ],
"suggesters": [ ],
"vectorSearch": [ ]
}
```

Add a vector search configuration

Next, add a `"vectorSearch"` configuration to your schema. It's useful to specify a configuration before field definitions, because the profiles you define here become part of the vector field's definition. In the schema, vector configuration is typically inserted after the fields collection, perhaps after `"analyzers"`, `"scoringProfiles"`, and `"suggesters"`. However, order doesn't matter.

A vector configuration includes:

- `vectorSearch.algorithms` used during indexing to create "nearest neighbor" information among the vector nodes.
- `vectorSearch.compressions` for scalar or binary quantization, oversampling, and reranking with original vectors.
- `vectorSearch.profiles` for specifying multiple combinations of algorithm and compression configurations.

Here are the steps:

1. Use the [Create or Update Index](#) REST API to create the index.
2. Add a `vectorSearch` section in the index that specifies the search algorithms used to create the embedding space.

JSON

```
"vectorSearch": {
    "compressions": [
        {
            "name": "scalar-quantization",
            "kind": "scalarQuantization",
            "scalarQuantizationParameters": {
                "quantizedDataType": "int8"
            },
            "rescoringOptions": {
                "enableRescoring": true,
                "defaultOversampling": 10,
                "rescoreStorageMethod": "preserveOriginals"
            }
        },
        {
            "name": "binary-quantization",
            "kind": "binaryQuantization",
            "binaryQuantizationParameters": {
                "quantizedDataType": "uint8"
            }
        }
    ],

                "cosineSimilarity"
            ],
            "compressions": [
                {
                    "name": "scalar-quantization"
                }
            ],
            "rescoringOptions": {
                "enableRescoring": true
            }
        }
    ]
}
```

```

        "name": "binary-quantization",
        "kind": "binaryQuantization",
        "rescoringOptions": {
            "enableRescoring": true,
            "defaultOversampling": 10,
            "rescoreStorageMethod": "discardOriginals"
        }
    }
],
"algorithms": [
{
    "name": "hnsw-1",
    "kind": "hnsw",
    "hnswParameters": {
        "m": 4,
        "efConstruction": 400,
        "efSearch": 500,
        "metric": "cosine"
    }
},
{
    "name": "hnsw-2",
    "kind": "hnsw",
    "hnswParameters": {
        "m": 8,
        "efConstruction": 800,
        "efSearch": 800,
        "metric": "hamming"
    }
},
{
    "name": "eknn",
    "kind": "exhaustiveKnn",
    "exhaustiveKnnParameters": {
        "metric": "euclidean"
    }
}
]

],
"profiles": [
{
    "name": "vector-profile-hnsw-scalar",
    "compression": "scalar-quantization",
    "algorithm": "hnsw-1"
}
]
}

```

Key points:

- Names for each configuration of compression, algorithm, and profile must be unique for its type within the index.

- `vectorSearch.compressions` can be `scalarQuantization` or `binaryQuantization`. Scalar quantization compresses float values into narrower data types. Binary quantization converts floats into binary 1-bit values.
- `vectorSearch.compressions.rescoringOptions` uses the original, uncompressed vectors to recalculate similarity and rerank the top results returned by the initial search query. The uncompressed vectors exist in the search index even if `stored` is false. This property is optional. Default is true.
- `vectorSearch.compressions.rescoringOptions.defaultOversampling` considers a broader set of potential results to offset the reduction in information from quantization. The formula for potential results consists of the `k` in the query, with an oversampling multiplier. For example, if the query specifies a `k` of 5, and oversampling is 20, the query effectively requests 100 documents for use in reranking, using the original uncompressed vector for that purpose. Only the top `k` reranked results are returned. This property is optional. Default is 4.
- `vectorSearch.compressions.scalarQuantizationParameters.quantizedDataType` must be set to `int8`. This is the only primitive data type supported at this time. This property is optional. Default is `int8`.
- `vectorSearch.algorithms` is either `hnsw` or `exhaustiveKnn`. These are the Approximate Nearest Neighbors (ANN) algorithms used to organize vector content during indexing.
- `vectorSearch.algorithms.m` is the bi-directional link count. Default is 4. The range is 4 to 10. Lower values should return less noise in the results.
- `vectorSearch.algorithms.efConstruction` is the number of nearest neighbors used during indexing. Default is 400. The range is 100 to 1,000.
- `"vectorSearch.algorithms.efSearch"` is the number of nearest neighbors used during search. Default is 500. The range is 100 to 1,000.
- `vectorSearch.algorithms.metric` should be `cosine` if you're using Azure OpenAI, otherwise use the similarity metric associated with the embedding model you're using. Supported values are `cosine`, `dotProduct`, `euclidean`, and `hamming` (used for [indexing binary data](#)).
- `vectorSearch.profiles` add a layer of abstraction for accommodating richer definitions. A profile is defined in `vectorSearch` and referenced by name in each vector field. It's a combination of compression and algorithm configurations. You

assign this property to a vector field, and it determines the fields' algorithm and compression.

Add a vector field to the fields collection

Once you have a vector configuration, you can add a vector field to the fields collection. Recall that the fields collection must include a field for the document key, vector fields, and any other nonvector fields you need for [hybrid search scenarios](#) or chat model completion in [RAG workloads](#).

Vector fields are characterized by [their data type](#), a `dimensions` property based on the embedding model used to output the vectors, and a vector profile that you created in a previous step.

1. Use the [Create or Update Index](#) REST API to create the index and add a vector field to the fields collection.

```
JSON

{
  "name": "example-index",
  "fields": [
    {
      "name": "contentVector",
      "type": "Collection(Edm.Single)",
      "searchable": true,
      "retrievable": false,
      "stored": false,
      "dimensions": 1536,
      "vectorSearchProfile": "vector-profile-1"
    }
  ]
}
```

2. Specify a vector field with the following attributes. You can store one generated embedding per field. For each vector field:

- `type` must be a [vector data type](#). `Collection(Edm.Single)` is the most common for embedding models.
- `dimensions` is the number of dimensions generated by the embedding model. For `text-embedding-ada-002`, it's fixed at 1536. For the `text-embedding-3` model series, there's a range of values. If you're using integrated vectorization and an embedding skill to generate vectors, make sure this property is set to the [same dimensions value](#) used by the embedding skill.
- `vectorSearchProfile` is the name of a profile defined elsewhere in the index.

- `searchable` must be true.
- `retrievable` can be true or false. True returns the raw vectors (1,536 of them) as plain text and consumes storage space. Set to true if you're passing a vector result to a downstream app.
- `stored` can be true or false. It determines whether an extra copy of vectors is stored for retrieval. For more information, see [Reduce vector size](#).
- `filterable`, `facettable`, and `sortable` must be false.

3. Add filterable nonvector fields to the collection, such as `title` with `filterable` set to true, if you want to invoke [prefiltering](#), [postfiltering](#), or [strict postfiltering \(preview\)](#) on the [vector query](#).
4. Add other fields that define the substance and structure of the textual content you're indexing. At a minimum, you need a document key.

You should also add fields that are useful in the query or in its response. The following example shows vector fields for title and content (`titleVector` and `contentVector`) that are equivalent to vectors. It also provides fields for equivalent textual content (`title` and `content`) that are useful for sorting, filtering, and reading in a search result.

The following example shows the fields collection:

HTTP

```
PUT https://my-search-service.search.windows.net/indexes/my-index?api-version=2025-09-01&allowIndexDowntime=true
Content-Type: application/json
api-key: {{admin-api-key}}
{
  "name": "{{index-name}}",
  "fields": [
    {

                "metric": "cosine"
            }
        }
    ],
    "profiles": [
        {
            "name": "vector-profile-1",
            "algorithm": "hnsw-1"
        }
    ]
}
}

```

Load vector data for indexing

Content that you provide for indexing must conform to the index schema and include a unique string value for the document key. Prevectorized data is loaded into one or more vector fields, which can coexist with other fields containing nonvector content.

For data ingestion, you can use [push or pull methodologies](#).

Push APIs

Use [Documents - Index](#) to load vector and nonvector data into an index. The push APIs for indexing are identical across all stable and preview versions. Use any of the following APIs to load documents:

HTTP

```
POST https://{{search-service-name}}.search.windows.net/indexes/{{index-name}}/docs/index?api-version=2025-09-01

{
    "value": [
        {
            "id": "1",
            "title": "Azure App Service",
            "content": "Azure App Service is a fully managed platform for building, deploying, and scaling web apps. You can host web apps, mobile app backends, and RESTful APIs. It supports a variety of programming languages and frameworks, such as .NET, Java, Node.js, Python, and PHP. The service offers built-in auto-scaling and load balancing capabilities. It also provides integration with other Azure services, such as Azure DevOps, GitHub, and Bitbucket.",
            "category": "Web",
            "titleVector": [
                -0.02250031754374504,
                . . .
                ],
            "contentVector": [

```

Query your index for vector content

For validation purposes, you can query the index using Search Explorer in the Azure portal or a REST API call. Because Azure AI Search can't convert a vector to human-readable text, try to return fields from the same document that provide evidence of the match. For example, if the vector query targets the `titleVector` field, you could select `title` for the search results.

Fields must be attributed as `retrievable` to be included in the results.

Azure portal

- Review the indexes in **Search management > Indexes** to view index size all-up and vector index size. A positive vector index size indicates vectors are present.
- Use [Search Explorer](#) to query an index. Search Explorer has two views: Query view (default) and JSON view.
 - Set **Query options > Hide vector values in search results** for more readable results.
 - [Use the JSON view for vector queries](#). You can paste a JSON definition of the vector query you want to execute. If your index has a [vectorizer assignment](#), you can also use the built-in text-to-vector or image-to-vector conversion. For more information about image search, see [Quickstart: Search for images in Search Explorer](#).
 - Use the default Query view for a quick confirmation that the index contains vectors. The query view is for full-text search. Although you can't use it for vector queries, you can send an empty search (`search=*`) to check for content. The content of all fields, including vector fields, is returned as plain text.

For more information, see [Create a vector query](#).

Update a vector index

To update a vector index, modify the schema and reload documents to populate new fields. APIs for schema updates include [Create or Update Index \(REST\)](#), `CreateOrUpdateIndex` in the Azure SDK for .NET, `create_or_update_index` in the Azure SDK for Python, and similar methods in other Azure SDKs.

For standard guidance on updating an index, see [Update or rebuild an index](#).

Key points include:

- Drop and full index rebuild is often required for updates to and deletion of existing fields.
- You can make the following modifications with no rebuild requirement:
 - Add new fields to a fields collection.
 - Add new vector configurations, assigned to new fields but not existing fields that are already vectorized.
 - Change `retrievable` (values are true or false) on an existing field. Vector fields must be searchable and retrievable, but if you want to disable access to a vector field in situations where drop and rebuild isn't feasible, you can set retrievable to false.

Next steps

As a next step, we recommend [Create a vector query](#).

Code samples in the [azure-search-vector-samples](#) repository demonstrate end-to-end workflows that include schema definition, vectorization, indexing, and queries.

There's demo code for [Python](#), [C#](#), and [JavaScript](#).

Chunk large documents for vector search solutions in Azure AI Search

Partitioning large documents into smaller chunks can help you stay under the maximum token input limits of embedding models. For example, the maximum length of input text for the [Azure OpenAI](#) text-embedding-ada-002 model is 8,191 tokens. Given that each token is around four characters of text for common OpenAI models, this maximum limit is equivalent to around 6,000 words of text. If you're using these models to generate embeddings, it's critical that the input text stays under the limit. Partitioning your content into chunks helps you meet embedding model requirements and prevents data loss due to truncation.

We recommend [integrated vectorization](#) for built-in data chunking and embedding. Integrated vectorization takes a dependency on [built-in indexers](#) and [skillsets](#) that enable text splitting and embeddings generation. If you can't use integrated vectorization, this article describes some alternative approaches for chunking your content.

Common chunking techniques

Chunking is only required if the source documents are too large for the maximum input size imposed by models, but it's also beneficial if content is poorly represented as a single vector. Consider a wiki page that covers a lot of varied sub-topics. The entire page might be small enough to meet model input requirements, but you might get better results if you chunk at a finer grain.

Here are some common chunking techniques, associated with built-in features if you use [indexers](#) and [skills](#).

[] Expand table

Approach	Usage	Built-in functionality
Fixed-size chunks	Define a fixed size that's sufficient for semantically meaningful paragraphs (for example, 200 words or 600 characters) and allows for some overlap (for example, 10-15% of the content) can produce good chunks as input for embedding vector generators.	Text Split skill , splitting by pages (defined by character length)
Variable-sized chunks based on content characteristics	Partition your data based end-of-sentence punctuation marks, end-of-line markers, or using features in the Natural Language Processing (NLP) libraries that detect document structure. Embedded markup, like HTML or Markdown, have heading syntax that can be used to chunk data by sections.	Document Layout skill or Text Split skill , splitting by sentences.

Approach	Usage	Built-in functionality
Custom combinations	Use a combination of fixed and variable sized chunking, or extend an approach. For example, when dealing with large documents, you might use variable-sized chunks, but also append the document title to chunks from the middle of the document to prevent context loss.	None
Document parsing	Indexers can parse larger source documents into smaller search documents for indexing. Strictly speaking, this approach isn't <i>chunking</i> but it can sometimes achieve the same objective.	Index Markdown blobs and files or one-to-many indexing or Index JSON blobs and files

Content overlap considerations

When you chunk data based on fixed size, overlapping a small amount of text between chunks can help maintaining continuity and context. We recommend starting with a chunk size of 512 tokens (approximately 2,000 characters) and an initial overlap of 25%, which equals 128 tokens. This overlap ensures smoother transitions between chunks without excessive duplication.

The optimal overlap may vary depending on your content type and use case. For example, highly structured data may require less overlap, while conversational or narrative text may benefit from more.

Factors for chunking data

When it comes to chunking data, think about these factors:

- Shape and density of your documents. If you need intact text or passages, larger chunks and variable chunking that preserves sentence structure can produce better results.
- User queries: Larger chunks and overlapping strategies help preserve context and semantic richness for queries that target specific information.
- Large Language Models (LLM) have performance guidelines for chunk size. Find a chunk size that works best for all of the models you're using. For instance, if you use models for summarization and embeddings, choose an optimal chunk size that works for both.

How chunking fits into the workflow

If you have large documents, insert a chunking step into indexing and query workflows that breaks up large text. When using [integrated vectorization](#), a default chunking strategy using the [Text Split skill](#) is common. You can also apply a custom chunking strategy using a [custom](#)

skill. See [this code reference](#) for a semantic chunking example using a custom skill. Some external libraries that provide chunking include:

- [LangChain Text Splitters](#)
- [Semantic Kernel TextChunker](#)

Most libraries provide common chunking techniques for fixed size, variable size, or a combination. You can also specify an overlap that duplicates a small amount of content in each chunk for context preservation.

Chunking examples

The following examples demonstrate how chunking strategies are applied to [NASA's Earth at Night e-book](#) PDF file:

- [Text Split skill](#)
- [LangChain](#)
- [Custom skill](#)

Text Split skill example

Integrated data chunking through [Text Split skill](#) is generally available.

This section describes built-in data chunking using a skills-driven approach and [Text Split skill parameters](#).

A sample notebook for this example can be found on the [azure-search-vector-samples](#) repository. Set `textSplitMode` to break up content into smaller chunks:

- `pages` (default). Chunks are made up of multiple sentences.
- `sentences`. Chunks are made up of single sentences. What constitutes a "sentence" is language dependent. In English, standard sentence ending punctuation such as `.` or `!` is used. The language is controlled by the `defaultLanguageCode` parameter.

The `pages` parameter adds extra parameters:

- `maximumPageLength` defines the maximum number of characters ¹ or tokens ² in each chunk. The text splitter avoids breaking up sentences, so the actual character count depends on the content.
- `pageOverlapLength` defines how many characters from the end of the previous page are included at the start of the next page. If set, this must be less than half the maximum page length.

- `maximumPagesToTake` defines how many pages / chunks to take from a document. The default value is 0, which means to take all pages or chunks from the document.

¹ Characters don't align to the definition of a [token](#). The number of tokens measured by the LLM might be different than the character size measured by the Text Split skill with the character fixed-size.

² Token chunking is available in the [2025-08-01-preview](#) and includes extra parameters for specifying a tokenizer and any tokens that shouldn't be split up during chunking.

The following table shows how the choice of parameters affects the total chunk count from the Earth at Night e-book:

[] [Expand table](#)

<code>textSplitMode</code>	<code>maximumPageLength</code>	<code>pageOverlapLength</code>	Total Chunk Count
pages	1000	0	172
pages	1000	200	216
pages	2000	0	85
pages	2000	500	113
pages	5000	0	34
pages	5000	500	38
sentences	N/A	N/A	13361

Using a `textSplitMode` of `pages` results in most chunks having total character counts close to `maximumPageLength`. Chunk character count varies due to differences on where sentence boundaries fall inside the chunk. Chunk token length varies due to differences in the contents of the chunk.

The optimal choice of parameters depends on how the chunks are used. For most applications, it's recommended to start with the following default parameters, when using number of characters:

[] [Expand table](#)

<code>textSplitMode</code>	<code>maximumPageLength</code>	<code>pageOverlapLength</code>
pages	2000	500

LangChain data chunking example

LangChain provides document loaders and text splitters. This example shows you how to load a PDF, get token counts, and set up a text splitter. Getting token counts helps you make an informed decision on chunk sizing.

A sample notebook for this example can be found on the [azure-search-vector-samples](#) repository.

Python

```
from langchain_community.document_loaders import PyPDFLoader
loader = PyPDFLoader("./data/earth_at_night_508.pdf")
pages = loader.load()
print(len(pages))
```

Output indicates 200 documents or pages in the PDF.

To get an estimated token count for these pages, use TikToken.

Python

```
import tiktoken

tokenizer = tiktoken.get_encoding('cl100k_base')
def tiktoken_len(text):
    tokens = tokenizer.encode(
        text,
        disallowed_special=()
    )
    return len(tokens)
tiktoken.encoding_for_model('gpt-4.1-mini')

# create the length function
token_counts = []
for page in pages:
    token_counts.append(tiktoken_len(page.page_content))
min_token_count = min(token_counts)
avg_token_count = int(sum(token_counts) / len(token_counts))
max_token_count = max(token_counts)

# print token counts
print(f"Min: {min_token_count}")
print(f"Avg: {avg_token_count}")
print(f"Max: {max_token_count}")
```

Output indicates that no pages have zero tokens, the average token length per page is 189 tokens, and the maximum token count of any page is 1,583.

Knowing the average and maximum token size gives you insight into setting chunk size. Although you could use the standard recommendation of 2,000 characters with a 500 character overlap, in this case it makes sense to go lower given the token counts of the sample document. In fact, setting an overlap value that's too large can result in no overlap appearing at all.

Python

```
from langchain.text_splitter import RecursiveCharacterTextSplitter
# split documents into text and embeddings

text_splitter = RecursiveCharacterTextSplitter(
    chunk_size=1000,
    chunk_overlap=200,
    length_function=len,
    is_separator_regex=False
)

chunks = text_splitter.split_documents(pages)

print(chunks[20])
print(chunks[21])
```

Output for two consecutive chunks shows the text from the first chunk overlapping onto the second chunk. Output is lightly edited for readability.

```

Custom skill

A [fixed-sized chunking and embedding generation sample](#) demonstrates both chunking and vector embedding generation using [Azure OpenAI](#) embedding models. This sample uses an [Azure AI Search custom skill](#) in the [Power Skills repo](#) to wrap the chunking step.

Last updated on 10/17/2025

Chunk and vectorize by document layout or structure

Text data chunking strategies play a key role in optimizing RAG responses and performance. By using the **Document Layout** skill, you can chunk content based on document structure, capturing headings and chunking the content body based on semantic coherence, such as paragraphs and sentences. Chunks are processed independently. Because LLMs work with multiple chunks, when those chunks are of higher quality and semantically coherent, the overall relevance of the query is improved.

The Document Layout skill calls the [layout model](#) from Azure Document Intelligence in Foundry Tools. The model articulates content structure in JSON using Markdown syntax (headings and content), with fields for headings and content stored in a search index on Azure AI Search. The searchable content produced from the Document Layout skill is plain text but you can apply integrated vectorization to generate embeddings for any field in your source documents, including images.

In this article, learn how to:

- ✓ Use the Document Layout skill to recognize document structure
- ✓ Use the Text Split skill to constrain chunk size to each markdown section
- ✓ Generate embeddings for each chunk
- ✓ Use index projections to map embeddings to fields in a search index

For illustration purposes, this article uses the [sample health plan PDFs](#) uploaded to Azure Blob Storage and then indexed using the **Import data (new)** wizard.

Prerequisites

- An [indexer-based indexing pipeline](#) with an index that accepts the output. The index must have fields for receiving headings and content.
- An [index projection](#) for one-to-many indexing.
- A [supported data source](#) having text content that you want to chunk.
- A skillset with these two skills:
 - [Document Layout skill](#) that splits documents based on paragraph boundaries. If you use [key-based billing](#), this skill requires Microsoft Foundry to be in the same region as Azure AI Search for AI enrichment. Region requirements are relaxed for keyless billing (preview).

- o Azure OpenAI Embedding skill that generates vector embeddings. This skill *doesn't* have region requirements.

Prepare data files

The raw inputs must be in a [supported data source](#) and the file needs to be a format which [Document Layout skill](#) supports.

- Supported file formats include: PDF, JPEG, JPG, PNG, BMP, TIFF, DOCX, XLSX, PPTX, HTML.
- Supported indexers can be any indexer that can handle the supported file formats. These indexers include [Blob indexers](#), [Microsoft OneLake indexers](#), [File indexers](#).
- Supported regions for the portal experience of this feature include: East US, West Europe, North Central US. If you're setting up your skillset programmatically, you can use any Azure Document Intelligence region that also provides the AI enrichment feature of Azure AI Search. For more information, see [Product availability by region](#).

You can use the Azure portal, REST APIs, or an Azure SDK package to [create a data source](#).

💡 Tip

Upload the [health plan PDF](#) sample files to your supported data source to try out the Document Layout skill and structure-aware chunking on your own search service. The [Import data \(new\) wizard](#) is an easy code-free approach for trying out this skill. Be sure to select the **default parsing mode** to use structure-aware chunking. Otherwise, the [Markdown parsing mode](#) is used.

Create an index for one-to-many indexing

Here's an example payload of a single search document designed around chunks. Whenever you're working with chunks, you need a chunk field and a parent field that identifies the origin of the chunk. In this example, parent fields are the `text_parent_id`. Child fields are the vector and nonvector chunks of the markdown section.

The Document Layout skill outputs headings and content. In this example, `header_1` through `header_3` store document headings, as detected by the skill. Other content, such as paragraphs, is stored in `chunk`. The `text_vector` field is a vector representation of the chunk field content.

You can use the [Import data \(new\)](#) wizard in the Azure portal, REST APIs, or an Azure SDK to [create an index](#). The following index is very similar to what the wizard creates by default. You might have more fields if you add image vectorization.

If you aren't using the wizard, the index must exist on the search service before you create the skillset or run the indexer.

Define a skillset for structure-aware chunking and vectorization

This section shows an example of a skillset definition that projects individual markdown sections, chunks, and their vector equivalents as fields in the search index. It uses the [Document Layout skill](#) to detect headings and populate a content field based on semantically coherent paragraphs and sentences in the source document. It uses the [Text Split skill](#) to split the Markdown content into chunks. It uses the [Azure OpenAI Embedding skill](#) to vectorize chunks and any other field for which you want embeddings.

Besides skills, the skillset includes `indexProjections` and `cognitiveServices`:

- `indexProjections` are used for indexes containing chunked documents. The projections specify how parent-child content is mapped to fields in a search index for one-to-many indexing. For more information, see [Define an index projection](#).
- `cognitiveServices` attaches a Foundry resource for billing purposes (the Document Layout skill is available through [Standard pricing ↗](#)).

          "name": "header_3",
          "source": "/document/markdownDocument/*/sections/h3"
        }
      ]
    }
  ],
  "parameters": {
    "projectionMode": "skipIndexingParentDocuments"
  }
}
}

```

Configure and run the indexer

Once you create a data source, index, and skillset, you're ready to [create and run the indexer](#). This step puts the pipeline into execution.

When using the [Document Layout skill](#), make sure to set the following parameters on the indexer definition:

- The `allowSkillsetToReadFileData` parameter should be set to `true`.
- the `parsingMode` parameter should be set to `default`.

`outputFieldMappings` don't need to be set in this scenario because `indexProjections` handle the source field to search field associations. Index projections handle field associations for the Document Layout skill and also regular chunking with the split skill for imported and vectorized data workloads. Output field mappings are still necessary for transformations or complex data mappings with functions which apply in other cases. However, for n-chunks per document, index projections handle this functionality natively.

Here's an example of an indexer creation request.

https

```
POST {endpoint}/indexers?api-version=2025-09-01

{
  "name": "my_indexer",
  "dataSourceName": "my_blob_datasource",
  "targetIndexName": "my_consolidated_index",
  "skillsetName": "my_skillset",
  "parameters": {
    "batchSize": 1,
    "configuration": {
      "dataToExtract": "contentAndMetadata",
      "parsingMode": "default",
      "allowSkillsetToReadFileData": true
    }
  },
  "fieldMappings": [
    {
      "sourceFieldName": "metadata_storage_path",
      "targetFieldName": "title"
    }
  ],
  "outputFieldMappings": []
}
```

When you send the request to the search service, the indexer runs.

Verify results

You can query your search index after processing concludes to test your solution.

To check the results, run a query against the index. Use [Search Explorer](#) as a search client, or any tool that sends HTTP requests. The following query selects fields that contain the output of markdown section nonvector content and its vector.

For Search Explorer, you can copy just the JSON and paste it into the JSON view for query execution.

HTTP

```
POST /indexes/[index name]/docs/search?api-version=[api-version]
{
  "search": "copay for in-network providers",
  "count": true,
  "searchMode": "all",
  "vectorQueries": [
    {
      "kind": "text",
      "text": "*",
      "fields": "text_vector,image_vector"
    }
  ],
  "queryType": "semantic",
  "semanticConfiguration": "healthplan-doc-layout-test-semantic-configuration",
  "captions": "extractive",
  "answers": "extractive|count-3",
  "queryLanguage": "en-us",
  "select": "header_1, header_2, header_3"
}
```

If you used the health plan PDFs to test this skill, Search Explorer results for the example query should look similar to the results in the following screenshot.

- The query is a [hybrid query](#) over text and vectors, so you see a `@search.rerankerScore` and results are ranked by that score. `searchMode=all` means that *all* query terms must be considered for a match (the default is *any*).
- The query uses semantic ranking, so you see `captions` (it also has `answers`, but those aren't shown in the screenshot). The results are the most semantically relevant to the query input, as determined by the [semantic ranker](#).
- The `select` statement (not shown in the screenshot) specifies the header fields that the Document Layout skill detects and populates. You can add more fields to the select clause to inspect the content of chunks, title, or any other human readable field.

JSON query editor

```
2   "search": "copay for in-network providers",
3   "count": true,
4   "searchMode": "all",
5   "vectorQueries": [
6     {
7       "kind": "text",
8       "text": "copay for in-network providers",
9       "fields": "text_vector,image_vector"
```

Search

Generate embeddings for search queries and documents

Azure AI Search doesn't host embedding models, so you're responsible for creating vectors for query inputs and outputs. Choose one of the following approaches:

 Expand table

Approach	Description
Integrated vectorization	Use built-in data chunking and vectorization in Azure AI Search. This approach takes a dependency on indexers, skillsets, and built-in or custom skills that point to external embedding models, such as those in Microsoft Foundry.
Manual vectorization	Manage data chunking and vectorization yourself. For indexing, you push prevectorized documents into vector fields in a search index. For querying, you provide precomputed vectors to the search engine. For demos of this approach, see the azure-search-vector-samples GitHub repository.

We recommend integrated vectorization for most scenarios. Although you can use any supported embedding model, this article uses Azure OpenAI models for illustration.

How embedding models are used in vector queries

Embedding models generate vectors for both query inputs and query outputs. Query inputs include:

- **Text or images that are converted to vectors during query processing.** As part of integrated vectorization, a [vectorizer](#) performs this task.
- **Precomputed vectors.** You can generate these vectors by passing the query input to an embedding model of your choice. To avoid [rate limiting](#), implement retry logic in your workload. Our [Python demo](#) uses [tenacity](#).

Based on the query input, the search engine retrieves matching documents from your search index. These documents are the query outputs.

Your search index must already contain documents with one or more vector fields populated by embeddings. You can create these embeddings through integrated or manual vectorization. To ensure accurate results, use the same embedding model for indexing and querying.

Tips for embedding model integration

- **Identify use cases.** Evaluate specific use cases where embedding model integration for vector search features adds value to your search solution. Examples include [multimodal search](#) or matching image content with text content, multilingual search, and similarity search.
- **Design a chunking strategy.** Embedding models have limits on the number of tokens they accept, so [data chunking](#) is necessary for large files.
- **Optimize cost and performance.** Vector search is resource intensive and subject to maximum limits, so vectorize only the fields that contain semantic meaning. [Reduce vector size](#) to store more vectors for the same price.
- **Choose the right embedding model.** Select a model for your use case, such as word embeddings for text-based searches or image embeddings for visual searches. Consider pretrained models, such as text-embedding-ada-002 from OpenAI or the Image Retrieval REST API from [Azure Vision in Foundry Tools](#).
- **Normalize vector lengths.** To improve the accuracy and performance of similarity search, normalize vector lengths before you store them in a search index. Most pretrained models are already normalized.
- **Fine-tune the model.** If needed, fine-tune the model on your domain-specific data to improve its performance and relevance to your search application.
- **Test and iterate.** Continuously test and refine the embedding model integration to achieve your desired search performance and user satisfaction.

Create resources in the same region

Although integrated vectorization with Azure OpenAI embedding models doesn't require resources to be in the same region, using the same region can improve performance and reduce latency.

To use the same region for your resources:

1. Check the [regional availability of text embedding models](#).
2. Check the [regional availability of Azure AI Search](#).
3. Create an Azure OpenAI resource and Azure AI Search service in the same region.

Tip

Want to use [semantic ranking](#) for [hybrid queries](#) or a machine learning model in a [custom skill](#) for [AI enrichment](#)? Choose an Azure AI Search region that provides those features.

Choose an embedding model in Foundry

When you add knowledge to an agent workflow in the [Foundry portal](#), you have the option of creating a search index. A wizard guides you through the steps.

One step involves selecting an embedding model to vectorize your plain text content. The following models are supported:

- text-embedding-3-small
- text-embedding-3-large
- text-embedding-ada-002
- Cohere-embed-v3-english
- Cohere-embed-v3-multilingual

Your model must already be deployed, and you must have permission to access it. For more information, see [Deployment overview for Foundry Models](#).

Generate an embedding for an improvised query

If you don't want to use integrated vectorization, you can manually generate an embedding and paste it into the `vectorQueries.vector` property of a vector query. For more information, see [Create a vector query in Azure AI Search](#).

The following examples assume the text-embedding-ada-002 model. Replace `YOUR-API-KEY` and `YOUR-OPENAI-RESOURCE` with your Azure OpenAI resource details.

.NET

C#

```
using System;
using System.Net.Http;
using System.Text;
using System.Threading.Tasks;
using Newtonsoft.Json;

class Program
{
```

```
static async Task Main(string[] args)
{
    var apiKey = "YOUR-API-KEY";
    var apiBase = "https://YOUR-OPENAI-RESOURCE.openai.azure.com";
    var apiVersion = "2024-02-01";
    var engine = "text-embedding-ada-002";

    var client = new HttpClient();
    client.DefaultRequestHeaders.Add("Authorization", $"Bearer {apiKey}");

    var requestBody = new
    {
        input = "How do I use C# in VS Code?"
    };

    var response = await client.PostAsync(
        $"{apiBase}/openai/deployments/{engine}/embeddings?api-version={apiVersion}",
        new StringContent(JsonConvert.SerializeObject(requestBody),
Encoding.UTF8, "application/json")
    );

    var responseBody = await response.Content.ReadAsStringAsync();
    Console.WriteLine(responseBody);
}
```

The output is a vector array of 1,536 dimensions.

Set up integrated vectorization in Azure AI Search using REST

In this article, you learn how to use a skillset to chunk and vectorize content from a [supported data source](#). The skillset calls the [Text Split skill](#) or [Document Layout skill](#) for chunking and an embedding skill that's attached to a [supported embedding model](#) for chunk vectorization. You also learn how to store the chunked and vectorized content in a [vector index](#).

This article describes the end-to-end workflow for [integrated vectorization](#) using REST. For portal-based instructions, see [Quickstart: Vectorize text and images in the Azure portal](#).

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- An [Azure AI Search service](#). We recommend the Basic tier or higher.
- A [supported data source](#).
- A [supported embedding model](#).
- Completion of [Quickstart: Connect without keys](#) and [Configure a system-assigned managed identity](#). Although you can use key-based authentication for data plane operations, this article assumes [roles and managed identities](#), which are more secure.
- [Visual Studio Code](#) with a [REST client](#).

Supported data sources

Integrated vectorization works with [all supported data sources](#). However, this article focuses on the most commonly used data sources, which are described in the following table.

 Expand table

Supported data source	Description
Azure Blob Storage	This data source works with blobs and tables. You must use a standard performance (general-purpose v2) account. Access tiers can be hot, cool, or cold.
Azure Data Lake Storage (ADLS) Gen2	This is an Azure Storage account with a hierarchical namespace enabled. To confirm that you have Data Lake Storage, check the Properties tab on the Overview page.

Supported data source	Description
	 Screenshot of an Azure Data Lake Storage account in the Azure portal.
Microsoft OneLake	This data source connects to OneLake files and shortcuts.

Supported embedding models

For integrated vectorization, use one of the following embedding models on an Azure AI platform. Deployment instructions are provided in a [later section](#).

 Expand table

Provider	Supported models
Azure OpenAI in Foundry Models ^{1, 2}	text-embedding-ada-002 text-embedding-3-small text-embedding-3-large
Microsoft Foundry resource ³	For text and images: Azure Vision multimodal ⁴

¹ The endpoint of your Azure OpenAI resource must have a [custom subdomain](#), such as <https://my-unique-name.openai.azure.com>. If you created your resource in the [Azure portal](#) , this subdomain was automatically generated during resource setup.

² Azure OpenAI resources (with access to embedding models) that were created in the [Foundry portal](#)  aren't supported. You must create an Azure OpenAI resource in the Azure portal.

³ For billing purposes, you must [attach your Foundry resource](#) to the skillset in your Azure AI Search service. Unless you use a [keyless connection \(preview\)](#) to create the skillset, both resources must be in the same region.

⁴ The Azure Vision multimodal embedding model is available in [select regions](#).

Role-based access

You can use Microsoft Entra ID with role assignments or key-based authentication with full-access connection strings. For Azure AI Search connections to other resources, we recommend role assignments.

To configure role-based access for integrated vectorization:

1. On your search service, [enable roles](#) and [configure a system-assigned managed identity](#).

2. On your data source platform and embedding model provider, create role assignments that allow your search service to access data and models. See [Prepare your data](#) and [Prepare your embedding model](#).

(!) Note

Free search services support role-based connections to Azure AI Search. However, they don't support managed identities on outbound connections to Azure Storage or Azure Vision. This lack of support requires that you use key-based authentication on connections between free search services and other Azure resources.

For more secure connections, use the Basic tier or higher. You can then enable roles and configure a managed identity for authorized access.

Get connection information for Azure AI Search

In this section, you retrieve the endpoint and Microsoft Entra token for your Azure AI Search service. Both values are necessary to establish connections in REST requests.

💡 Tip

The following steps assume that you're using [role-based access](#) for proof-of-concept testing. If you want to use integrated vectorization for app development, see [Connect your app to Azure AI Search using identities](#).

1. Sign in to the [Azure portal](#) and select your Azure AI Search service.
2. To obtain your search endpoint, copy the URL on the **Overview** page. An example search endpoint is `https://my-service.search.windows.net`.
3. To obtain your Microsoft Entra token, run the following command on your local system. This step requires completion of [Quickstart: Connect without keys](#).

Azure CLI

```
az account get-access-token --scope https://search.azure.com/.default --query accessToken --output tsv
```

Prepare your data

In this section, you prepare your data for integrated vectorization by uploading files to a [supported data source](#), assigning roles, and obtaining connection information.

Azure Blob Storage

1. Sign in to the [Azure portal](#) and select your Azure Storage account.
2. From the left pane, select **Data storage > Containers**.
3. Create a container or select an existing container, and then upload your files to the container.
4. To assign roles:
 - a. From the left pane, select **Access Control (IAM)**.
 - b. Select **Add > Add role assignment**.
 - c. Under **Job function roles**, select [Storage Blob Data Reader](#), and then select **Next**.
 - d. Under **Members**, select **Managed identity**, and then select **Select members**.
 - e. Select your subscription and the managed identity of your search service.
5. To obtain a connection string:
 - a. From the left pane, select **Security + networking > Access keys**.
 - b. Copy either connection string, which you specify later in [Set variables](#).
6. (Optional) Synchronize deletions in your container with deletions in the search index.
To configure your indexer for deletion detection:
 - a. [Enable soft delete](#) on your storage account. If you're using [native soft delete](#), the next step isn't required.
 - b. [Add custom metadata](#) that an indexer can scan to determine which blobs are marked for deletion. Give your custom property a descriptive name. For example, you can name the property "IsDeleted" and set it to false. Repeat this step for every blob in the container. When you want to delete the blob, change the property to true. For more information, see [Change and delete detection when indexing from Azure Storage](#).

Prepare your embedding model

In this section, you prepare your Azure AI resource for integrated vectorization by assigning roles, obtaining an endpoint, and deploying a [supported embedding model](#).

Azure OpenAI

Azure AI Search supports text-embedding-ada-002, text-embedding-3-small, and text-embedding-3-large. Internally, Azure AI Search calls the [Azure OpenAI Embedding skill](#) to connect to Azure OpenAI.

1. Sign in to the [Azure portal](#) and select your Azure OpenAI resource.
2. To assign roles:
 - a. From the left pane, select **Access control (IAM)**.
 - b. Select **Add > Add role assignment**.
 - c. Under **Job function roles**, select [Cognitive Services OpenAI User](#), and then select **Next**.
 - d. Under **Members**, select **Managed identity**, and then select **Select members**.
 - e. Select your subscription and the managed identity of your search service.
3. To obtain an endpoint:
 - a. From the left pane, select **Resource Management > Keys and Endpoint**.
 - b. Copy the endpoint for your Azure OpenAI resource. You specify this URL later in [Set variables](#).
4. To deploy an embedding model:
 - a. Sign in to the [Foundry portal](#) and select your Azure OpenAI resource.
 - b. Deploy a [supported embedding model](#).
 - c. Copy the deployment and model names, which you specify later in [Set variables](#).
The deployment name is the custom name you chose, while the model name is the model you deployed, such as `text-embedding-ada-002`.

Set variables

In this section, you specify the connection information for your Azure AI Search service, your supported data source, and your [supported embedding model](#).

1. In Visual Studio Code, paste the following placeholders into your `.rest` or `.http` file.

HTTP

```
@baseUrl = PUT-YOUR-SEARCH-SERVICE-URL-HERE  
@token = PUT-YOUR-MICROSOFT-ENTRA-TOKEN-HERE
```

2. Replace `@baseUrl` with the search endpoint and `@token` with the Microsoft Entra token you obtained in [Get connection information for Azure AI Search](#).
3. Depending on your data source, add the following variables.

[+] [Expand table](#)

Data source	Variables	Enter this information
Azure Blob Storage	<code>@storageConnectionString</code> and <code>@blobContainer</code>	The connection string and the name of the container you created in Prepare your data .
ADLS Gen2	<code>@storageConnectionString</code> and <code>@blobContainer</code>	The connection string and the name of the container you created in Prepare your data .
OneLake	<code>@workspaceId</code> and <code>@lakehouseId</code>	The workspace and lakehouse IDs you obtained in Prepare your data .

4. Depending on your embedding model provider, add the following variables.

[+] [Expand table](#)

Embedding model provider	Variables	Enter this information
Azure OpenAI	<code>@aoaiEndpoint</code> , <code>@aoaiDeploymentName</code> , and <code>@aoaimodelName</code>	The endpoint, deployment name, and model name you obtained in Prepare your embedding model .
Azure Vision	<code>@AiFoundryEndpoint</code>	The endpoint you obtained in Prepare your embedding model .

5. To verify the variables, send the following request.

HTTP

```
### List existing indexes by name
GET {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
Authorization: Bearer {{token}}
```

A response should appear in an adjacent pane. If you have existing indexes, they're listed. Otherwise, the list is empty. If the HTTP code is `200 OK`, you're ready to proceed.

Connect to your data

In this section, you connect to a [supported data source](#) for indexer-based indexing. An [indexer](#) in Azure AI Search requires a data source that specifies the type, credentials, and container.

1. Use [Create Data Source](#) to define a data source that provides connection information during indexing.

HTTP

```
### Create a data source
POST {{baseUrl}}/datasources?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
Authorization: Bearer {{token}}

{
  "name": "my-data-source",
  "type": "azureblob",
  "subtype": null,
  "credentials": {
    "connectionString": "{{storageConnectionString}}"
  },
  "container": {
    "name": "{{blobContainer}}",
    "query": null
  },
  "dataChangeDetectionPolicy": null,
  "dataDeletionDetectionPolicy": null
}
```

2. Set `type` to your data source: `azureblob` or `adlsgen2`.
3. To create the data source, select **Send request**.
4. If you're using OneLake, set `credentials.connectionString` to `ResourceId={{workspaceId}}` and `container.name` to `{{lakehouseId}}`.

Create a skillset

In this section, you create a [skillset](#) that calls a built-in skill to chunk your content and an embedding skill to create vector representations of the chunks. The skillset is executed during indexing in a [later section](#).

Call a built-in skill to chunk your content

Partitioning your content into chunks helps you meet the requirements of your embedding model and prevents data loss due to truncation. For more information about chunking, see [Chunk large documents for vector search solutions](#).

For built-in data chunking, Azure AI Search offers the [Text Split skill](#) and [Document Layout skill](#). The Text Split skill breaks text into sentences or pages of a particular length, while the Document Layout skill breaks content based on paragraph boundaries.

1. Use [Create Skillset](#) to define a skillset.

HTTP

```
### Create a skillset
POST {{baseUrl}}/skillsets?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
Authorization: Bearer {{token}}

{
  "name": "my-skillset",
  "skills": []
}
```

2. In the `skills` array, call the Text Split skill or Document Layout skill. You can paste one of the following definitions.

HTTP

```
"skills": [
  {
    "@odata.type": "#Microsoft.Skills.Text.SplitSkill",
    "name": "my-text-split-skill",
    "textSplitMode": "pages",
    "maximumPageLength": 2000,
    "pageOverlapLength": 500,
    "maximumPagesToTake": 0,
    "unit": "characters",
    "defaultLanguageCode": "en",
    "inputs": [
      {
        "name": "text",
        "source": "/document/text",
        "inputs": []
    }
]
```

```
        }
    ],
    "outputs": [
    {
        "name": "textItems"
    }
]
},
{
    "@odata.type": "#Microsoft.Skills.Util.DocumentIntelligenceLayoutSkill",
    "name": "my-document-layout-skill",
    "context": "/document",
    "outputMode": "oneToMany",
    "markdownHeaderDepth": "h3",
    "inputs": [
    {
        "name": "file_data",
        "source": "/document/file_data"
    }
],
    "outputs": [
    {
        "name": "markdown_document"
    }
]
}
]
```

ⓘ Note

The Document Layout skill is in public preview. If you want to call this skill, use a preview API, such as [2025-03-01-preview](#).

Call an embedding skill to vectorize the chunks

To vectorize your chunked content, the skillset needs an embedding skill that points to a [supported embedding model](#).

1. After the built-in chunking skill in the `skills` array, call the [Azure OpenAI Embedding skill](#) or [Azure Vision skill](#). You can paste one of the following definitions.

HTTP

```
{
    "@odata.type": "#Microsoft.Skills.Text.AzureOpenAIEmbeddingSkill",
    "resourceUri": "{{aoaiEndpoint}}",
    "deploymentId": "{{aoaiDeploymentName}}",
    "modelName": "{{aoai modelName}}",
    "dimensions": 1536,
```

```
"inputs": [
  {
    "name": "text",
    "source": "/document/text"
  }
],
"outputs": [
  {
    "name": "embedding"
  }
]
},
{
  "@odata.type": "#Microsoft.Skills.Vision.VectorizeSkill",
  "context": "/document",
  "modelVersion": "2023-04-15",
  "inputs": [
    {
      "name": "url",
      "source": "/document/metadata_storage_path"
    },
    {
      "name": "queryString",
      "source": "/document/metadata_storage_sas_token"
    }
  ],
  "outputs": [
    {
      "name": "vector"
    }
  ]
}
```

ⓘ Note

The Azure Vision multimodal embeddings skill is in public preview. If you want to call this skill, use the latest preview API.

2. If you're using the Azure OpenAI Embedding skill, set `dimensions` to the [number of embeddings generated by your embedding model](#).
3. If you're using the Azure Vision multimodal embeddings skill, [attach your Foundry resource](#) after the `skills` array. This attachment is for billing purposes.

HTTP

```
"skills": [ ... ],
"cognitiveServices": {
  "@odata.type": "#Microsoft.Azure.Search.AIServicesByIdentity",
```

```
        "subdomainUrl": "{{AiFoundryEndpoint}}"  
    }  
}
```

4. To create the skillset, select **Send request**.

Create a vector index

In this section, you set up physical data structures on your Azure AI Search service by creating a [vector index](#). The schema of a vector index requires the following:

- Name
- Key field (string)
- One or more vector fields
- Vector configuration

Vector fields store numerical representations of your chunked data. They must be searchable and retrievable, but they can't be filterable, facetable, or sortable. They also can't have analyzers, normalizers, or synonym map assignments.

In addition to vector fields, the sample index in the following steps contains nonvector fields for human-readable content. It's common to include plain-text equivalents of the content you want to vectorize. For more information, see [Create a vector index](#).

1. Use [Create Index](#) to define the schema of a vector index.

HTTP

```
### Create a vector index  
POST {{baseUrl}}/indexes?api-version=2025-09-01 HTTP/1.1  
Content-Type: application/json  
Authorization: Bearer {{token}}  
  
{  
    "name": "my-vector-index",  
    "fields": [],  
    "vectorSearch": []  
}
```

2. Add a [vector search configuration](#) to the `vectorSearch` section.

HTTP

```
"vectorSearch": {  
    "algorithms": [  
        {  
            "name": "hnsw-algorithm",  
            "kind": "hnsw",
```

```

    "hnswParameters": {
        "m": 4,
        "efConstruction": 400,
        "efSearch": 100,
        "metric": "cosine"
    }
},
],
"profiles": [
{
    "name": "vector-profile-hnsw",
    "algorithm": "hnsw-algorithm",
}
]
}

```

`vectorSearch.algorithms` specifies the algorithm used for indexing and querying vector fields, while `vectorSearch.profiles` links the algorithm configuration to a profile you can assign to vector fields.

3. Depending on your embedding model, update `vectorSearch.algorithms.metric`. Valid values for distance metrics are `cosine`, `dotproduct`, `euclidean`, and `hamming`.
4. Add fields to the `fields` arrays. Include a key field for document identification, nonvector fields for human-readable content, and vector fields for embeddings.

HTTP

```

"fields": [
{
    "name": "id",
    "type": "Edm.String",
    "key": true,
    "filterable": true
},
{
    "name": "title",
    "type": "Edm.String",
    "searchable": true,
    "filterable": true,
    "sortable": true,
    "retrievable": true
},
{
    "name": "titleVector",
    "type": "Collection(Edm.Single)",
    "searchable": true,
    "retrievable": false,
    "stored": true,
    "dimensions": 1536,
    "vectorSearchProfile": "vector-profile-hnsw"
}
]
}

```

```

},
{
  "name": "content",
  "type": "Edm.String",
  "searchable": true,
  "retrievable": true
},
{
  "name": "contentVector",
  "type": "Collection(Edm.Single)",
  "searchable": true,
  "retrievable": false,
  "stored": false,
  "dimensions": 1536,
  "vectorSearchProfile": "vector-profile-hnsw"
}
]

```

5. Depending on your embedding skill, set `dimensions` for each vector field to the following value.

[] [Expand table](#)

Embedding skill	Enter this value
Azure OpenAI	The number of embeddings generated by your embedding model .
Azure Vision	<code>1024</code>

Add a vectorizer to the index

In this section, you enable vectorization at query time by [defining a vectorizer](#) in your index. The vectorizer uses the embedding model that indexes your data to decode a search string or image into a vector for vector search.

1. Add the [Azure OpenAI vectorizer](#) or [Azure Vision vectorizer](#) after `vectorSearch.profiles`. You can paste one of the following definitions.

HTTP

```

"profiles": [ ... ],
"vectorizers": [
  {
    "name": "my-openai-vectorizer",
    "kind": "azureOpenAI",
    "azureOpenAIParameters": {
      "resourceUri": "{{aoaiEndpoint}}",
      "deploymentId": "{{aoaiDeploymentName}}",
      "modelName": "{{aoai modelName}}"
    }
  }
]

```

```
        }
    },
{
    "name": "my-ai-services-vision-vectorizer",
    "kind": "aiServicesVision",
    "aiServicesVisionParameters": {
        "resourceUri": "{{AiFoundryEndpoint}}",
        "modelVersion": "2023-04-15"
    }
}
]
```

ⓘ Note

The Azure Vision vectorizer is in public preview. If you want to call this vectorizer, use a preview API, such as [2025-03-01-preview](#).

2. Specify your vectorizer in `vectorSearch.profiles`.

HTTP

```
"profiles": [
{
    "name": "vector-profile-hnsw",
    "algorithm": "hnsw-algorithm",
    "vectorizer": "my-openai-vectorizer"
}]
```

3. To create the vector index, select **Send request**.

Create an indexer

In this section, you create an [indexer](#) to drive the entire vectorization pipeline, from data retrieval to skillset execution to indexing. We recommend that you [run the indexer on a schedule](#) to process changes or documents that were missed due to throttling.

1. Use [Create Indexer](#) to define an indexer that executes the vectorization pipeline.

HTTP

```
### Create an indexer
POST {{baseUrl}}/indexers?api-version=2025-09-01 HTTP/1.1
Content-Type: application/json
Authorization: Bearer {{token}}
{
}
```

```
"name": "my-indexer",
"dataSourceName": "my-data-source",
"targetIndexName": "my-vector-index",
"skillsetName": "my-skillset",
"schedule": {
    "interval": "PT2H"
},
"parameters": {
    "batchSize": null,
    "maxFailedItems": null,
    "maxFailedItemsPerBatch": null
}
}
```

2. To create the indexer, select **Send request**.

Run a vector query to confirm indexing

In this section, you verify that your content was successfully indexed by [creating a vector query](#). Because you configured a vectorizer in a [previous section](#), the search engine can decode plain text or an image into a vector for query execution.

1. Use [Documents - Search Post](#) to define a query that's vectorized at query time.

HTTP

```
### Run a vector query
POST {{baseUrl}}/indexes('my-vector-index')/docs/search.post.search?api-
version=2025-09-01 HTTP/1.1
Content-Type: application/json
Authorization: Bearer {{token}}

{
  "count": true,
  "select": "title, content",
  "vectorQueries": [
    {
      "kind": "text",
      "text": "a sample text string for integrated vectorization",
      "fields": "titleVector, contentVector",
      "k": "3"
    }
  ]
}
```

ⓘ Note

The Azure Vision vectorizer is in public preview. If you previously called this vectorizer, use a preview API, such as [2025-03-01-preview](#).

For queries that invoke integrated vectorization, `kind` must be set to `text`, and `text` must specify a text string. This string is passed to the vectorizer assigned to the vector field. For more information, see [Query with integrated vectorization](#).

2. To run the vector query, select **Send request**.

Use embedding models from the Microsoft Foundry model catalog for integrated vectorization

Important

This feature is in public preview under [Supplemental Terms of Use](#). The latest preview version of [Skillsets - Create Or Update \(REST API\)](#) supports this feature.

In this article, you learn how to access embedding models from the [Microsoft Foundry model catalog](#) for vector conversions during indexing and query execution in Azure AI Search.

The workflow requires that you deploy a model from the catalog, which includes embedding models from Microsoft and other companies. Deploying a model is billable according to the billing structure of each provider.

After the model is deployed, you can use it with the [AML skill](#) for integrated vectorization during indexing or with the [Microsoft Foundry model catalog vectorizer](#) for queries.

Tip

Use the [Import data \(new\) wizard](#) to generate a skillset that includes an AML skill for deployed embedding models on Foundry. AML skill definition for inputs, outputs, and mappings are generated by the wizard, which gives you an easy way to test a model before writing any code.

Prerequisites

- An [Azure AI Search service](#) in any region and on any pricing tier.
- A [Microsoft Foundry hub-based project](#).

Supported embedding models

Supported embedding models from the model catalog vary by usage method:

- For the latest list of models supported programmatically, see the [AML skill](#) and [Microsoft Foundry model catalog vectorizer](#) references.

- For the latest list of models supported in the Azure portal, see [Quickstart: Vector search in the Azure portal](#) and [Quickstart: Multimodal search in the Azure portal](#).

Deploy an embedding model from the model catalog

1. Follow [these instructions](#) to deploy a supported model to your project.
2. Make a note of the target URI, key, and model name. You need these values for the vectorizer definition in a search index and for the skillset that calls the model endpoints during indexing.

If you prefer [token authentication](#) to key-based authentication, you only need to copy the URI and model name. However, make a note of the region to which the model is deployed.
3. Configure a search index and indexer to use the deployed model.
 - To use the model during indexing, see [How to use integrated vectorization](#). Be sure to use the [AML skill](#), not the [Azure OpenAI Embedding skill](#). The next section describes the skill configuration.
 - To use the model as a vectorizer at query time, see [Configure a vectorizer](#). Be sure to use the [Microsoft Foundry model catalog vectorizer](#) for this step.

Sample AML skill payload

When you deploy embedding models from the model catalog, you connect to them using the [AML skill](#) in Azure AI Search for indexing workloads.

This section describes the AML skill definition and index mappings. It includes a sample payload that's already configured to work with its corresponding deployed endpoint. For more information, see [Skill context and input annotation language](#).

Cohere embedding models

This AML skill payload works with the following embedding models:

- Cohere-embed-v3-english
- Cohere-embed-v3-multilingual
- Cohere-embed-v4

It assumes that you're chunking your content using the Text Split skill and therefore your text to be vectorized is in the `/document/pages/*` path. If your text comes from a different path, update all references to the `/document/pages/*` path accordingly.

You must add the `/v1/embed` path onto the end of the URL that you copied from your Foundry deployment. You might also change the values for the `input_type`, `truncate`, and `embedding_types` inputs to better fit your use case. For more information on the available options, review the [Cohere Embed API reference](#).

The URI and key are generated when you deploy the model from the catalog. For more information about these values, see [How to deploy Cohere Embed models with Foundry](#).

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.AmlSkill",  
    "context": "/document/pages/*",  
    "uri": "https://cohere-embed-v3-multilingual-  
    hin.eastus.models.ai.azure.com/v1/embed",  
    "key": "aaaaaaaa-0b0b-1c1c-2d2d-333333333333",  
    "inputs": [  
        {  
            "name": "texts",  
            "source": "[$(/document/pages/*)]"  
        },  
        {  
            "name": "input_type",  
            "source": "'search_document'"  
        },  
        {  
            "name": "truncate",  
            "source": "'NONE'"  
        },  
        {  
            "name": "embedding_types",  
            "source": "[ 'float']"  
        }  
    "outputs": [  
        {  
            "name": "embeddings",  
            "targetName": "aml_vector_data"  
        }  
}
```

In addition, the output of the Cohere model isn't the embeddings array directly, but rather a JSON object that contains it. You need to select it appropriately when mapping it to the index

definition via `indexProjections` or `outputFieldMappings`. Here's a sample `indexProjections` payload that would allow you to do implement this mapping.

If you selected a different `embedding_types` in your skill definition, change `float` in the `source` path to the type you selected.

JSON

```
"indexProjections": {  
    "selectors": [  
        {  
            "targetIndexName": "<YOUR_TARGET_INDEX_NAME_HERE>",  
            "parentKeyFieldName": "ParentKey", // Change this to the name of the field in  
            // your index definition where the parent key will be stored  
            "sourceContext": "/document/pages/*",  
            "mappings": [  
                {  
                    "name": "aml_vector", // Change this to the name of the field in your  
                    // index definition where the Cohere embedding will be stored  
                    "source": "/document/pages/*/aml_vector_data/float/0"  
                }  
            ]  
        },  
        ],  
        "parameters": {}  
    }  
}
```

Sample vectorizer payload

The [Microsoft Foundry model catalog vectorizer](#), unlike the AML skill, is tailored to work only with embedding models that are deployable via the model catalog. The main difference is that you don't have to worry about the request and response payload. However, you must provide the `modelName`, which corresponds to the "Model ID" that you copied after deploying the model.

Here's a sample payload of how you would configure the vectorizer on your index definition given the properties copied from Foundry.

For Cohere models, you should NOT add the `/v1/embed` path to the end of your URL like you did with the skill.

JSON

```
"vectorizers": [  
    {  
        "name": "<YOUR_VECTORIZER_NAME_HERE>",  
        "kind": "aml",  
        "model": "aml_id",  
        "modelType": "cohere",  
        "modelVersion": "1.0",  
        "modelPath": "https://models.foundry.ai/v1/models/aml_id/versions/1.0/embed",  
        "modelFormat": "cohere",  
        "modelConfig": {},  
        "modelMetadata": {}  
    }  
]
```

```
        "amlParameters": {  
            "uri": "<YOUR_URL_HERE>",  
            "key": "<YOUR_PRIMARY_KEY_HERE>",  
            "modelName": "<YOUR_MODEL_ID_HERE>"  
        },  
    },  
]
```

Connect using token authentication

If you can't use key-based authentication, you can configure the AML skill and Microsoft Foundry model catalog vectorizer connection for [token authentication](#) via role-based access control on Azure.

Your search service must have a [system or user-assigned managed identity](#), and the identity must have **Owner** or **Contributor** permissions for your project. You can then remove the `key` field from your skill and vectorizer definition, replacing it with `resourceId`. If your project and search service are in different regions, also provide the `region` field.

JSON

```
"uri": "<YOUR_URL_HERE>,  
"resourceId":  
"subscriptions/<YOUR_SUBSCRIPTION_ID_HERE>/resourceGroups/<YOUR_RESOURCE_GROUP_NAME_<br/>HERE>/providers/Microsoft.MachineLearningServices/workspaces/<YOUR_AML_WORKSPACE_NAME_<br/>HERE>/onlineendpoints/<YOUR_AML_ENDPOINT_NAME_HERE>",<br/>"region": "westus", // Only needed if project is in different region from search<br/>service
```

ⓘ Note

This integration doesn't currently support token authentication for Cohere models. You must use key-based authentication.

Vector index size and limits

For each vector field, Azure AI Search constructs an internal vector index using the algorithm parameters specified on the field. Because Azure AI Search imposes quotas on vector index size, you should know how to estimate and monitor vector size to ensure you stay under the limits.

Internally, the physical data structures of a search index include:

- Raw content (used for retrieval patterns requiring nontokenized content)
- Inverted indexes (used for searchable text fields)
- Vector indexes (used for searchable vector fields)

This article explains the limits for the internal vector indexes that back each of your vector fields.

Tip

[Vector optimization techniques](#) are generally available. Use capabilities like narrow data types, scalar and binary quantization, and elimination of redundant storage to reduce your vector quota and storage quota consumption.

Key points about quota and vector index size

- Vector index size is measured in bytes.
- The total storage of your service contains all of your vector index files. Azure AI Search maintains different copies of vector index files for different purposes. We offer other options to reduce the [storage overhead of vector indexes](#) by eliminating some of these copies.
- Vector quotas are enforced on the search service as a whole, per partition. If you add partitions, vector quota also increases. Per-partition vector quotas are higher on newer services. For more information, see [Vector index size limits](#).
- Not all algorithms consume vector index size quota. Vector quotas are established based on memory requirements of Approximate Nearest Neighbor (ANN) search. Vector fields created with the Hierarchical Navigable Small World (HNSW) algorithm need to reside in memory during query execution because of the random-access nature of graph-based traversals. Vector fields using the exhaustive K-Nearest Neighbors (KNN) algorithm are loaded into memory dynamically in pages during query execution and thus don't consume vector quota.

Check partition size and quantity

If you aren't sure what your search service limits are, here are two ways to get that information:

- In the Azure portal, on the search service **Overview** page, both the **Properties** tab and **Usage** tab show partition size and storage, and also vector quota and vector index size.
- In the Azure portal, on the **Scale** page, you can review the number and size of partitions.

Your vector limit varies depending on your [service creation date](#).

Check vector index size

A request for vector metrics is a data plane operation. You can use the Azure portal, REST APIs, or Azure SDKs to get vector usage at the service level through service statistics and for individual indexes.

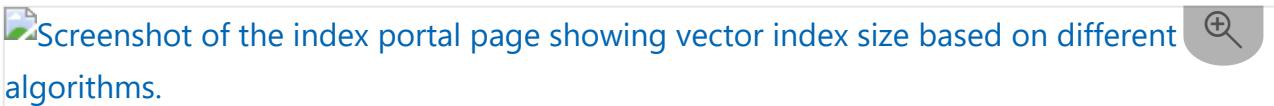

Vector size per index

To get vector index size per index, select **Search management > Indexes** to view a list of indexes and the document count, the size of in-memory vector indexes, and total index size as stored on disk.

Recall that vector quota is based on memory constraints. For vector indexes created using the HNSW algorithm, all searchable vector indexes are permanently loaded into memory. For indexes created using the exhaustive KNN algorithm, vector indexes are loaded in chunks, sequentially, during query time. There's no memory residency requirement for exhaustive KNN indexes. The lifetime of the loaded pages in memory is similar to text search and there are no other metrics applicable to exhaustive KNN indexes other than total storage.

The following screenshot shows two versions of the same vector index. One version is created using HNSW algorithm, where the vector graph is memory resident. Another version is created using exhaustive KNN algorithm. With exhaustive KNN, there's no specialized in-memory vector index, so the portal shows 0 MB for vector index size. Those vectors still exist and are counted in overall storage size, but they don't occupy the in-memory resource that the vector index size metric is tracking.

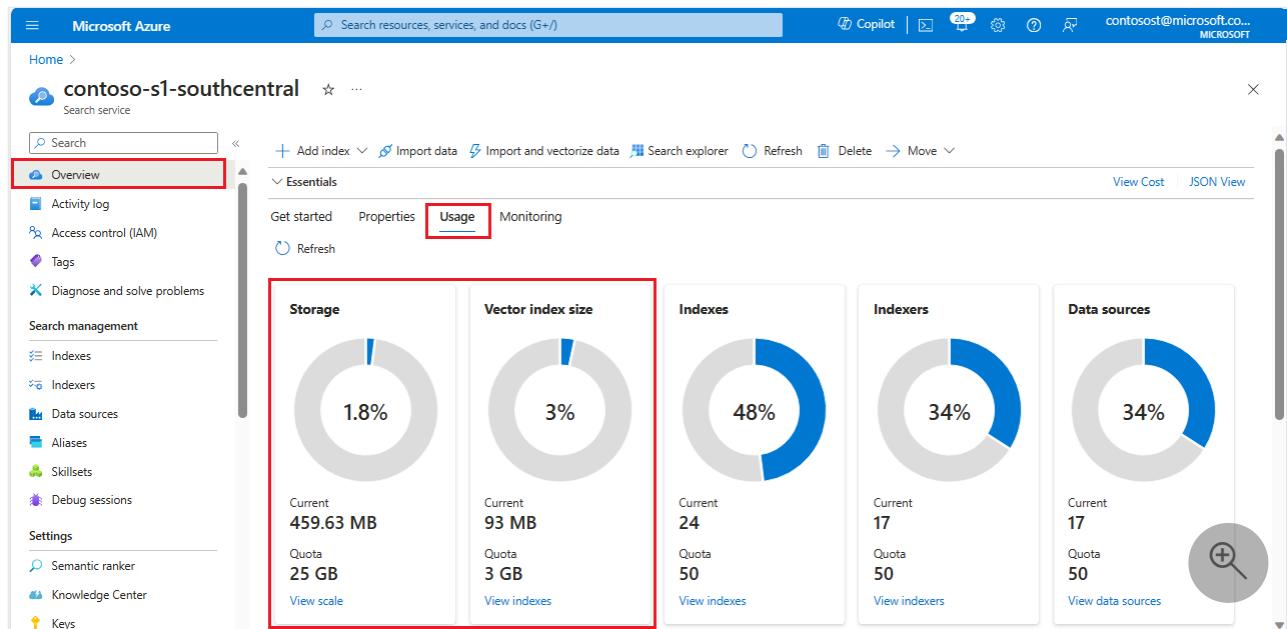

Vector size per service

To get vector index size for the search service as a whole, select the **Overview** page's **Usage** tab. Portal pages refresh every few minutes so if you recently updated an index, wait a bit before checking results.

The following screenshot is for an older Standard 1 (S1) search service, configured for one partition and one replica.

- Storage quota is a disk constraint, and it's inclusive of all indexes (vector and nonvector) on a search service.
- Vector index size quota is a memory constraint. It's the amount of memory required to load all internal vector indexes created for each vector field on a search service.

The screenshot indicates that indexes (vector and nonvector) consume almost 460 megabytes of available disk storage. Vector indexes consume almost 93 megabytes of memory at the service level.

Quotas for both storage and vector index size increase or decrease as you add or remove partitions. If you change the partition count, the tile shows a corresponding change in storage and vector quota.

Note

On disk, vector indexes aren't 93 megabytes. Vector indexes on disk take up about three times more space than vector indexes in memory. See [How vector fields affect disk storage](#) for details.

Factors affecting vector index size

There are three major components that affect the size of your internal vector index:

- Raw size of the data
- Overhead from the selected algorithm
- Overhead from deleting or updating documents within the index

Raw size of the data

Each vector is usually an array of single-precision floating-point numbers, in a field of type `Collection(Edm.Single)`.

Vector data structures require storage, represented in the following calculation as the "raw size" of your data. Use this *raw size* to estimate the vector index size requirements of your vector fields.

The dimensionality of one vector determines its storage size. Multiply the size of one vector by the number of documents containing that vector field to obtain the *raw size*:

```
raw size = (number of documents) * (dimensions of vector field) * (size of data type)
```

[] [Expand table](#)

EDM data type	Size of the data type
<code>Collection(Edm.Single)</code>	4 bytes
<code>Collection(Edm.Half)</code>	2 bytes
<code>Collection(Edm.Int16)</code>	2 bytes
<code>Collection(Edm.SByte)</code>	1 byte

Memory overhead from the selected algorithm

Every ANN algorithm generates extra data structures in memory to enable efficient searching. These structures consume extra space within memory.

For the HNSW algorithm, the memory overhead ranges between 1% and 20% for uncompressed float32 (Edm.Single) vectors.

As dimensionality increases, the memory overhead percentage decreases. This occurs because the raw size of the vectors increases in size while the other data structures, which store graph connectivity information, remain a fixed size for a given m . As a result, the relative impact of these extra data structures diminishes in relation to the overall vector size.

The memory overhead increases with larger values of the HNSW parameter m , which specifies the number of bi-directional links created for each new vector during index construction. This happens because each link contributes approximately 8 to 10 bytes per document, and the total overhead scales proportionally with m .

The following table summarizes the overhead percentages observed in internal tests for *uncompressed* vector fields:

[+] Expand table

Dimensions	HNSW parameter (m)	Overhead percentage
96	4	20%
200	4	8%
768	4	2%
1536	4	1%
3072	4	0.5%

These results demonstrate the relationship between dimensions, HNSW parameter m , and memory overhead for the HNSW algorithm.

For vector fields that use compression techniques, such as [scalar or binary quantization](#), the overhead percentage appears to consume a greater percentage of the total vector index size. As the size of the data decreases, the relative impact of the fixed-size data structures used to store graph connectivity information becomes more significant.

Overhead from deleting or updating documents within the index

When a document with a vector field is either deleted or updated (updates are internally represented as a delete and insert operation), the underlying document is marked as deleted and skipped during subsequent queries. As new documents are indexed and the internal vector

index grows, the system cleans up these deleted documents and reclaims the resources. This means you'll likely observe a lag between deleting documents and the underlying resources being freed.

We refer to this as the *deleted documents ratio*. Since the deleted documents ratio depends on the indexing characteristics of your service, there's no universal heuristic to estimate this parameter, and there's no API or script that returns the ratio in effect for your service. We observe that half of our customers have a deleted documents ratio less than 10%. If you tend to perform high-frequency deletions or updates, then you might observe a higher deleted documents ratio.

This is another factor impacting the size of your vector index. Unfortunately, we don't have a mechanism to surface your current deleted documents ratio.

Estimate total size of data in memory

Taking the previously described factors into account, to estimate the total size of your vector index, use the following calculation:

```
(raw_size) * (1 + algorithm_overhead (in percent)) * (1 + deleted_docs_ratio (in percent))
```

For example, to calculate the `raw_size`, let's assume you're using a popular Azure OpenAI model, `text-embedding-ada-002` with 1,536 dimensions. This means one document would consume 1,536 `Edm.Single` (floats), or 6,144 bytes since each `Edm.Single` is 4 bytes. 1,000 documents with a single, 1,536-dimensional vector field would consume in total 1000 docs x 1536 floats/doc = 1,536,000 floats, or 6,144,000 bytes.

If you have multiple vector fields, you need to perform this calculation for each vector field within your index and add them all together. For example, 1,000 documents with **two** 1,536-dimensional vector fields, consume 1000 docs x **2 fields** x 1536 floats/doc x 4 bytes/float = 12,288,000 bytes.

To obtain the **vector index size**, multiply this `raw_size` by the **algorithm overhead** and **deleted document ratio**. If your algorithm overhead for your chosen HNSW parameters is 10% and your deleted document ratio is 10%, then we get: `6.144 MB * (1 + 0.10) * (1 + 0.10) = 7.434 MB`.

How vector fields affect disk storage

Most of this article provides information about the size of vectors in memory. For information about the storage overhead of vector indexes, see [Eliminate optional vector instances from](#)

storage.

Choose an approach for optimizing vector storage and processing

06/12/2025

Embeddings, or the numerical representation of heterogeneous content, are the basis of vector search workloads, but the sizes of embeddings make them hard to scale and expensive to process. Significant research and productization have produced multiple solutions for improving scale and reducing processing times. Azure AI Search taps into a number of these capabilities for faster and cheaper vector workloads.

This article covers all of the optimization techniques in Azure AI Search that can help you reduce vector size and query processing times.

Vector optimization settings are specified in vector field definitions in a search index. Most of the features described in this article are generally available in the [2024-07-01 REST API](#) and Azure SDK packages targeting that version. The [latest preview version](#) adds support for truncated dimensions if you're using text-embedding-3-large or text-embedding-3-small for vectorization.

Evaluate the options

Review the approaches in Azure AI Search for reducing the amount of storage used by vector fields. These approaches aren't mutually exclusive and can be combined for [maximum reduction in vector size](#).

We recommend built-in quantization because it compresses vector size in memory *and* on disk with minimal effort, which tends to provide the most benefit in most scenarios. In contrast, narrow types (except for float16) require special effort to create them, and `stored` saves on disk storage, which isn't as expensive as memory.

 Expand table

Approach	Why use this approach
Add scalar or binary quantization	Compress native float32 or float16 embeddings to int8 (scalar) or byte (binary). This option reduces storage in memory and on disk with no degradation of query performance. Smaller data types, such as int8 or byte, produce vector indexes that are less content-rich than those with larger embeddings. To offset information loss, built-in compression includes options for post-query processing using uncompressed embeddings and oversampling to return more relevant results. Reranking and oversampling are specific features of built-in quantization of float32

Approach	Why use this approach
	or float16 fields and can't be used on embeddings that undergo custom quantization.
Truncate dimensions for MRL-capable text-embedding-3 models (preview)	Use fewer dimensions on text-embedding-3 models. On Azure OpenAI, these models are retrained on the Matryoshka Representation Learning (MRL) technique that produces multiple vector representations at different levels of compression. This approach produces faster searches and reduced storage costs with minimal loss of semantic information. In Azure AI Search, MRL support supplements scalar and binary quantization. When you use either quantization method, you can also specify a <code>truncateDimension</code> property on your vector fields to reduce the dimensionality of text embeddings.
Assign smaller primitive data types to vector fields	Narrow data types, such as float16, int16, int8, and byte (binary), consume less space in memory and on disk, but you must have an embedding model that outputs vectors in a narrow data format. Alternatively, you must have custom quantization logic that outputs small data. A third use case that requires less effort is recasting native float32 embeddings produced by most models to float16. For information about binary vectors, see Index binary vectors .
Eliminate optional storage of retrievable vectors	Vectors returned in a query response are stored separately from vectors used during query execution. If you don't need to return vectors, you can turn off retrievable storage, reducing overall per-field disk storage by up to 50 percent.

All of these options are defined on an empty index. To implement any of them, use the Azure portal, REST APIs, or an Azure SDK package targeting that API version.

After the index is defined, you can load and index documents as a separate step.

Example: Vector size by vector compression technique

[Code sample: Vector quantization and storage options using Python](#) is a Python code sample that creates multiple search indexes that vary by their use of vector storage quantization, [narrow data types](#), and [storage properties](#).

This code creates and compares storage and vector index size for each vector storage optimization option. From these results, you can see that [quantization](#) reduces vector size the most, but the greatest storage savings are achieved if you use multiple options.

[+] [Expand table](#)

Index name	Storage size	Vector size
compressiontest-baseline	21.3613 MB	4.8277 MB

Index name	Storage size	Vector size
compressiontest-scalar-compression	17.7604 MB	1.2242 MB
compressiontest-narrow	16.5567 MB	2.4254 MB
compressiontest-no-stored	10.9224 MB	4.8277 MB
compressiontest-all-options	4.9192 MB	1.2242 MB

Search APIs report storage and vector size at the index level, so indexes and not fields must be the basis of comparison. Use [GET Index Statistics](#) or an equivalent API in the Azure SDKs to obtain vector size.

Compress vectors using scalar or binary quantization

09/28/2025

Azure AI Search supports scalar and binary quantization for reducing the size of vectors in a search index. Quantization is recommended because it reduces both memory and disk storage for float16 and float32 embeddings. To offset the effects of lossy compression, you can add oversampling and rescore.

To use built-in quantization, follow these steps:

- ✓ Start with [vector fields and a vectorSearch configuration](#) to an index
- ✓ Add `vectorSearch.compressions`
- ✓ Add a `scalarQuantization` or `binaryQuantization` configuration and give it a name
- ✓ Set optional properties to mitigate the effects of lossy indexing
- ✓ Create a new vector profile that uses the named configuration
- ✓ Create a new vector field having the new vector profile
- ✓ Load the index with float32 or float16 data that's quantized during indexing with the configuration you defined
- ✓ Optionally, [query quantized data](#) using the oversampling parameter. If the vector field doesn't specify oversampling in its definition, you can add it at query time.

💡 Tip

[Azure AI Search: Cut Vector Costs Up To 92.5% with New Compression Techniques](#) ↗

compares compression strategies and explains savings in storage and costs. It also includes metrics for measuring relevance based on Normalized discounted cumulative gain (NDCG), demonstrating that you can compress your data without sacrificing search quality.

Prerequisites

- [Vector fields in a search index](#), with a `vectorSearch` configuration specifying either the Hierarchical Navigable Small Worlds (HNSW) or exhaustive K-Nearest Neighbor (KNN) algorithm, and a new vector profile.

Supported quantization techniques

Quantization applies to vector fields receiving float-type vectors. In the examples in this article, the field's data type is `Collection(Edm.Single)` for incoming float32 embeddings, but float16 is also supported. When the vectors are received on a field with compression configured, the engine performs quantization to reduce the footprint of the vector data in memory and on disk.

Two types of quantization are supported:

- Scalar quantization compresses float values into narrower data types. AI Search currently supports int8, which is 8 bits, reducing vector index size fourfold.
- Binary quantization converts floats into binary bits, which takes up 1 bit. This results in up to 28 times reduced vector index size.

 **Note**

While free services support quantization, they don't demonstrate the full storage savings due to the limited storage quota.

How scalar quantization works in Azure AI Search

Scalar quantization reduces the resolution of each number within each vector embedding. Instead of describing each number as a 16-bit or 32-bit floating point number, it uses an 8-bit integer. It identifies a range of numbers (typically 99th percentile minimum and maximum) and divides them into a finite number of levels or bin, assigning each bin an identifier. In 8-bit scalar quantization, there are 2^8 , or 256, possible bins.

Each component of the vector is mapped to the closest representative value within this set of quantization levels in a process akin to rounding a real number to the nearest integer. In the quantized 8-bit vector, the identifier number stands in place of the original value. After quantization, each vector is represented by an array of identifiers for the bins to which its components belong. These quantized vectors require much fewer bits to store compared to the original vector, thus reducing storage requirements and memory footprint.

How binary quantization works in Azure AI Search

Binary quantization compresses high-dimensional vectors by representing each component as a single bit, either 0 or 1. This method drastically reduces the memory footprint and accelerates vector comparison operations, which are crucial for search and retrieval tasks. Benchmark tests show up to 96% reduction in vector index size.

It's particularly effective for embeddings with dimensions greater than 1024. For smaller dimensions, we recommend testing the quality of binary quantization, or trying scalar instead. Additionally, we've found binary quantization performs very well when embeddings are centered around zero. Most popular embedding models offered by OpenAI, Cohere, and Mistral are centered around zero.

Supported rescoring techniques

Rescoring is an optional technique used to offset information loss due to vector quantization. During query execution, it uses oversampling to pick up extra vectors, and supplemental information to rescore initial results found by the query. Supplemental information is either uncompressed original full-precision vectors - or for binary quantization only - you have the option of rescoring using the binary quantized document candidates against the query vector.

Only HNSW graphs allow rescoring. Exhaustive KNN doesn't support rescoring because by definition, all vectors are scanned at query time, which makes rescoring and oversampling irrelevant.

Rescoring options are specified in the index, but you can invoke rescoring at query time by adding the oversampling query parameter.

[] Expand table

Object	Properties
Index	Add RescoringOptions to the vector compressions section. The examples in this article use <code>RescoringOptions</code> .
Query	Add <code>oversampling</code> on RawVectorQuery or VectorizableTextQuery definitions. Adding <code>oversampling</code> invokes rescoring at query time.

! Note

Rescoring parameter names have changed over the last several releases. If you're using an older preview API, review the [upgrade instructions](#) for addressing breaking changes.

The generalized process for rescoring is:

1. The vector query executes over compressed vector fields.
2. The vector query returns the top k oversampled candidates.
3. Oversampled k candidates are rescored using either the uncompressed original vectors for scalar quantization, or the dot product of binary quantization.

4. After rescoring, results are adjusted so that more relevant matches appear first.

Oversampling for scalar quantized vectors requires the availability of the original full precision vectors. Oversampling for binary quantized vectors can use either full precision vectors (`preserveOriginals`) or the dot product of the binary vector (`discardOriginals`). If you're optimizing vector storage, make sure to keep the full precision vectors in the index if you need them for rescoring purposes. For more information, see [Eliminate optional vector instances from storage](#).

Add "compressions" to a search index

This section explains how to specify a `vectorsSearch.compressions` section in the index. The following example shows a partial index definition with a `fields` collection that includes a vector field.

The compression example includes both `scalarQuantization` or `binaryQuantization`. You can specify as many compression configurations as you need, and then assign the ones you want to a vector profile.

Syntax for `vectorSearch.Compressions` varies between stable and preview REST APIs, with the preview adding more options for storage optimization, plus changes to existing syntax. Backwards compatibility is preserved through internal API mappings, but we recommend adopting the newer properties in code that targets 2024-11-01-preview and future versions.

Use the [Create Index](#) or [Create or Update Index](#) REST API to configure compression settings.

HTTP

```
POST https://[servicename].search.windows.net/indexes?api-version=2025-09-01

{
    "name": "my-index",
    "description": "This is a description of this index",
    "fields": [
        { "name": "Id", "type": "Edm.String", "key": true, "retrievable": true,
"searchable": true, "filterable": true },
        { "name": "content", "type": "Edm.String", "retrievable": true, "searchable": true },
        { "name": "vectorContent", "type": "Collection(Edm.Single)", "retrievable": false, "searchable": true, "dimensions": 1536, "vectorSearchProfile": "vector-profile-1" },
    ],
    "vectorSearch": {
        "profiles": [
            {
                "name": "vector-profile-1",
                "algorithm": "use-hnsw",
            }
        ]
    }
}
```

```

        "compression": "use-scalar"
    }
],
"algorithms": [
{
    "name": "use-hnsw",
    "kind": "hnsw",
    "hnswParameters": { },
    "exhaustiveKnnParameters": null
}
],
"compressions": [
{
    "scalarQuantizationParameters": {
        "quantizedDataType": "int8"
    },
    "name": "mySQ8",
    "kind": "scalarQuantization",
    "rescoringOptions": {
        "enableRescoring": true,
        "defaultOversampling": 10,
        "rescoreStorageMethod": "preserveOriginals"
    },
    "truncationDimension": 2
},
{
    "name": "myBQC",
    "kind": "binaryQuantization",
    "rescoringOptions": {
        "enableRescoring": true,
        "defaultOversampling": 10,
        "rescoreStorageMethod": "discardOriginals"
    },
    "truncationDimension": 2
}
]
},
}

```

Key points:

- `kind` must be set to `scalarQuantization` or `binaryQuantization`.
- `rescoringOptions` are a collection of properties used to offset lossy compression by rescoring query results using the original full-precision vectors that exist prior to quantization. For rescoring to work, you must have the vector instance that provides this content. Setting `rescoreStorageMethod` to `discardOriginals` prevents you from using `enableRescoring` or `defaultOversampling`. For more information about vector storage, see [Eliminate optional vector instances from storage](#).

- `"rescoreStorageMethod": "preserveOriginals"` rescores vector search results with the original full-precision vectors can result in adjustments to search score and rankings, promoting the more relevant matches as determined by the rescoring step. For binary quantization, you can set `rescoreStorageMethod` to `discardOriginals` to further reduce storage, without reducing quality. Original vectors aren't needed for binary quantization.
- `defaultOversampling` considers a broader set of potential results to offset the reduction in information from quantization. The formula for potential results consists of the `k` in the query, with an oversampling multiplier. For example, if the query specifies a `k` of 5, and oversampling is 20, then the query effectively requests 100 documents for use in reranking, using the original uncompressed vector for that purpose. Only the top `k` reranked results are returned. This property is optional. Default is 4.
- `quantizedDataType` is optional and applies to scalar quantization only. If you add it, it must be set to `int8`. This is the only primitive data type supported for scalar quantization at this time. Default is `int8`.
- `truncationDimension` taps inherent capabilities of the text-embedding-3 models to "encode information at different granularities and allows a single embedding to adapt to the computational constraints of downstream tasks" (see [Matryoshka Representation Learning](#)). You can use truncated dimensions with or without rescoring options. For more information about how this feature is implemented in Azure AI Search, see [Truncate dimensions using MRL compression](#).

Add the vector search algorithm

You can use the HNSW or eKNN algorithm in the 2024-11-01-preview REST API or later. For the stable version, use HNSW only. If you want rescoring, you must choose HNSW.

JSON

```
"vectorSearch": {
  "profiles": [ ],
  "algorithms": [
    {
      "name": "use-hnsw",
      "kind": "hnsw",
      "hnswParameters": {
        "m": 4,
        "efConstruction": 400,
        "efSearch": 500,
        "metric": "cosine"
      }
    }
  ],
}
```

```
        "compressions": [ <see previous section> ]  
    }
```

Create and assign a new vector profile

To use a new quantization configuration, you must create a *new* vector profile. Creation of a new vector profile is necessary for building compressed indexes in memory. Your new profile uses HNSW.

1. In the same index definition, create a new vector profile and add a compression property and an algorithm. Here are two profiles, one for each quantization approach.

JSON

```
"vectorSearch": {  
    "profiles": [  
        {  
            "name": "vector-profile-hnsw-scalar",  
            "compression": "use-scalar",  
            "algorithm": "use-hnsw",  
            "vectorizer": null  
        },  
        {  
            "name": "vector-profile-hnsw-binary",  
            "compression": "use-binary",  
            "algorithm": "use-hnsw",  
            "vectorizer": null  
        }  
    ],  
    "algorithms": [ <see previous section> ],  
    "compressions": [ <see previous section> ]  
}
```

2. Assign a vector profile to a *new* vector field. The data type of the field is either float32 or float16.

In Azure AI Search, the Entity Data Model (EDM) equivalents of float32 and float16 types are `Collection(Edm.Single)` and `Collection(Edm.Half)`, respectively.

JSON

```
{  
    "name": "vectorContent",  
    "type": "Collection(Edm.Single)",  
    "searchable": true,  
    "retrievable": true,  

```

```
        "vectorSearchProfile": "vector-profile-hnsw-scalar",  
    }
```

3. Load the index using indexers for pull model indexing, or APIs for push model indexing.

Query a quantized vector field using oversampling

Query syntax for a compressed or quantized vector field is the same as for noncompressed vector fields, unless you want to override parameters associated with oversampling and rescoring. You can add an `oversampling` parameter to invoke oversampling and rescoring at query time.

Use [Search Documents](#) for the request.

Recall that the [vector compression definition](#) in the index has settings for `enableRescoring`, `rescoreStorageMethod`, and `defaultOversampling` to mitigate the effects of lossy compression. You can override the default values to vary the behavior at query time. For example, if `defaultOversampling` is 10.0, you can change it to something else in the query request.

You can set the oversampling parameter even if the index doesn't explicitly have rescoring options or `defaultOversampling` definition. Providing `oversampling` at query time overrides the index settings for that query and executes the query with an effective `enableRescoring` as true.

HTTP

```
POST https://[service-name].search.windows.net/indexes/demo-index/docs/search?api-version=2025-09-01  
  
{  
    "vectorQueries": [  
        {  
            "kind": "vector",  
            "vector": [8, 2, 3, 4, 3, 5, 2, 1],  
            "fields": "myvector",  
            "oversampling": 12.0,  
            "k": 5  
        }  
    ]  
}
```

Key points:

- Oversampling applies to vector fields that undergo vector compression, per the vector profile assignment.

- Oversampling in the query overrides the `defaultOversampling` value in the index, or invokes oversampling and rescoring at query time, even if the index's compression configuration didn't specify oversampling or reranking options.

Index binary vectors for vector search

09/29/2025

Azure AI Search supports a packed binary type of `Collection(Edm.Byte)` for further reducing the storage and memory footprint of vector data. You can use this data type for output from models such as [Cohere's Embed v3 binary embedding models](#) or any other embedding model or process that outputs vectors as binary bytes.

There are three steps to configuring an index for binary vectors:

- ✓ Add a vector search algorithm that specifies Hamming distance for binary vector comparison
- ✓ Add a vector profile that points to the algorithm
- ✓ Add a vector field of type `Collection(Edm.Byte)` and assign the Hamming distance

This article assumes you're familiar with [creating an index in Azure AI Search](#) and [adding vector fields](#). It uses the REST APIs to illustrate each step, but you could also add a binary field to an index in the Azure portal or Azure SDK.

The binary data type is assigned to fields using the [Create Index](#) or [Create Or Update Index](#) APIs.

Tip

If you're investigating binary vector support for its smaller footprint, you might also consider the vector quantization and storage reduction features in Azure AI Search. Inputs are float32 or float16 embeddings. Output is stored data in a much smaller format. For more information, see [Compress using binary or scalar quantization](#) and [Assign narrow data types](#).

Prerequisites

- Binary vectors, with 1 bit per dimension, packaged in uint8 values with 8 bits per value. These can be obtained by using models that directly generate *packaged binary* vectors, or by quantizing vectors into binary vectors client-side during indexing and searching.

Limitations

- No Azure portal support in the **Import data (new)** wizard.

- No support for binary fields in the [AML skill](#) that's used for integrated vectorization of models in the Azure AI Foundry model catalog.

Add a vector search algorithm and vector profile

Vector search algorithms are used to create the query navigation structures during indexing. For binary vector fields, vector comparisons are performed using the Hamming distance metric.

1. To add a binary field to an index, set up a [Create or Update Index](#) request using the REST API or the Azure portal.
2. In the index schema, add a `vectorSearch` section that specifies profiles and algorithms.
3. Add one or more [vector search algorithms](#) that have a similarity metric of `hamming`. It's common to use Hierarchical Navigable Small Worlds (HNSW), but you can also use Hamming distance with exhaustive K-Nearest Neighbors (KNN).
4. Add one or more vector profiles that specify the algorithm.

The following example shows a basic `vectorSearch` configuration:

JSON

```
"vectorSearch": {  
    "profiles": [  
        {  
            "name": "myHnswProfile",  
            "algorithm": "myHnsw",  
            "compression": null,  
            "vectorizer": null  
        }  
    ],  
    "algorithms": [  
        {  
            "name": "myHnsw",  
            "kind": "hnsw",  
            "hnswParameters": {  
                "metric": "hamming"  
            }  
        },  
        {  
            "name": "myExhaustiveKnn",  
            "kind": "exhaustiveKnn",  
            "exhaustiveKnnParameters": {  
                "metric": "hamming"  
            }  
        }  
    ]  
}
```

```
    ]  
}
```

Add a binary field to an index

The fields collection of an index must include a field for the document key, vector fields, and any other fields that you need for hybrid search scenarios.

Binary fields are of type `Collection(Edm.Byte)` and contain embeddings in packed form. For example, if the original embedding dimension is `1024`, the packed binary vector length is `ceiling(1024 / 8) = 128`. You get the packed form by setting the `vectorEncoding` property on the field.

- ✓ Add a field to the fields collection and give it name.
- ✓ Set data type to `Collection(Edm.Byte)`.
- ✓ Set `vectorEncoding` to `packedBit` for binary encoding.
- ✓ Set `dimensions` to `1024`. Specify the original (unpacked) vector dimension.
- ✓ Set `vectorSearchProfile` to a profile you defined in the previous step.
- ✓ Make the field searchable.

The following field definition is an example of the properties you should set:

JSON

```
"fields": [  
    . . .  
    {  
        "name": "my-binary-vector-field",  
        "type": "Collection(Edm.Byte)",  
        "vectorEncoding": "packedBit",  
        "dimensions": 1024,  
        "vectorSearchProfile": "myHnswProfile",  
        "searchable": true  
    },  
    . . .  
]
```

Assign narrow data types to vector fields in Azure AI Search

06/12/2025

An easy way to reduce vector size is to store embeddings in a smaller data format. Most embedding models output 32-bit floating point numbers. However, if you quantize your vectors or use an embedding model that natively supports quantization, the output might be float16, int16, or int8, which are significantly smaller than float32. You can accommodate these smaller vector sizes by assigning a narrow data type to a vector field. In the vector index, narrow data types consume less storage.

Data types are assigned to fields in an index definition. You can use the Azure portal, the [Search REST APIs](#), or an Azure SDK package that provides the feature.

Prerequisites

- An embedding model that outputs small data formats, such as text-embedding-3 or Cohere V3 embedding models.

Supported narrow data types

1. Review the [data types used for vector fields](#) for recommended usage:

- `Collection(Edm.Single)` 32-bit floating point (default)
- `Collection(Edm.Half)` 16-bit floating point (narrow)
- `Collection(Edm.Int16)` 16-bit signed integer (narrow)
- `Collection(Edm.SByte)` 8-bit signed integer (narrow)
- `Collection(Edm.Byte)` 8-bit unsigned integer (only allowed with packed binary data types)

2. From that list, determine which data type is valid for your embedding model's output or for vectors that undergo custom quantization.

The following table provides links to several embedding models that can use a narrow data type (`Collection(Edm.Half)`) without extra quantization. You can cast from float32 to float16 (using `Collection(Edm.Half)`) with no extra work.

[] Expand table

Embedding model	Native output	Assign this type in Azure AI Search
text-embedding-ada-002	Float32	Collection(Edm.Single) or Collection(Edm.Half)
text-embedding-3-small	Float32	Collection(Edm.Single) or Collection(Edm.Half)
text-embedding-3-large	Float32	Collection(Edm.Single) or Collection(Edm.Half)
Cohere V3 embedding models with int8 embedding_type ↴	Int8	Collection(Edm.SByte)

You can use other narrow data types if your model emits embeddings in the smaller data format or if you have custom quantization that converts vectors to a smaller format.

3. Make sure you understand the tradeoffs of a narrow data type. `Collection(Edm.Half)` has less information, which results in lower resolution. If your data is homogeneous or dense, losing extra detail or nuance could lead to unacceptable results at query time because there's less detail that can be used to distinguish nearby vectors apart.

Assign the data type

[Define and build an index](#). You can use the Azure portal, [Create or Update Index \(REST API\)](#), or an Azure SDK package for this step.

This field definition uses a narrow data type, `Collection(Edm.Half)`, that can accept a float32 embedding stored as a float16 value. As is true for all vector fields, `dimensions` and `vectorSearchProfile` are set. The specifics of the `vectorSearchProfile` are immaterial to the datatype.

We recommend that you set `retrievable` and `stored` to true if you want to visually check the values of the field. On a subsequent rebuild, you can change these properties to false for reduced storage requirements.

JSON

```
{
  "name": "nameEmbedding",
  "type": "Collection(Edm.Half)",
  "searchable": true,
  "filterable": false,
  "retrievable": true,
  "sortable": false,
```

```
"facetable": false,  
"key": false,  
"indexAnalyzer": null,  
"searchAnalyzer": null,  
"analyzer": null,  
"synonymMaps": [],  
"dimensions": 1536,  
"vectorSearchProfile": "myHnswProfile"  
}
```

Recall that vector fields aren't filterable, sortable, or facetable. They can't be used as keys and don't use analyzers or synonym maps.

Working with a production index

Data types are assigned on new fields when they're created. You can't change the data type of an existing field, and you can't drop a field without [rebuilding the index](#). For established indexes already in production, it's common to work around this issue by creating new fields with the desired revisions and then removing obsolete fields during a planned index rebuild.

Check results

1. Verify the field content matches the data type. Assuming the vector field is marked as [retrievable](#), use [Search explorer](#) or [Search - POST](#) to return vector field content.
2. To check vector index size, refer to the vector index size column on the [Search management > Indexes](#) page in the [Azure portal](#). Alternatively, you can use [GET Index Statistics \(REST API\)](#) or an equivalent Azure SDK method.

! Note

The field's data type is used to create the physical data structure. If you want to change a data type later, either [drop and rebuild the index](#) or create a second field with the new definition.

Eliminate optional vector instances from storage

09/29/2025

Azure AI Search stores multiple copies of vector fields that are used in specific workloads. If your search scenarios don't require all of these copies, you can omit storage for that workload.

Use cases where an extra copy is used include:

- Returning raw vectors in a query response or supporting incremental updates to vector content.
- Rescoring compressed (quantized) vectors as a query optimization technique.

Removing storage is irreversible and requires reindexing if you want it back.

Prerequisites

- [Vector fields in a search index](#), with a `vectorSearch` configuration specifying either the Hierarchical Navigable Small Worlds (HNSW) or exhaustive K-Nearest Neighbor (KNN) algorithm, and a new vector profile.

How vector fields are stored

[Expand table](#)

Instance	Usage	Required for search	How removed
Vectors in the HNSW graph for Approximate Nearest Neighbors (ANN) search (HNSW graph) or vectors for exhaustive K-Nearest Neighbors (eKNN index)	Used for query execution. Consists of either full-precision vectors (when no compression is applied) or quantized vectors.	Essential	There are no parameters for removing this instance.

Instance	Usage	Required for search	How removed
Source vectors received during document indexing (JSON data)	Used for incremental data refresh with <code>merge</code> or <code>mergeOrUpload</code> indexing actions. Also used to return "retrievable" vectors in the query response.	No	Set <code>stored</code> property to false.
Original full-precision vectors (binary data) ¹	For compressed vectors, it's used for <code>preserveOriginals</code> rescore on an oversampled candidate set of results from ANN search. This applies to vector fields that undergo scalar or binary quantization , and it applies to queries using the HNSW graph. If you're using eKNN, all vectors are in scope for the query, so rescore has no effect and thus not supported.	No	Set <code>rescoringOptions.rescoreStorageMethod</code> property to <code>discardOriginals</code> in <code>vectorSearch.compressions</code> .

¹ This copy is also for internal index operations and for exhaustive KNN search in older API versions, on indexes created using the 2023 APIs. On newer indexes, an eKNN-configured field consists of full-precision vectors so no extra copy is needed.

Remove source vectors (JSON data)

In a vector field definition, `stored` is a boolean property that determines whether storage is allocated for retrievable vector content obtained during indexing (the source instance). By default, `stored` is set to `true`. If you don't need raw vector content in a query response, changing `stored` to `false` can save up to 50% storage per field.

Considerations for setting `"stored": false`:

- Because vectors aren't human readable, you can generally omit them from results sent to LLMs in RAG scenarios or from results rendered on a search page. However, you should keep them if you're using vectors in a downstream process that consumes vector content.
- If your indexing strategy uses [partial document updates](#), such as `merge` or `mergeOrUpload` on an existing document, setting `"stored": false` prevents content updates to those

fields during the merge. You must include the entire vector field (and nonvector fields you're updating) in each reindexing operation. Otherwise, the vector data is lost without an error or warning. To avoid this risk altogether, set "stored": true.

ⓘ Important

Setting the "stored": false attribution is irreversible. This property can only be set when you create the index and is only allowed on vector fields. Updating an existing index with new vector fields can't set this property to false. If you want retrievable vector content later, you must drop and rebuild the index or create and load a new field that has the new attribution.

For new vector fields in a search index, set "stored": false to permanently remove retrievable storage for the vector field. The following example shows a vector field definition with the stored property.

HTTP

```

{
  "name": "demo-index",
  "fields": [
    {
      "name": "vectorContent",
      "type": "Collection(Edm.Single)",
      "retrievable": false,
      "stored": false,
      "dimensions": 1536,
      "vectorSearchProfile": "vectorProfile"
    }
  ]
}
```

Summary of key points

- Applies to fields that have a [vector data type](#).
- Affects storage on disk, not memory, and has no effect on queries. Query execution uses a separate vector index that's unaffected by the stored property because that copy of the vector is always stored.

- The `stored` property is set during index creation on vector fields and is irreversible. If you want retrievable content later, you must drop and rebuild the index or create and load a new field that has the new attribution.
- Defaults are `"stored": true` and `" retrievable": false`. In a default configuration, a retrievable copy is stored but isn't automatically returned in results. When `stored` is `true`, you can toggle `retrievable` between `true` and `false` at any time without having to rebuild an index. When `stored` is `false`, `retrievable` must be `false` and can't be changed.

Remove full-precision vectors

Original full-precision vectors are used in rescoring operations over compressed (quantized) vectors. The intent of rescoring is to mitigate the loss in information due to compression. The effect of rescoring is retrieval of a larger set of candidate documents from the compressed index, with recomputation of similarity scores using the original vectors or the dot product. For rescoring to work, original vectors must be retained in storage for certain scenarios. As a result, while quantization reduces memory usage (vector index size usage), it slightly increases storage requirements since both compressed and original vectors are stored. The extra storage is approximately equal to the size of the compressed index.

Rescoring requirements by quantization approach:

- Rescoring of scalar quantized vectors requires retention of the original full-precision vectors.
- Rescoring of binary quantized vectors can use either the original full-precision vectors, or the dot product of the binary embedding, which produces high quality search results, without having to reference full-precision vectors in the index.

Rescoring recommendations:

- For scalar quantization, preserve original full-precision vectors in the index because they're required for rescore.
- For binary quantization, either preserve original full-precision vectors for the highest quality of rescoring, or discard full-precision vectors if you want to rescore based on the dot product of the binary embeddings.

The `rescoreStorageMethod` property controls whether full-precision vectors are stored. In `vectorSearch.compressions`, the `rescoreStorageMethod` property is set to `preserveOriginals` by default, which retains full-precision vectors for [oversampling and rescoring capabilities](#) to reduce the effect of lossy compression on the HNSW graph. If you don't need rescoring, or if

you used binary quantization and the dot product for rescoring, you can reduce vector storage by setting `rescoreStorageMethod` to `discardOriginals`.

Important

Setting the `rescoreStorageMethod` property is irreversible and can adversely affect search quality, although the degree depends on the compression method and any mitigations you apply.

To set this property:

1. Use [Create Index](#) or [Create or Update Index](#) REST APIs, or an Azure SDK.
2. Add a `vectorSearch` section to your index with profiles, algorithms, and compressions.
3. Under `vectorSearch.compressions`, add `rescoringOptions` with `enableRescoring` set to true, `defaultOversampling` set to a positive integer, and `rescoreStorageMethod` set to `discardOriginals` for binary quantization and `preserveOriginals` for scalar quantization.

    "truncationDimension": null
}
]
}
```

ⓘ Note

Vector storage strategies have been evolving over the last several releases. Index creation date and API version determine your storage options. For example, in the 2024-11-01-preview, if you set `discardOriginals` to remove full-precision vectors, there was no rescoring for binary quantization because the dot product approach wasn't available. We recommend using the latest APIs for the best mitigation options.

Truncate dimensions using MRL compression

10/08/2025

Exercise the ability to use fewer dimensions on text-embedding-3 models. On Azure OpenAI, text-embedding-3 models are retrained on the [Matryoshka Representation Learning](#) (MRL) technique that produces multiple vector representations at different levels of compression. This approach produces faster searches and reduced storage costs with minimal loss of semantic information.

In Azure AI Search, MRL support supplements [scalar and binary quantization](#). When you use either quantization method, you can specify a `truncationDimension` property on your vector fields to reduce the dimensionality of text embeddings.

MRL multilevel compression saves on vector storage and improves query response times for vector queries based on text embeddings. In Azure AI Search, MRL support is only offered together with another method of quantization. Using binary quantization with MRL provides the maximum vector index size reduction. To achieve maximum storage reduction, use binary quantization with MRL and set `stored` to `false`.

⚠ Warning

If you set `stored` to `false`, vector data is lost during partial document updates unless you provide the entire vector in each update. Set `stored` to `true` to avoid this issue. For more information, see [Eliminate optional vector instances from storage](#).

Prerequisites

- A text-embedding-3 model, such as text-embedding-3-small or text-embedding-3-large.
- A [supported client](#).
- [New vector fields](#) of type `Edm.Half` or `Edm.Single`. You can't add MRL compression to an existing field.
- [Hierarchical Navigable Small World \(HNSW\) algorithm](#).
- [Scalar or binary quantization](#). Truncated dimensions can be set only when scalar or binary quantization is configured. We recommend binary quantization for MRL compression.

Supported clients

You can use the REST APIs or Azure SDK packages to implement MRL compression. At this time, there's no Azure portal or Azure AI Foundry support.

- Check the change logs for each Azure SDK package for feature support: [Python](#), [.NET](#), [Java](#), [JavaScript](#).

Use MRL-extended text embeddings

MRL is built into the text embedding model you're already using. To use MRL capabilities in Azure AI Search:

1. Use [Create or Update Index](#) or an equivalent API to specify the index schema.
2. [Add vector fields](#) to the index definition.
3. Specify a `vectorSearch.compressions` object in your index definition.
4. Include a quantization method, either scalar or binary (recommended).
5. Include the `truncationDimension` parameter and set it to 512. If you're using the text-embedding-3-large model, you can set it as low as 256.
6. Include a vector profile that specifies the HNSW algorithm and the vector compression object.
7. Assign the vector profile to a vector field of type `Edm.Half` or `Edm.Single` in the fields collection.

There are no query-side modifications for using an MRL-capable text embedding model. MRL support doesn't affect integrated vectorization, text-to-query conversions at query time, semantic ranking, and other relevance-enhancement features, such as reranking with original vectors and oversampling.

Although indexing is slower due to the extra steps, queries are faster.

Example: Vector search configuration that supports MRL

The following example illustrates a vector search configuration that meets the requirements and recommendations of MRL.

`truncationDimension` is a compression property. It specifies how much to shrink the vector graph in memory together with a compression method like scalar or binary compression. We recommend 1,024 or higher for `truncationDimension` with binary quantization. A dimensionality of less than 1,000 degrades the quality of search results when using MRL and binary compression.

JSON

```
{
  "vectorSearch": {
    "profiles": [
      {
        "name": "use-bq-with-mrl",
        "compression": "use-mrl,use-bq",
        "algorithm": "use-hnsw"
      }
    ],
    "algorithms": [
      {
        "name": "use-hnsw",
        "kind": "hnsw",
        "hnswParameters": {
          "m": 4,
          "efConstruction": 400,
          "efSearch": 500,
          "metric": "cosine"
        }
      }
    ],
    "compressions": [
      {
        "name": "use-mrl",
        "kind": "binaryQuantization",
        "rescoringOptions": {
          "enableRescoring": true,
          "defaultOversampling": 10,
          "rescoreStorageMethod": "preserveOriginals"
        },
        "truncationDimension": 1024
      },
      {
        "name": "use-bq",
        "kind": "binaryQuantization",
        "rescoringOptions": {
          "enableRescoring": true,
          "defaultOversampling": 10,
          "rescoreStorageMethod": "discardOriginals"
        }
      }
    ]
  }
}
```

```
    }  
}
```

Here's an example of a [fully specified vector field definition](#) that satisfies the requirements for MRL. Recall that vector fields must:

- Be of type `Edm.Half` or `Edm.Single`.
- Have a `vectorSearchProfile` property that specifies the algorithm and compression settings.
- Have a `dimensions` property that specifies the number of dimensions for scoring and ranking results. Its value should be the dimensions limit of the model you're using (1,536 for text-embedding-3-small).

JSON

```
{  
  "name": "text_vector",  
  "type": "Collection(Edm.Single)",  
  "searchable": true,  
  "filterable": false,  
  "retrievable": false,  
  "stored": false,  
  "sortable": false,  
  "facetable": false,

  "vectorSearchProfile": "use-bq-with-mrl",  
  "vectorEncoding": null,  
  "synonymMaps": []  
}
```

Import data wizards in the Azure portal

i Important

We're consolidating the Azure AI Search wizards. Key changes include:

- The **Import and vectorize data** wizard is now called **Import data (new)**.
- The **Import data** workflow is now available in **Import data (new)**.

The **Import data** wizard will eventually be deprecated. For now, you can still use this wizard, but we recommend the new wizard for an improved search experience that uses the latest frameworks.

The wizards don't have identical keyword search workflows. Certain skills and capabilities are only available in the old wizard. For more information about their similarities and differences, continue reading this article.

Azure AI Search has two wizards that automate indexing, enrichment, and object creation for various search scenarios:

- The **Import data** wizard supports keyword (nonvector) search. You can extract text and numbers from raw documents. You can also configure applied AI and built-in skills to infer structure and generate searchable text from image files and unstructured data.
- The **Import data (new)** wizard supports keyword search, RAG, and multimodal RAG. For keyword search, it modernizes the **Import data** workflow but lacks some functionality, such as automatic metadata field creation. For RAG and multimodal RAG, it connects to your embedding model deployment, sends requests, and generates vectors from text or images.

Despite their differences, the wizards follow similar workflows for content ingestion and indexing. The following table summarizes their capabilities.

[] Expand table

Capability	Import data wizard	Import data (new) wizard
Index creation	✓	✓
Indexer pipeline creation	✓	✓
Azure Logic Apps connectors	✗	✓
Built-in sample data	✗	✗

Capability	Import data wizard	Import data (new) wizard
Skills-based enrichment	✓	✓
Vector and multimodal support	✗	✓
Semantic ranking support	✗	✓
Knowledge store support	✓	✗

Built-in sample data for the hotels sample index is no longer provided, but you can create an identical index by following the [Quickstart: Create an index for keyword search](#).

This article explains how the wizards work to help you with proof-of-concept testing. For step-by-step instructions, see [Try the wizards](#).

Supported data sources and scenarios

This section describes the available options in each wizard.

Data sources

The wizards support the following data sources, most of which use [built-in indexers](#). Exceptions are noted in the table's footnotes.

[] Expand table

Data source	Import data wizard	Import data (new) wizard
ADLS Gen2	✓	✓
Azure Blob Storage	✓	✓
Azure File Storage	✗	✓ ^{1, 2}
Azure Queues	✗	✓ ¹
Azure Table Storage	✓	✓
Azure SQL Database and Managed Instance	✓	✓
Cosmos DB for NoSQL	✓	✓
Cosmos DB for MongoDB	✓	✓
Cosmos DB for Apache Gremlin	✓	✓
MySQL	✗	✗

Data source	Import data wizard	Import data (new) wizard
OneDrive	✗	✓ ¹
OneDrive for Business	✗	✓ ¹
OneLake	✓	✓
Service Bus	✗	✓ ¹
SharePoint	✗	✓ ^{1, 2}
SQL Server on virtual machines	✓	✓

¹ This data source uses an [Azure Logic Apps connector \(preview\)](#) instead of a built-in indexer.

² Instead of using a Logic Apps connector, you can use the Search Service REST APIs to programmatically index data from [Azure File Storage](#) or [SharePoint](#).

Skills

Each wizard generates a skillset and outputs field mappings based on options you select. After the skillset is created, you can modify its JSON definition to add or remove skills.

The following skills might appear in a wizard-generated skillset.

[Expand table](#)

Skill	Import data wizard	Import data (new) wizard
Azure Vision multimodal	✗	✓ ¹
Azure OpenAI embedding	✗	✓ ¹
Azure Machine Learning (Microsoft Foundry model catalog)	✗	✓ ¹
Document layout	✗	✓ ¹
Entity recognition	✓	✓
Image analysis ²	✓	✓
Key phrase extraction	✓	✓
Language detection	✓	✓
Text translation	✓	✗

Skill	Import data wizard	Import data (new) wizard
OCR ²	✓	✓
PII detection	✓	✗
Sentiment analysis	✓	✗
Shaper ³	✓	✗
Text Split ⁴	✓	✓
Text Merge ⁴	✓	✓

¹ This skill is available for RAG and multimodal RAG workflows only. Keyword search isn't supported.

² This skill is available for Azure Storage blobs and Microsoft OneLake files, assuming the default parsing mode. Images can be an image content type (such as PNG or JPG) or an embedded image in an application file (such as PDF).

³ This skill is added when you configure a knowledge store.

⁴ This skill is added for data chunking when you choose an embedding model. For nonembedding skills, it's added when you set the source field granularity to pages or sentences.

Semantic ranker

You can [configure semantic ranking](#) to improve the relevance of search results.

[] [Expand table](#)

Capability	Import data wizard	Import data (new) wizard
Semantic ranker	✗	✓

Knowledge store

You can [generate a knowledge store](#) for secondary storage of enriched (skills-generated) content. A knowledge store is useful for information retrieval workflows that don't require a search engine.

[] [Expand table](#)

Capability	Import data wizard	Import data (new) wizard
Knowledge store	✓	✗

What the wizards create

The following table lists the objects created by the wizards. After the objects are created, you can review their JSON definitions in the Azure portal or call them from code.

[] Expand table

Object	Description
Indexer	Configuration object that specifies a data source, target index, optional skillset, optional schedule, and optional configuration settings for error handling and base-64 encoding.
Data source	Persists connection information to a supported data source on Azure. A data source object is used exclusively with indexers.
Index	Physical data structure for full-text search, vector search, and other queries.
Skillset	(Optional) Complete set of instructions for manipulating, transforming, and shaping content, including analyzing and extracting information from image files. Skillsets are also used for integrated vectorization. If the volume of work exceeds 20 transactions per indexer per day, the skillset must include a reference to a Foundry resource that provides enrichment. For integrated vectorization, you can use either Azure Vision or an embedding model in the Foundry model catalog.
Knowledge store	(Optional) Stores enriched skillset output from tables and blobs in Azure Storage for independent analysis or downstream processing in nonsearch scenarios. Available only in the Import data wizard.

To view these objects after the wizards run:

1. Sign in to the [Azure portal](#) and select your search service.
2. From the left pane, select **Search management** to find pages for indexes, indexers, data sources, and skillsets.

Benefits

Before you write any code, you can use the wizards for prototyping and proof-of-concept testing. The wizards connect to external data sources, sample the data to create an initial index, and then import and optionally vectorize the data as JSON documents into an index on Azure AI Search.

If you're evaluating skillsets, the wizards handle output field mappings and add helper functions to create usable objects. [Text Split](#) is added when you specify a parsing mode. [Text Merge](#) is added when you choose image analysis so that the wizards can reunite text descriptions with image content. [Shaper](#) is added to support valid projections when you choose the knowledge store option. All of these tasks come with a learning curve. If you're new to enrichment, having these steps handled for you allows you to measure the value of a skill without investing much time and effort.

Sampling is the process by which an index schema is inferred, which has some limitations. When the data source is created, the wizards pick a random sample of documents to decide what columns are part of the data source. Not all files are read, as doing so could potentially take hours for large data sources. Given a selection of documents, source metadata (such as field name or type) is used to create a fields collection in an index schema. Based on the complexity of the source data, you might need to edit the initial schema for accuracy or extend it for completeness. You can make your changes inline on the index definition page.

Overall, the advantages of the wizards are clear: as long as requirements are met, you can create a queryable index within minutes. The wizards handle some of the complexities of indexing, such as serializing data as JSON documents.

Limitations

The wizards have the following limitations:

- The wizards don't support iteration or reuse. Each pass through the wizards creates an index, skillset, and indexer configuration. You can reuse data sources only in the **Import data** wizard. After you finish the wizards, you can edit the created objects by using other portal tools, the REST APIs, or the Azure SDKs.
- Source content must reside in a [supported data source](#).
- Sampling occurs over a subset of source data. For large data sources, it's possible for the wizards to miss fields. If sampling is insufficient, you might need to extend the schema or correct the inferred data types.
- [AI enrichment](#), as exposed in the Azure portal, is limited to a subset of built-in skills.
- A [knowledge store](#), which is only available through the **Import data** wizard, is limited to a few default projections and uses a default naming convention. To customize projections and names, you must create the knowledge store through the REST APIs or Azure SDKs.

Secure connections

The wizards use the Azure portal controller and public endpoints to make outbound connections. You can't use the wizards if Azure resources are accessed over a private connection or through a shared private link.

You can use the wizards over restricted public connections, but not all functionality is available.

- On supported Azure data sources protected by firewalls, you can retrieve data if you have the right firewall rules in place.

The Azure resource must admit network requests from the IP address of the device used on the connection. You should also list Azure AI Search as a trusted service on the resource's network configuration. For example, in Azure Storage, you can list

`Microsoft.Search/searchServices` as a trusted service.

- On connections to a Foundry resource for AI enrichment, or on connections to embedding models deployed in the [Foundry portal](#) or Azure OpenAI, public internet access must be enabled unless your search service meets the creation date, tier, and region requirements for private connections. For more information, see [Make outbound connections through a shared private link](#).

For AI enrichment, connections to Foundry resources are for [billing purposes](#). You're billed when API calls for built-in skills (in the **Import data** wizard or the keyword search workflow in the **Import data (new)** wizard) and integrated vectorization (in the **Import data (new)** wizard) exceed the free transaction count (20 per indexer run).

If Azure AI Search can't connect:

- In the **Import data (new)** wizard, the error is `"Access denied due to Virtual Network/Firewall rules."`.
- In the **Import data** wizard, there's no error, but the skillset won't be created.

If firewall settings prevent your wizard workflows from succeeding, consider scripted or programmatic approaches instead.

Workflow

Both wizards follow a similar high-level workflow:

1. Connect to a supported Azure data source.
2. (Optional) Add skills to extract or generate content and structure.
3. Create an index schema, inferred by sampling source data.

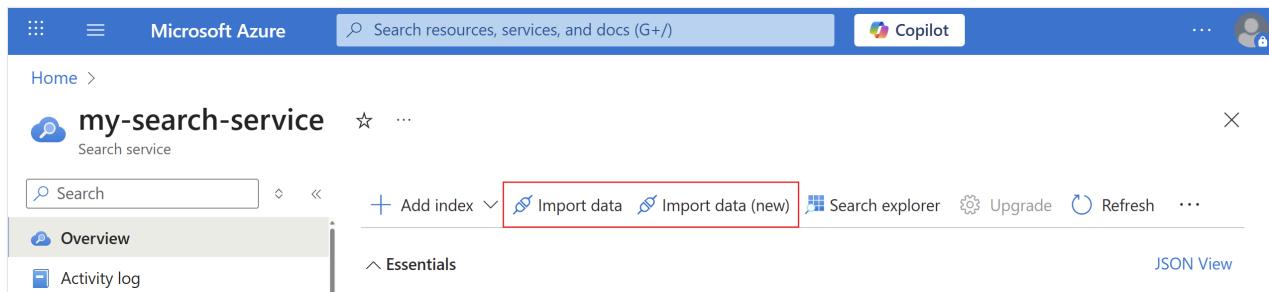

4. Run the wizard to create objects, optionally vectorize data, load data into an index, set a schedule, and configure other options.

The workflow is a one-way pipeline. You can't use the wizard to edit any of the objects that were created, but you can use other portal tools, such as the index designer, indexer designer, or JSON editors, to make allowed updates.

Starting the wizards

To start the wizards:

1. Sign in to the [Azure portal](#) and select your search service.
2. On the **Overview** page, select **Import data** or **Import data (new)**.

The wizards open fully expanded in the browser window, giving you more room to work.

3. Follow the remaining steps to create the index, indexer, and other applicable objects.

You can also launch **Import data** from other Azure services, including Azure Cosmos DB, Azure SQL Database, SQL Managed Instance, and Azure Blob Storage. Look for **Add Azure AI Search** in the left pane on the service overview page.

Data source configuration in the wizard

The wizards connect to an external [supported data source](#) using the internal logic provided by indexers, which are equipped to sample the source, read metadata, crack documents to read content and structure, and serialize contents as JSON for subsequent import to Azure AI Search.

In the **Import data** wizard, you can paste a connection to a supported data source in a different subscription or region, but the **Choose an existing connection** picker is scoped to the active subscription.

Microsoft Azure | Search resources, services, and docs (G+) ...

Dashboard > srch-eastus > Import data X

*Connect to your data Add cognitive skills (Optional) Customize target index Create an indexer

Create and load a search index using data from an external data source. Azure Cognitive Search crawls the data structure you provide, extracts searchable content, optionally enriches it with cognitive skills, and loads it into an index. [Learn more](#)

Data Source Azure Blob Storage

Data source name *

Data to extract Content and metadata

Parsing mode Default

Connection string * DefaultEndpointsProtocol=https;AccountName=[account...]
Choose an existing connection Under same subscription

Managed identity authentication None System-assigned User-assigned

Container name * Container name

Blob folder your/folder/here

Not all preview data sources are guaranteed to be available in the wizards. Because each data source has the potential to introduce changes downstream, a preview data source is only added when it fully supports all of the wizard's experiences, such as skillset definition and index schema inference.

You can only import from a single table, database view, or equivalent data structure. However, the structure can include hierarchical or nested substructures. For more information, see [How to model complex types](#).

Skillset configuration in the wizard

Skillset configuration occurs after the data source definition because the type of data source informs the availability of certain built-in skills. For example, if you're indexing files from Azure Blob Storage, the parsing mode you choose for those files determines whether sentiment analysis is available.

The wizards add not only skills you choose but also skills that are necessary for a successful outcome. For example, if you specify a knowledge store in the **Import data** wizard, the wizard adds a Shaper skill to support projections or physical data structures.

Skillsets are optional, and there's a button at the bottom of the page to skip ahead if you don't want AI enrichment.

Index schema configuration in the wizard

The wizards sample your data source to detect the fields and field types. Depending on the data source, they might also offer fields for indexing metadata.

Because sampling is an imprecise exercise, review the index for the following considerations:

1. Is the field list accurate? If your data source contains fields that weren't picked up in sampling, you can manually add the missed fields. You can also remove fields that don't add value to the search experience or won't be used in a [filter expression](#) or [scoring profile](#).
2. Is the data type appropriate for the incoming data? Azure AI Search supports the [entity data model \(EDM\) data types](#). For Azure SQL data, there's a [mapping chart](#) that lays out equivalent values. For more information, see [Field mappings and transformations](#).
3. Do you have one field that can serve as the *key*? This field must be an Edm.String that uniquely identifies a document. For relational data, it might be mapped to a primary key. For blobs, it might be the `metadata-storage-path`. If field values include spaces or dashes, you must set the **Base-64 Encode Key** option in the **Create an indexer** step, under **Advanced options**, to suppress the validation check for these characters.
4. Set attributes to determine how that field is used in an index.

Take your time with this step because attributes determine the physical expression of fields in the index. If you want to change attributes later, even programmatically, you almost always need to drop and rebuild the index. Core attributes like **Searchable** and **Retrievable** have a [negligible effect on storage](#). Enabling filters and using suggesters increase storage requirements.

- **Searchable** enables full-text search. Every field used in free-form queries or in query expressions must have this attribute. Inverted indexes are created for each field that you mark as **Searchable**.
- **Retrievable** returns the field in search results. Every field that provides content to search results must have this attribute. Setting this field doesn't appreciably affect index size.
- **Filterable** allows the field to be referenced in filter expressions. Every field used in a `$filter` expression must have this attribute. Filter expressions are for exact matches.

Because text strings remain intact, more storage is required to accommodate the verbatim content.

- **Facetable** enables the field for faceted navigation. Only fields also marked as **Filterable** can be marked as **Facetable**.
- **Sortable** allows the field to be used in a sort. Every field used in an `$Orderby` expression must have this attribute.

5. Do you need [lexical analysis](#)? For `Edm.String` fields that are **Searchable**, you can set an **Analyzer** if you want language-enhanced indexing and querying.

The default is *Standard Lucene*, but you can choose *Microsoft English* if you wanted to use Microsoft's analyzer for advanced lexical processing, such as resolving irregular noun and verb forms. Only language analyzers can be specified in the Azure portal. If you want to use a custom analyzer or non-language analyzer, such as Keyword or Pattern, you must create it programmatically. For more information, see [Add language analyzers](#).

6. Do you need typeahead functionality in the form of autocomplete or suggested results? Select the **Suggester** checkbox to enable [typeahead query suggestions and autocomplete](#) on selected fields. Suggesters add to the number of tokenized terms in your index and thus consume more storage.

Indexer configuration in the wizard

The last page of the wizard collects user inputs for indexer configuration. You can [specify a schedule](#) and set other options that vary by the data source type.

Internally, the wizard sets up the following definitions, which aren't visible in the indexer until after it's created.

- [Field mappings](#) between the data source and index.
- [Output field mappings](#) between the skill output and an index.

Try the wizards

The best way to understand the benefits and limitations of the wizards is to step through them. The following quickstarts are based on the wizards.

- [Quickstart: Create a search index](#)
- [Quickstart: Create a text translation and entity skillset](#)
- [Quickstart: Create a vector index](#)
- [Quickstart: Create a multimodal index](#)

Use an Azure Logic Apps workflow for automated indexing in Azure AI Search

10/09/2025

In Azure AI Search, you can use the [Import data \(new\) wizard](#) in the Azure portal to create a logic app workflow that indexes and vectorizes your content. This capability is equivalent to an [indexer](#) and data source that generates an indexing pipeline and creates searchable content.

After you create a workflow in the wizard, you can manage the workflow in Azure Logic Apps alongside your other workflows. Behind the scenes, the wizard follows a workflow template that pulls in (ingests) content from a source for indexing in AI Search. The connectors used in this scenario are prebuilt and already exist in Azure Logic Apps, so the workflow template just provides details for those connectors to create connections to the data source, AI Search, and other items to complete the ingestion workflow.

Key features

Azure Logic Apps integration in Azure AI Search adds support for:

- [More data sources](#) from Microsoft and other providers
- Integrated vectorization
- Scheduled or on-demand indexing
- Change detection of new and existing documents

The [Import data \(new\) wizard](#) inputs include:

- A supported data source
- A supported text embedding model

After the wizard completes, you have the following components:

 Expand table

Component	Location	Description
Search index	Azure AI Search	Contains indexed content from a supported Logic Apps connector. The index schema is a default index created by the wizard. You can add extra elements, such as scoring profile or semantic configuration, but you can't change existing fields. You view, manage, and access the search index on Azure AI Search.
Logic app resource and	Azure Logic	You can view the running workflow, or you can open the designer in Azure Logic Apps to edit the workflow, as you regularly do if you'd

Component	Location	Description
workflow	Apps	started from Azure Logic Apps instead. You can edit and extend the workflow, but exercise caution so as to not break the indexing pipeline. The workflow created by the wizard uses the Consumption hosting option.
Logic app templates	Azure Logic Apps	Up to two templates created per workflow: one for on-demand indexing, and a second template for scheduled indexing. You can modify the indexing schedule in the Index multiple documents step of the workflow.

Prerequisites

Review the following requirements before you start:

- You must be an **Owner** or **Contributor** in your Azure subscription, with permissions to create resources.
- Azure AI Search, Basic pricing tier or higher if you want to use a search service identity for connections to an Azure data source, otherwise you can use any tier, subject to tier limits.
- Azure OpenAI, with a [supported embedding model](#) deployment. Vectorization is integrated into the workflow. If you don't need vectors, you can ignore the fields or try another indexing strategy.
- Azure Logic Apps is a [supported region](#). It should have a [system-assigned managed identity](#) if you want to use Microsoft Entra ID authentication on connections rather than API keys.

 **Note**

A logic app workflow is a billable resource. For more information, see [Azure Logic Apps pricing](#).

Supported regions

End-to-end functionality is available in the following regions, which provide the data source connection, document cracking, document chunks, support for Azure OpenAI embedding models, and the built-in indexing support for pulling the data. The following regions for Azure Logic Apps provide the `ParseDocument` action upon which indexing integration is based.

- East US
- East US 2

- South Central US
- West US 2
- West US 3
- Brazil South
- Australia East
- East Asia
- Southeast Asia
- North Europe
- Sweden Central
- UK South

Supported models

The logic app path through the **Import data (new)** wizard supports a selection of embedding models.

Deploy one of the following [embedding models](#) on Azure OpenAI for your end-to-end workflow.

- text-embedding-3-small
- text-embedding-3-large
- text-embedding-ada-002

Supported connectors

The following connectors are useful for indexing unstructured data, as a complement to classic indexers that primarily target structured data.

- [SharePoint](#)
- [OneDrive](#)
- [OneDrive for Business](#)
- [Azure File Storage](#)
- [Azure Queues](#)
- [Service Bus](#)

Supported actions

Logic apps integration includes the following indexing actions. For more information, see [Connect to Azure AI services from workflows in Azure Logic Apps](#).

- Check for new data.

- Get the data. An HTTP action that retrieves the uploaded document using the file URL from the trigger output.
- Compose document details. A Data Operations action that concatenates various items.
- Create token string. A Data Operations action that produces a token string using the output from the Compose action.
- Create content chunks. A Data Operations action that splits the token string into pieces, based on either the number of characters or tokens per content chunk.
- Convert tokenized data to JSON. A Data Operations action that converts the token string chunks into a JSON array.
- Select JSON array items. A Data Operations action that selects multiple items from the JSON array.
- Generate the embeddings. An Azure OpenAI action that creates embeddings for each JSON array item.
- Select embeddings and other information. A Data Operations action that selects embeddings and other document information.
- Index the data. An Azure AI Search action that indexes the data based on each selected embedding.

It also supports the following query actions:

- Wait for input prompt. A trigger that either polls or waits for new data to arrive, either based on a scheduled recurrence or in response to specific events respectively.
- Input system message for the model. A Data Operations action that provides input to train the model.
- Input sample questions and responses. A Data Operations action that provides sample customer questions and associated roles to train the model.
- Input system message for search query. A Data Operations action that provides search query input to train the model.
- Generate search query. An Inline Code action that uses JavaScript to create a search query for the vector store, based on the outputs from the preceding Compose actions.
- Convert query to embedding. An Azure OpenAI action that connects to the chat completion API, which guarantees reliable responses in chat conversations.
- Get an embedding. An Azure OpenAI action that gets a single vector embedding.
- Search the vector database. An Azure AI Search action that executes searches in the vector store.
- Create prompt. An Inline Code action that uses JavaScript to build prompts.
- Perform chat completion. An Azure OpenAI action that connects to the chat completion API, which guarantees reliable responses in chat conversations.
- Return a response. A Request action that returns the results to the caller when you use the Request trigger.

Limitations

- The search index is generated using a fixed schema (document ID, content, and vectorized content), with text extraction only. You can [modify the index](#) as long as the update doesn't affect existing fields.
- Vectorization supports text embedding only.
- Deletion detection isn't supported. You must manually [delete orphaned documents](#) from the index.
- Duplicate documents in the search index are a known issue in this preview. Consider deleting objects and starting over if this becomes an issue.
- No support for private endpoints in the logic app workflow created by the portal wizard. The workflow is hosted using the [Consumption hosting option](#) and is subject to its constraints. To use the [Standard](#) hosting option, use a programmatic approach to creating the workflow.
- All actions are generally available except for

Create a logic app workflow

Follow these steps to create a logic app workflow for indexing content in Azure AI Search.

1. Start the [Import data \(new\)](#) wizard in the Azure portal.
2. Choose a [supported Azure Logic Apps connector](#).

Home > Quickstart wizard ...

Let's start by picking a data source... Available options are listed below. [Learn more](#)

Filter by name...

Azure Blob Storage Built-in indexer	Azure Data Lake Storage Gen2 Built-in indexer	Azure Cosmos DB Built-in indexer
Azure SQL Database Built-in indexer	Azure Table Storage Built-in indexer	Fabric OneLake files (Preview) Built-in indexer
SharePoint Logic Apps indexer	OneDrive Logic Apps indexer	OneDrive for Business Logic Apps indexer
Azure File Storage Logic Apps indexer	Azure Queues Logic Apps indexer	Service Bus Logic Apps indexer
Amazon S3 Logic Apps indexer	Dropbox Logic Apps indexer	SFTP - SSH Logic Apps indexer

3. In **Connect to your data**, provide a name prefix used for the search index and workflow.
Having a common name helps you manage them together.
4. Specify the indexing frequency. If you choose on a schedule, a template that includes a scheduling option is used to create the workflow. You can modify the indexing schedule in the **Index multiple documents** step of the workflow after it's created.
5. Select an authentication type where the logic app workflow connects to the search engine and starts the indexing process. The workflow can connect using [Azure AI Search API keys](#) or the wizard can create a role assignment that grants permissions to the Logic Apps system-assigned managed identity, assuming one exists.
6. Select **Next** to continue to the next page.
7. In **Vectorize your text**, provide the model deployment and Azure OpenAI connection information. Choose the subscription and service, a [supported text embedding model](#), and the authentication type that the workflow uses to connect to Azure OpenAI.
8. Select **Next** to continue to the next page. Review the configuration.
9. Select **Create** to begin processing.

The workflow runs as a serverless workflow in Logic Apps (Consumption), separate from the AI Search service.

10. Confirm index creation in the Azure portal, in the **Indexes** page in Azure AI Search. [Search Explorer](#) is the first tab. Select **Search** to return some content.

Modify existing objects

You can make the following modifications to a search index without breaking indexing:

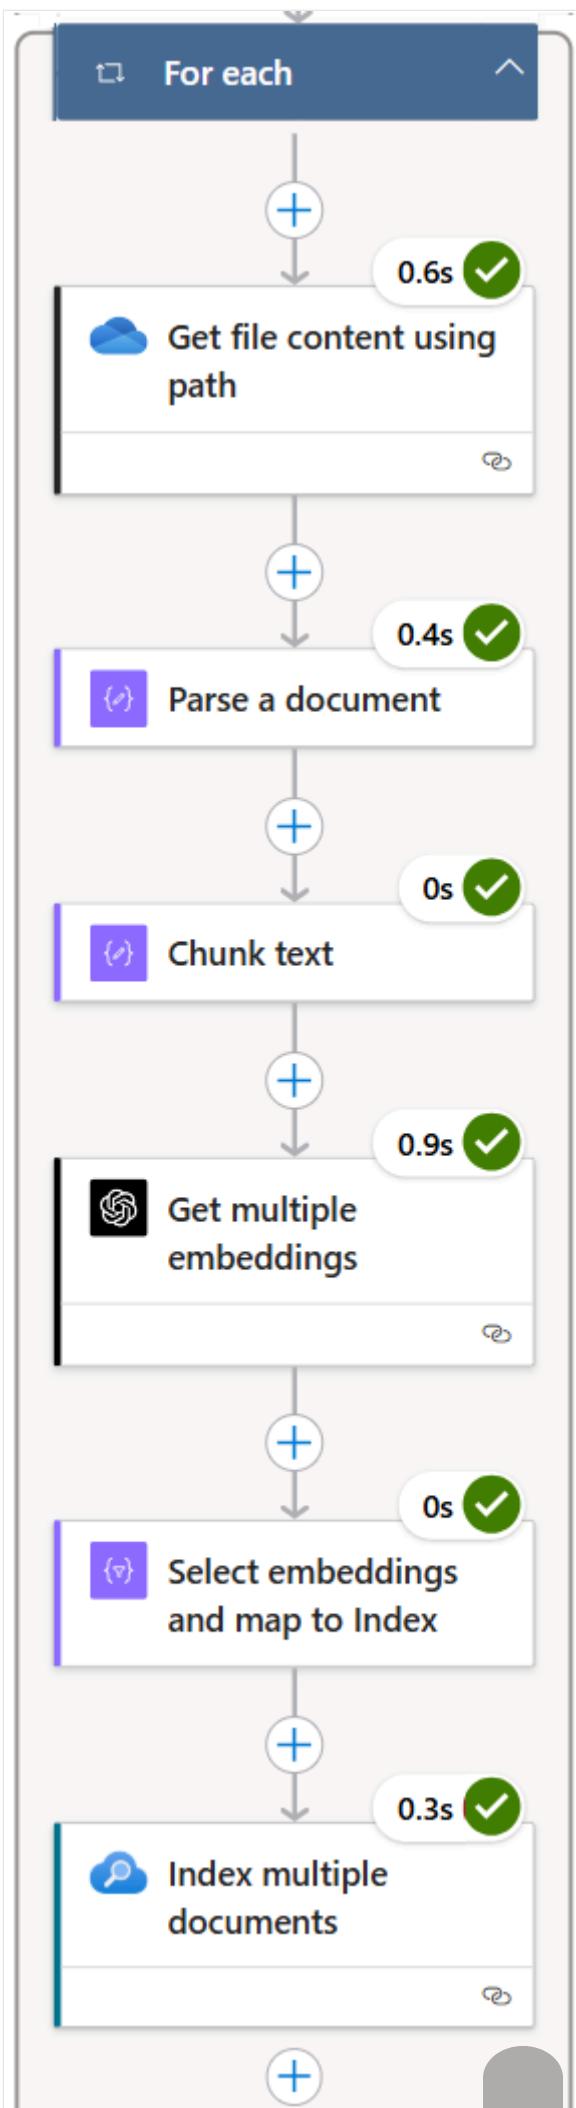

- [Add scoring profiles](#)
- [Add semantic ranking](#)
- [Add spell check](#)
- [Add synonym maps](#)
- [Add suggesters](#)

You can make the following updates to a workflow without breaking indexing:

- Modify **List files in folder** to change the number of documents sent to indexing.
- Modify **Chunk Text** to vary token inputs. The recommended token size is 512 tokens for most scenarios.
- Modify **Chunk Text** to add a page overlap length.

- Modify **Index multiple documents** step to control indexing frequency if you chose scheduled indexing in the wizard.

In logic apps designer, review the workflow and each step in the indexing pipeline. The workflow specifies document extraction, default document chunking ([Text Split skill](#)), embedding ([Azure OpenAI embedding skill](#)), output field mappings, and finally indexing.

Template and workflow management

The wizard creates templates and workflows when you specify a Logic Apps indexer. To create and manage them, including template deletion, use the logic app designer. The Azure portal search service dashboard doesn't provide template or workflow management, and currently there's no programmatic support in Azure AI Search APIs.

Create an indexer in Azure AI Search

06/17/2025

This article focuses on the basic steps of creating an indexer that's used to automate data ingestion for supported data sources. Depending on the data source and your workflow, more configuration might be necessary.

You can use an indexer to automate data import and indexing in Azure AI Search. An indexer is a named object on a search service that connects to an external Azure data source, reads and serializes the data, and passes it to a search engine for indexing. Using indexers significantly reduces the quantity and complexity of the code you need to write if you're using a supported data source.

Indexers support two workflows:

- **Raw content indexing (plain text or vectors):** Extract strings and metadata from textual content used for full text search scenarios. Extracts raw vector content used for vector search (for example, vectors in an Azure SQL database or Azure Cosmos DB collection). In this workflow, indexing occurs only over existing content that you provide.
- **Skills-based indexing:** Extends indexing through built-in or custom skills that create or generate new searchable content. For example, you can add integrated machine learning for analysis over images and unstructured text, extracting or inferring text and structure. Or, use skills to chunk and vectorize content from text and images. Skills-based indexing creates or generates new content that doesn't exist in your external data source. New content becomes part of your index when you add fields to the index schema that accepts the incoming data. To learn more, see [AI enrichment in Azure AI Search](#).

Prerequisites

- A [supported data source](#) that contains the content you want to ingest.
- An [indexer data source](#) that sets up a connection to external data.
- A [search index](#) that can accept incoming data.
- Be under the [maximum limits](#) for your service tier. The Free tier allows three objects of each type and 1-3 minutes of indexer processing, or 3-10 minutes if there's a skillset.

Indexer patterns

When you create an indexer, the definition is one of two patterns: *content-based indexing* or *skills-based indexing*. The patterns are the same, except that skills-based indexing has more definitions.

Indexer example for content-based indexing

Content-based indexing for full text or vector search is the primary use case for indexers. For this workflow, an indexer looks like this example.

JSON

```
{  
  "name": (required) String that uniquely identifies the indexer,  
  "description": (optional),  
  "dataSourceName": (required) String indicating which existing data source to  
use,  
  "targetIndexName": (required) String indicating which existing index to use,  
  "parameters": {  
    "batchSize": null,  
    "maxFailedItems": 0,  
    "maxFailedItemsPerBatch": 0,  
    "base64EncodeKeys": false,  
    "configuration": {}  
  },  
  "fieldMappings": (optional) unless field discrepancies need resolution,  
  "disabled": null,  
  "schedule": null,  
  "encryptionKey": null  
}
```

Indexers have the following requirements:

- A `name` property that uniquely identifies the indexer in the indexer collection
- A `dataSourceName` property that points to a data source object. It specifies a connection to external data
- A `targetIndexName` property that points to the destination search index

Other parameters are optional and modify run time behaviors, such as how many errors to accept before failing the entire job. Required parameters are specified in all indexers and are documented in the [REST API reference](#).

Data source-specific indexers for blobs, SQL, and Azure Cosmos DB provide extra `configuration` parameters for source-specific behaviors. For example, if the source is Blob Storage, you can set a parameter that filters on file extensions, such as:

JSON

```
"parameters" : { "configuration" : { "indexedFileNameExtensions" : ".pdf,.docx" } }
```

If the source is Azure SQL, you can set a query time-out parameter.

[Field mappings](#) are used to explicitly map source-to-destination fields if there are discrepancies by name or type between a field in the data source and a field in the search index.

By default, an indexer runs immediately when you create it on the search service. If you don't want indexer execution, set `disabled` to `true` when creating the indexer.

You can also [specify a schedule](#) or set an [encryption key](#) for supplemental encryption of the indexer definition.

Indexer example for skills-based indexing

Skills-based indexing uses [AI enrichment](#) to process content that isn't searchable in its raw form. All of the above properties and parameters apply, but the following extra properties are specific to AI enrichment: `skillSetName`, `cache`, `outputFieldMappings`.

JSON

```
{
  "name": (required) String that uniquely identifies the indexer,
  "dataSourceName": (required) String, provides raw content that will be enriched,
  "targetIndexName": (required) String, name of an existing index,
  "skillsetName" : (required for AI enrichment) String, name of an existing
skillset,
  "cache": {
    "storageConnectionString" : (required if you enable the cache) Connection
string to a blob container,
    "enableReprocessing": true
  },
  "parameters": { },
  "fieldMappings": (optional) Maps fields in the underlying data source to fields
in an index,
  "outputFieldMappings" : (required) Maps skill outputs to fields in an index,
}
```

AI enrichment is its own subject area and is out of scope for this article. For more information, start with [AI enrichment](#), [Skillsets in Azure AI Search](#), [Create a skillset](#), [Map enriched output fields](#), and [Enable caching for AI enrichment](#).

Prepare external data

Indexers work with data sets. When you run an indexer, it connects to your data source, retrieves the data from the container or folder, optionally serializes it into JSON before passing it to the search engine for indexing. This section describes the requirements of incoming data for text-based indexing.

[] Expand table

Source	Tasks
data	
JSON documents	JSON documents can contain text, numbers, and vectors. Make sure the structure or shape of incoming data corresponds to the schema of your search index. Most search indexes are fairly flat, where the fields collection consists of fields at the same level. However, hierarchical or nested structures are possible through complex fields and collections .
Relational	<p>Provide data as a flattened row set, where each row becomes a full or partial search document in the index.</p> <p>To flatten relational data into a row set, you should create a SQL view, or build a query that returns parent and child records in the same row. For example, the built-in hotels sample dataset is an SQL database that has 50 records (one for each hotel), linked to room records in a related table. The query that flattens the collective data into a row set embeds all of the room information in JSON documents in each hotel record. The embedded room information is generated by a query that uses a FOR JSON AUTO clause.</p> <p>You can learn more about this technique in define a query that returns embedded JSON. This is just one example; you can find other approaches that produce the same result.</p>
Files	An indexer generally creates one search document for each file, where the search document consists of fields for content and metadata. Depending on the file type, the indexer can sometimes parse one file into multiple search documents . For example, in a CSV file, each row can become a standalone search document.

Remember that you only need to pull in searchable and filterable data:

- Searchable data is text or vectors
- Filterable data is text and numbers (non-vector fields)

Azure AI Search can't do a full-text search over binary data in any format, although it can extract and infer text descriptions of image files (see [AI enrichment](#)) to create searchable content. Likewise, large text can be broken down and analyzed by natural language models to find structure or relevant information, generating new content that you can add to a search document. It can also do vector search over embeddings, including quantized embeddings in a binary format.

Given that indexers don't fix data problems, other forms of data cleansing or manipulation might be needed. For more information, you should refer to the product documentation of

your Azure database product.

Prepare a data source

Indexers require a data source that specifies the type, container, and connection.

1. Make sure you're using a [supported data source type](#).
2. [Create a data source](#) definition. The following data sources are a few of the more frequently used sources:
 - [Azure Blob Storage](#)
 - [Azure Cosmos DB](#)
 - [Azure SQL Database](#)
3. If the data source is a database, such as Azure SQL or Cosmos DB, enable change tracking. Azure Storage has built-in change tracking through the `LastModified` property on every blob, file, and table. The links for the various data sources explain which change tracking methods are supported by indexers.

Prepare an index

Indexers also require a search index. Recall that indexers pass data off to the search engine for indexing. Just as indexers have properties that determine execution behavior, an index schema has properties that profoundly affect how strings are indexed (only strings are analyzed and tokenized).

1. Start with [Create a search index](#).
2. Set up the fields collection and field attributes.

Fields are the only receptors of external content. Depending on how the fields are attributed in the schema, the values for each field are analyzed, tokenized, or stored as verbatim strings for filters, fuzzy search, and typeahead queries.

Indexers can automatically map source fields to target index fields when the names and types are equivalent. If a field can't be implicitly mapped, remember that you can [define an explicit field mapping](#) that tells the indexer how to route the content.

3. Review the analyzer assignments on each field. Analyzers can transform strings. As such, indexed strings might be different from what you passed in. You can evaluate the effects of analyzers using [Analyze Text \(REST\)](#). For more information about analyzers, see [Analyzers for text processing](#).

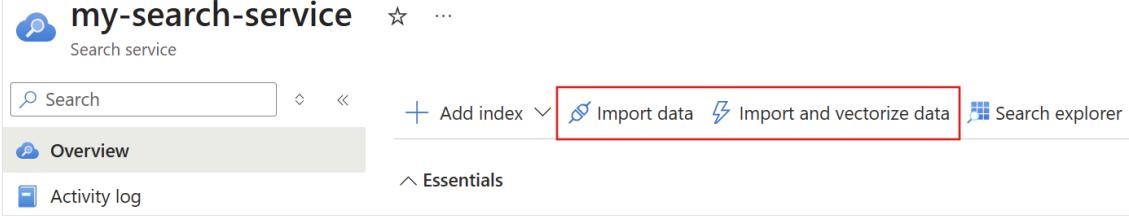

During indexing, an indexer only checks field names and types. There's no validation step that ensures incoming content is correct for the corresponding search field in the index.

Create an indexer

When you're ready to create an indexer on a remote search service, you need a search client. A search client can be the Azure portal, a REST client, or code that instantiates an indexer client. We recommend the Azure portal or REST APIs for early development and proof-of-concept testing.

Azure portal

1. Sign in to the [Azure portal](#) and select your search service.
2. Choose from the following options:
 - **Import wizards:** The wizards are unique in that they create all of the required elements. Other approaches require a predefined data source and index.
 - **Add indexer:** A visual editor for specifying an indexer definition.

The screenshot shows the Azure portal interface for a search service named 'my-search-service'. The 'Indexers' blade is open. On the left, there's a sidebar with various navigation links. The 'Indexers' link is currently selected and highlighted in grey. At the top right, there are buttons for 'Add indexer' (which is highlighted with a red box), 'Refresh', and 'Delete'. Below the top bar, there's a search bar and a 'Filter by name...' input field. The main content area displays a table with columns for 'Status' and 'Name', though no specific data rows are visible.

Run the indexer

By default, an indexer runs immediately when you create it on the search service. You can override this behavior by setting `disabled` to `true` in the indexer definition. Indexer execution is the moment of truth where you find out if there are problems with connections, field mappings, or skillset construction.

There are several ways to run an indexer:

- Run on indexer creation or update (default).
- Run on demand when there are no changes to the definition, or precede with `reset` for full indexing. For more information, see [Run or reset indexers](#).
- [Schedule indexer processing](#) to invoke execution at regular intervals.

Scheduled execution is usually implemented when you have a need for incremental indexing so that you can pick up the latest changes. As such, scheduling has a dependency on change detection.

Indexers are one of the few subsystems that make overt outbound calls to other Azure resources. In terms of Azure roles, indexers don't have separate identities; a connection from the search engine to another Azure resource is made using the [system or user-assigned managed identity](#) of a search service. If the indexer connects to an Azure resource on a virtual

network, you should create a [shared private link](#) for that connection. For more information about secure connections, see [Security in Azure AI Search](#).

Check results

[Monitor indexer status](#) to check for status. Successful execution can still include warning and notifications. Be sure to check both successful and failed status notifications for details about the job.

For content verification, [run queries](#) on the populated index that return entire documents or selected fields.

Change detection and internal state

If your data source supports change detection, an indexer can detect underlying changes in the data and process just the new or updated documents on each indexer run, leaving unchanged content as-is. If indexer execution history says that a run was successful with *0/0* documents processed, it means that the indexer didn't find any new or changed rows or blobs in the underlying data source.

Change detection logic is built into the data platforms. How an indexer supports change detection varies by data source:

- Azure Storage has built-in change detection, which means an indexer can recognize new and updated documents automatically. Blob Storage, Azure Table Storage, and Azure Data Lake Storage Gen2 stamp each blob or row update with a date and time. An indexer automatically uses this information to determine which documents to update in the index. For more information about deletion detection, see [Change and delete detection using indexers for Azure Storage](#).
- Cloud database technologies provide optional change detection features in their platforms. For these data sources, change detection isn't automatic. You need to specify in the data source definition which policy is used:
 - [Azure SQL \(change detection\)](#)
 - [Azure DB for MySQL \(change detection\)](#)
 - [Azure Cosmos DB for NoSQL \(change detection\)](#)
 - [Azure Cosmos DB for MongoDB \(change detection\)](#)
 - [Azure Cosmos DB for Apache Gremlin \(change detection\)](#)

Indexers keep track of the last document it processed from the data source through an internal *high water mark*. The marker is never exposed in the API, but internally the indexer keeps track

of where it stopped. When indexing resumes, either through a scheduled run or an on-demand invocation, the indexer references the high water mark so that it can pick up where it left off.

If you need to clear the high water mark to reindex in full, you can use [Reset Indexer](#). For more selective reindexing, use [Reset Skills](#) or [Reset Documents](#). Through the reset APIs, you can clear internal state, and also flush the cache if you enabled [incremental enrichment](#). For more background and comparison of each reset option, see [Run or reset indexers, skills, and documents](#).

Run or reset indexers, skills, or documents

10/02/2025

In Azure AI Search, there are several ways to run an indexer:

- [Run immediately upon indexer creation](#). This is the default unless you create the indexer in a "disabled" state.
- [Run on a schedule](#) to invoke execution at regular intervals.
- Run on demand, with or without a "reset".

This article explains how to run indexers on demand, with and without a reset. It also describes indexer execution, duration, and concurrency.

How indexers connect to Azure resources

Indexers are one of the few subsystems that make overt outbound calls to other Azure resources. Depending on the external data source, you can use keys or roles to authenticate the connection.

In terms of Azure roles, indexers don't have separate identities: a connection from the search engine to another Azure resource is made using the [system or user-assigned managed identity](#) of a search service, plus a role assignment on the target Azure resource. If the indexer connects to an Azure resource on a virtual network, you should create a [shared private link](#) for that connection.

Indexer execution

A search service runs one indexer job per [search unit](#). Every search service starts with one search unit, but each new partition or replica increases the search units of your service. You can check the search unit count in the Azure portal's Essential section of the [Overview](#) page. If you need concurrent processing, make sure your search units include sufficient replicas. Indexers don't run in the background, so you might experience more query throttling than usual if the service is under pressure.

The following screenshot shows the number of search units, which determines how many indexers can run at once.

Essentials		View Cost	JSON View
Resource group (move) :		Url	: https://demo-srch.search.windows.net
Location (move)	: South Central US	Pricing tier	: Basic
Subscription (move)	:	Replicas	: 2 (99.9% read SLA)
Subscription ID	:	Partitions	: 1
Status	: Running	Search units : 2	

Once indexer execution starts, you can't pause or stop it. Indexer execution stops when there are no more documents to load or refresh, or when the [maximum running time limit](#) is reached.

You can run multiple indexers at one time assuming sufficient capacity, but each indexer itself is single-instance. Starting a new instance while the indexer is already in execution produces this error: "Failed to run indexer "<indexer name>" error: "Another indexer invocation is currently in progress; concurrent invocations are not allowed."

Indexer execution environment

An indexer job runs in a managed execution environment. Currently, there are two environments:

- A private execution environment runs on search clusters that are specific to your search service.
- A multitenant environment has content processors that are managed and secured by Microsoft at no extra cost. This environment is used to offload computationally intensive processing, leaving service-specific resources available for routine operations. Whenever possible, most skillsets execute in the multitenant environment. This is the default.

Computationally intensive processing refers to skillsets running on content processors and indexer jobs that process a high volume of documents, or documents of a large size. Non-skillset processing on the multitenant content processors is determined by heuristics and system information and isn't under customer control.

You can prevent usage of the multitenant environment on Standard2 or higher services by pinning an indexer and skillset processing exclusively to your search clusters. [Set the executionEnvironment parameter](#) in the indexer definition to always run an indexer in the private execution environment.

[IP firewalls](#) block the multitenant environment, so if you have a firewall, [create a rule](#) that allows multitenant processor connections.

Indexer limits vary for each environment:

Workload	Maximum duration	Maximum jobs	Execution environment
Private execution	24 hours	One indexer job per search unit ¹	Indexing doesn't run in the background. Instead, the search service balances all indexing jobs against ongoing queries and object management actions (such as creating or updating indexes). When running indexers, you should expect to see some query latency if indexing volumes are large.
Multitenant	2 hours ²	Indeterminate ³	Because the content processing cluster is multitenant, content processors are added to meet demand. If you experience a delay in on-demand or scheduled execution, it's probably because the system is either adding processors or waiting for one to become available.

¹ Search units can be [flexible combinations](#) of partitions and replicas, but indexer jobs aren't tied to one or the other. In other words, if you have 12 units, you can have 12 indexer jobs running concurrently in private execution, no matter how the search units are deployed.

² If more than two hours are needed to process all of the data, [enable change detection](#) and [schedule the indexer](#) to run at 5-minute intervals to resume indexing quickly if it stops due to a time out. See [Indexing a large data set](#) for more strategies.

³ "Indeterminate" means that the limit isn't quantified by the number of jobs. Some workloads, such as skillset processing, can run in parallel, which could result in many jobs even though only one indexer is involved. Although the environment doesn't impose constraints, [indexer limits](#) for your search service still apply.

Run without reset

A [Run Indexer](#) operation detects and processes only what it necessary to synchronize the search index with changes in the underlying data source. Incremental indexing starts by locating an internal high-water mark to find the last updated search document, which becomes the starting point for indexer execution over new and updated documents in the data source.

[Change detection](#) is essential for determining what's new or updated in the data source. Indexers use the change detection capabilities of the underlying data source to determine what's new or updated in the data source.

- Azure Storage has built-in change detection through its LastModified property.

- Other data sources, such as Azure SQL or Azure Cosmos DB, have to be configured for change detection before the indexer can read new and updated rows.

If the underlying content is unchanged, a run operation has no effect. In this case, indexer execution history indicates `0\0` documents processed.

You need to reset the indexer, as explained in the next section, to reprocess in full.

Resetting indexers

After the initial run, an indexer keeps track of which search documents are indexed through an internal *high-water mark*. The marker is never exposed, but internally the indexer knows where it last stopped.

If you need to rebuild all or part of an index, use Reset APIs available at decreasing levels in the object hierarchy:

- [Reset Indexers](#) clears the high-water mark and performs a full reindex of all documents
- [Resync Indexers \(preview\)](#) performs an efficient partial reindex of all documents
- [Reset Documents \(preview\)](#) reindexes a specific document or list of documents
- [Reset Skills \(preview\)](#) invokes skill processing for a specific skill

After reset, follow with a Run command to reprocess new and existing documents. Orphaned search documents having no counterpart in the data source can't be removed through reset/run. If you need to delete documents, see [Documents - Index](#) instead.

(!) Note

Tables can't be empty. If you use TRUNCATE TABLE to clear rows, a reset and rerun of the indexer won't remove the corresponding search documents. To remove orphaned search documents, you must [index them with a delete action](#).

How to reset and run indexers

Reset clears the high-water mark. All documents in the search index are flagged for full overwrite, without inline updates or merging into existing content. For indexers with a skillset and [enrichment caching](#), resetting the index also implicitly resets the skillset.

The actual work occurs when you follow a reset with a Run command:

- All new documents found the underlying source are added to the search index.

- All documents that exist in both the data source and search index are overwritten in the search index.
- Any enriched content created from skillsets are rebuilt. The enrichment cache, if one is enabled, is refreshed.

As previously noted, reset is a passive operation: you must follow with a Run request to rebuild the index.

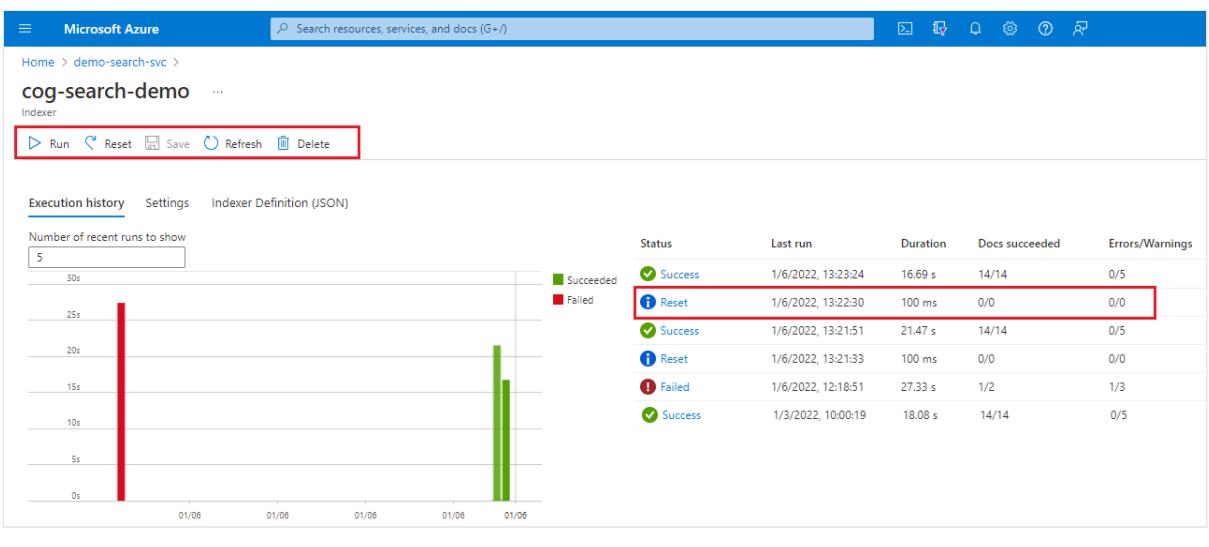

Reset/run operations apply to a search index or a knowledge store, to specific documents or projections, and to cached enrichments if a reset explicitly or implicitly includes skills.

Reset also applies to create and update operations. It won't trigger deletion or clean up of orphaned documents in the search index. For more information about deleting documents, see [Documents - Index](#).

Once you reset an indexer, you can't undo the action.

Azure portal

1. Sign in to the [Azure portal](#) and open the search service page.
2. On the **Overview** page, select the **Indexers** tab.
3. Select an indexer.
4. Select the **Reset** command, and then select **Yes** to confirm the action.
5. Refresh the page to show the status. You can select the item to view its details.
6. Select **Run** to start indexer processing, or wait for the next scheduled execution.

The screenshot shows the Azure portal interface for a search service named "demo-search-svc". Under the "Indexers" tab, there is a single indexer named "cog-search-demo". The "Run" button is highlighted with a red box. Below the indexer name, there's a "Execution history" section with a bar chart showing recent run durations (0s, 5s, 10s, 15s, 20s, 25s, 30s) and a table of execution logs. The log table includes columns for Status, Last run, Duration, Docs succeeded, and Errors/Warnings. One entry for a "Reset" operation is highlighted with a red box.

Status	Last run	Duration	Docs succeeded	Errors/Warnings
✓ Success	1/6/2022, 13:23:24	16.69 s	14/14	0/5
↻ Reset	1/6/2022, 13:22:30	100 ms	0/0	0/0
✓ Success	1/6/2022, 13:21:51	21.47 s	14/14	0/5
↻ Reset	1/6/2022, 13:21:33	100 ms	0/0	0/0
⚠ Failed	1/6/2022, 12:18:51	27.33 s	1/2	1/3
✓ Success	1/3/2022, 10:00:19	18.08 s	14/14	0/5

How to reset skills (preview)

The Reset Skills request selectively processes one or more skills on the next indexer run. For indexers that have skillsets, you can reset individual skills to force reprocessing of just that skill and any downstream skills that depend on its output. The [enrichment cache](#), if you enabled it, is also refreshed.

For indexers that have caching enabled, you can explicitly request processing for skill updates that the indexer cannot detect. For example, if you make external changes, such as revisions to a custom skill, you can use this API to rerun the skill. Outputs, such as a knowledge store or search index, are refreshed using reusable data from the cache and new content per the updated skill.

We recommend the [latest preview API](#).

HTTP

```
POST /skillsets/[skillset name]/resetskills?api-version=2025-08-01-preview
{
    "skillNames" : [
        "#1",
        "#5",
        "#6"
    ]
}
```

You can specify individual skills, as indicated in the example above, but if any of those skills require output from unlisted skills (#2 through #4), unlisted skills will run unless the cache can provide the necessary information. In order for this to be true, cached enrichments for skills #2 through #4 must not have dependency on #1 (listed for reset).

If no skills are specified, the entire skillset is executed and if caching is enabled, the cache is also refreshed.

Remember to follow up with [Run Indexer](#) to invoke actual processing.

How to reset docs (preview)

The [Indexers - Reset Docs \(preview\)](#) accepts a list of document keys so that you can refresh specific documents. If specified, the reset parameters become the sole determinant of what gets processed, regardless of other changes in the underlying data. For example, if 20 blobs were added or updated since the last indexer run, but you only reset one document, only that document is processed.

On a per-document basis, all fields in the search document are refreshed with values and metadata from the data source. You can't pick and choose which fields to refresh.

If the data source is Azure Data Lake Storage (ADLS) Gen2, and the blobs are associated with permission metadata, those permissions are also re-ingested in the search index if permissions change in the underlying data. For more information, see [Re-indexing ACL and RBAC scope with ADLS Gen2 indexers](#).

If the document is enriched through a skillset and has cached data, the skillset is invoked for just the specified documents, and the cache is updated for the reprocessed documents.

When you're testing this API for the first time, the following APIs can help you validate and test the behaviors. We recommend the latest preview API.

1. Call [Indexers - Get Status](#) with a preview API version to check reset status and execution status. You can find information about the reset request at the end of the status response.
2. Call [Indexers - Reset Docs](#) with a preview API version to specify which documents to process.

HTTP

```
POST https://[service name].search.windows.net/indexers/[indexer
name]/resetdocs?api-version=2025-08-01-preview
{
    "documentKeys" : [
        "1001",
        "4452"
    ]
}
```

- The API accepts two types of document identifiers as input: Document keys that uniquely identify documents in a search index, and datasource document identifiers that uniquely identify documents in a data source. The body should contain either a list of document keys or a list of data source document identifiers that the indexer looks for in the data source. Invoking the API adds the document keys or data source document identifiers to be reset to the indexer metadata. On the next scheduled or on-demand run of the indexer, the indexer processes only the reset documents.
- If you use document keys to reset documents and your document keys are referenced in an indexer field mapping, the indexer uses field mapping to locate the appropriate field in the underlying data source.

- The document keys provided in the request are values from the search index, which can be different from the corresponding fields in the data source. If you're unsure of the key value, [send a query](#) to return the value. You can use `select` to return just the document key field.
- For blobs that are parsed into multiple search documents (where parsingMode is set to `jsonLines` or `jsonArrays`, or `delimitedText`), the document key is generated by the indexer and might be unknown to you. In this scenario, a query for the document key to return the correct value.
- If you want the indexer to stop trying to process reset documents, you can set "documentKeys" or "datasourceDocumentIds" to an empty list "[]". This results in the indexer resuming regular indexing based on the high water mark. Invalid document keys or document keys that don't exist are ignored.

3. Call [Run Indexer](#) (any API version) to process the documents you specified. Only those specific documents are indexed.

4. Call [Run Indexer](#) a second time to process from the last high-water mark.

5. Call [Search Documents](#) to check for updated values, and also to return document keys if you're unsure of the value. Use `"select": "<field names>"` if you want to limit which fields appear in the response.

Overwriting the document key list

Calling Reset Documents API multiple times with different keys appends the new keys to the list of document keys reset. Calling the API with the `overwrite` parameter set to true will overwrite the current list with the new one:

HTTP

```
POST https://[service name].search.windows.net/indexers/[indexer name]/resetdocs?
api-version=2025-08-01-Preview
{
  "documentKeys" : [
    "200",
    "630"
  ],
  "overwrite": true
}
```

How to resync indexers (preview)

[Resync Indexers](#) is a preview REST API that performs a partial reindex of all documents. An indexer is considered synchronized with its data source when specific fields of all documents in the target index are consistent with the data in the data source. Typically, an indexer achieves synchronization after a successful initial run. If a document is deleted from the data source, the indexer remains synchronized according to this definition. However, during the next indexer run, the corresponding document in the target index will be removed if delete tracking is enabled.

If a document is modified in the data source, the indexer becomes unsynchronized. Generally, change tracking mechanisms will resynchronize the indexer during the next run. For example, in Azure Storage, modifying a blob updates its last modified time, allowing it to be re-indexed in the subsequent indexer run because the updated time surpasses the high-water mark set by the previous run.

In contrast, for certain data sources like ADLS Gen2, altering the Access Control Lists (ACLs) of a blob does not change its last modified time, rendering change tracking ineffective if ACLs are to be ingested. Consequently, the modified blob will not be re-indexed in the subsequent run, as only documents modified after the last high-water mark are processed.

While using either "reset" or "reset docs" can address this issue, "reset" can be time-consuming and inefficient for large datasets, and "reset docs" requires identifying the document key of the blob intended for update.

Resync Indexers offers an efficient and convenient alternative. Users simply place the indexer in resync mode and specify the content to resynchronize by calling the resync indexers API. In the next run, the indexer will inspect only relevant portion of data in the source and avoid any unnecessary processing that is unrelated to the specified data. It will also query the existing documents in the target index and only update the documents that show discrepancies between the data source and the target index. After the resync run, the indexer will be synchronized and revert to regular indexer run mode for subsequent runs.

How to resync and run indexers

1. Call [Indexers - Resync](#) with a preview API version to specify what content to re-synchronize.

HTTP

```
POST https://[service name].search.windows.net/indexers/[indexer  
name]/resync?api-version=2025-08-01-preview  
{  
    "options" : [  
        "permissions"  
    ]  
}
```

```
    ]  
}
```

- The `options` field is required. Currently the only supported option is `permissions`. That is, only permission filter fields in the target index will be updated.

2. Call [Run Indexer](#) (any API version) to re-synchronize the indexer.
3. Call [Run Indexer](#) a second time to process from the last high-water mark.

Check reset status "currentState"

To check reset status and to see which document keys are queued up for processing, following these steps.

1. Call [Get Indexer Status](#) with a preview API.

The preview API will return the `currentState` section, found at the end of the response.

JSON

```
"currentState": {  
    "mode": "indexingResetDocs",  
    "allDocsInitialTrackingState": "{\"LastFullEnumerationStartTime\":\"2021-02-06T19:02:07.0323764+00:00\", \"LastAttemptedEnumerationStartTime\":\"2021-02-06T19:02:07.0323764+00:00\", \"NameHighWaterMark\":null}",  
    "allDocsFinalTrackingState": "{\"LastFullEnumerationStartTime\":\"2021-02-06T19:02:07.0323764+00:00\", \"LastAttemptedEnumerationStartTime\":\"2021-02-06T19:02:07.0323764+00:00\", \"NameHighWaterMark\":null}",  
    "resetDocsInitialTrackingState": null,  
    "resetDocsFinalTrackingState": null,  
    "resyncInitialTrackingState": null,  
    "resyncFinalTrackingState": null,  
    "resetDocumentKeys": [  
        "200",  
        "630"  
    ]  
}
```

2. Check the "mode":

For Reset Skills, "mode" should be set to `indexingAllDocs` (because potentially all documents are affected, in terms of the fields that are populated through AI enrichment).

For Resync Indexers, "mode" should be set to `indexingResync`. The indexer checks all documents and focuses on interested data in data source and interested fields in the target index.

For Reset Documents, "mode" should be set to `indexingResetDocs`. The indexer retains this status until all the document keys provided in the reset documents call are processed, during which time no other indexer jobs will execute while the operation is progressing. Finding all of the documents in the document keys list requires cracking each document to locate and match on the key, and this can take a while if the data set is large. If a blob container contains hundreds of blobs, and the docs you want to reset are at the end, the indexer won't find the matching blobs until all of the others have been checked first.

3. After the documents are reprocessed, run Get Indexer Status again. The indexer returns to the `indexingAllDocs` mode and will process any new or updated documents on the next run.

Check indexer runtime quota for S3 HD search services

Applies to search services at the Standard 3 High Density (S3 HD) pricing tier.

To help you monitor indexer running times relative to the 24-hour window, [Get Service Statistics](#) and [Get Indexer Status](#) now return more information in the response.

Track cumulative runtime quota

Track a search service's cumulative indexer runtime usage and determine how much runtime quota is left within the current 24-hour window period.

Send a GET request to the search service resource provider. For help with setting up a REST client and getting an access token, see [Connect to a search service](#).

HTTP

```
GET {{search-endpoint}}/servicestats?api-version=2025-08-01-preview
Content-Type: application/json
Authorization: Bearer {{accessToken}}
```

Responses include `indexersRuntime` properties, showing start and end times, seconds used, seconds remaining, and cumulative runtime within the last 24 hours.

Track indexer runtime quota

Return the same information for a single indexer.

HTTP

```
GET {{search-endpoint}}/indexers/hotels-sample-indexer/search.status?api-version=2025-08-01-preview
Content-Type: application/json
Authorization: Bearer {{accessToken}}
```

Responses include a `runtime` properties, showing start and end times, seconds used, and seconds remaining.

Next steps

Reset APIs are used to inform the scope of the next indexer run. For actual processing, you'll need to invoke an on-demand indexer run or allow a scheduled job to complete the work. After the run is finished, the indexer returns to normal processing, whether that is on a schedule or on-demand processing.

After you reset and rerun indexer jobs, you can monitor status from the search service, or obtain detailed information through resource logging.

- [Monitor search indexer status](#)
- [Collect and analyze log data](#)
- [Schedule an indexer](#)

Schedule an indexer in Azure AI Search

09/24/2025

Indexers can be configured to run on a schedule when you set the `schedule` property. Some situations where indexer scheduling is useful include:

- Source data is changing over time, and you want the indexer to automatically process the difference.
- Source data is very large, and you need a recurring schedule to index all of the content.
- An index is populated from multiple sources, using multiple indexers, and you want to stagger the jobs to reduce conflicts.

When indexing can't complete within the [typical 2-hour processing window](#), you can schedule the indexer to run on a 2-hour cadence to work through a large volume of data. As long as your data source supports [change detection logic](#), indexers can automatically pick up where they left off on each run.

Once an indexer is on a schedule, it remains on the schedule until you clear the interval or start time, or set `disabled` to true. Leaving the indexer on a schedule when there's nothing to process won't impact system performance. Checking for changed content is a relatively fast operation.

Prerequisites

- A valid indexer configured with a data source and index.
- [Change detection](#) in the data source. Azure Storage and SharePoint have built-in change detection. Other data sources, such as [Azure SQL](#) and [Azure Cosmos DB](#) must be enabled manually.

Schedule definition

A schedule is part of the indexer definition. If the `schedule` property is omitted, the indexer will only run on demand. The property has two parts.

[] [Expand table](#)

Property	Description
"interval"	(required) The amount of time between the start of two consecutive indexer executions. The smallest interval allowed is 5 minutes, and the longest is 1440 minutes (24 hours). It must be formatted as an XSD "dayTimeDuration" value (a restricted subset of an ISO 8601

Property	Description
	<p>duration ↗ value).</p> <p>The pattern for this is: <code>P(nD)(T(nH)(nM))</code>.</p> <p>Examples: <code>PT15M</code> for every 15 minutes, <code>PT2H</code> for every two hours.</p>
"startTime"	(optional) Start time is specified in coordinated universal time (UTC). If omitted, the current time is used. This time can be in the past, in which case the first execution is scheduled as if the indexer has been running continuously since the original start time.

The following example is a schedule that starts on January 1 at midnight and runs every two hours.

JSON

```
{
  "dataSourceName" : "hotels-ds",
  "targetIndexName" : "hotels-idx",
  "schedule" : { "interval" : "PT2H", "startTime" : "2024-01-01T00:00:00Z" }
}
```

Configure a schedule

Schedules are specified in an indexer definition. To set up a schedule, you can use Azure portal, REST APIs, or an Azure SDK.

Azure portal

1. Sign in to the [Azure portal](#) [↗](#) and open the search service page.
2. On the left pane, select **Indexes**.
3. Open an indexer.
4. Select **Settings**.
5. Scroll down to **Schedule**, and then choose Hourly, Daily, or Custom to set a specific date, time, or custom interval.

Switch to the **Indexer Definition (JSON)** tab at the top of the index to view the schedule definition in XSD format.

Scheduling behavior FAQ

Can I run multiple indexer jobs in parallel?

You can run multiple indexers simultaneously, but each indexer is single instance. You can't run two copies of the same indexer concurrently.

For text-based indexing, the scheduler can kick off as many indexer jobs as the search service supports, which is determined by the number of [search units](#). For example, if the service has three replicas and four partitions, you can have 12 indexer jobs in active execution, whether initiated on demand or on a schedule.

For skills-based indexing, indexers run in a specific [execution environment](#). For this reason, the number of service units has no bearing on the number of skills-based indexer jobs you can run. Multiple skills-based indexers can run in parallel, but doing so depends on content processor availability within the execution environment.

Do scheduled jobs always start at the designated time?

Indexer processes can be queued up and might not start exactly at the time posted, depending on the processing workload and other factors. For example, if an indexer happens to still be running when its next scheduled execution is set to start, the pending execution is postponed until the next scheduled occurrence, allowing the current job to finish.

Let's consider an example to make this more concrete. Suppose we configure an indexer schedule with an interval of hourly and a start time of January 1, 2024 at 8:00:00 AM UTC. Here's what could happen when an indexer run takes longer than an hour:

1. The first indexer execution starts at or around January 1, 2024 at 8:00 AM UTC. Assume this execution takes 20 minutes (or any amount of time that's less than 1 hour).
2. The second execution starts at or around January 1, 2024 9:00 AM UTC. Suppose that this execution takes 70 minutes – more than an hour – and it will not complete until 10:10 AM UTC.
3. The third execution is scheduled to start at 10:00 AM UTC, but at that time the previous execution is still running. This scheduled execution is then skipped. The next execution of the indexer won't start until 11:00 AM UTC.

In rare cases, such as during maintenance or when recovering from transient conditions, multiple indexer runs are queued up. When this occurs, the indexer executes pending workloads sequentially within the scheduled window. For example, if an indexer is scheduled to run hourly and several runs were delayed or triggered on-demand, those queued up jobs will execute back-to-back until the queue is drained. These are not additional runs, but represent previously scheduled or requested executions. While this behavior is uncommon in most scenarios, the indexer is designed to eventually process all queued tasks to maintain consistency and data freshness.

Note

If you have strict indexer execution requirements that are time-sensitive, you should consider using the [push API model](#) so you can control the indexing pipeline directly.

What happens if indexing fails repeatedly on the same document?

If an indexer is set to a certain schedule but repeatedly fails on the same document each time, the indexer will begin running on a less frequent interval (up to the maximum interval of at least once every 2 hours or 24 hours, depending on different implementation factors) until it successfully makes progress again. If you believe you have fixed the underlying issue, you can [run the indexer manually](#), and if indexing succeeds, the indexer will return to its regular schedule.

Next steps

For indexers that run on a schedule, you can monitor operations by retrieving status from the search service, or obtain detailed information by enabling resource logging.

- [Index large data sets](#)

Field mappings and transformations using Azure AI Search indexers

09/23/2025

This article explains how to set explicit field mappings that establish the data path between source fields in a supported data source and target fields in a search index.

When to set a field mapping

When an [Azure AI Search indexer](#) loads a search index, it determines the data path using source-to-destination field mappings. Implicit field mappings are internal and occur when field names and data types are compatible between the source and destination. If inputs and outputs don't match, you can define explicit *field mappings* to set up the data path, as described in this article.

Field mappings can also be used for light-weight data conversions, such as encoding or decoding, through [mapping functions](#). If more processing is required, consider [Azure Data Factory](#) to bridge the gap.

Field mappings apply to:

- Physical data structures on both sides of the data path. Logical data structures created by skills reside only in memory. Use [outputFieldMappings](#) to map in-memory nodes to output fields in a search index.
- Parent AI Search indexes only. For "secondary" indexes with "child" documents or "chunks", refer to the [advanced field mapping scenarios](#).
- Top-level search fields only, where the `targetFieldName` is either a simple field or a collection. A target field can't be a complex type.

Supported scenarios

Make sure you're using a [supported data source](#) for indexer-driving indexing.

Use-case	Description
Name discrepancy	<p>Suppose your data source has a field named <code>_city</code>. Given that Azure AI Search doesn't allow field names that start with an underscore, a field mapping lets you effectively map "<code>_city</code>" to "city".</p> <p>If your indexing requirements include retrieving content from multiple data sources, where field names vary among the sources, you could use a field mapping to clarify the path.</p>
Type discrepancy	<p>Supposed you want a source integer field to be of type <code>Edm.String</code> so that it's searchable in the search index. Because the types are different, you'll need to define a field mapping in order for the data path to succeed. Note that Azure AI Search has a smaller set of supported data types than many data sources. If you're importing SQL data, a field mapping allows you to map the SQL data type you want in a search index.</p>
One-to-many data paths	<p>You can populate multiple fields in the index with content from the same source field. For example, you might want to apply different analyzers to each field to support different use cases in your client app.</p>
Encoding and decoding	<p>You can apply mapping functions to support Base64 encoding or decoding of data during indexing.</p>
Split strings or recast arrays into collections	<p>You can apply mapping functions to split a string that includes a delimiter, or to send a JSON array to a search field of type <code>Collection(Edm.String)</code>.</p>

Note

If no field mappings are present, indexers assume data source fields should be mapped to index fields with the same name. Adding a field mapping overrides the default field mappings for the source and target field. Some indexers, such as the [blob storage indexer](#), add default field mappings for the index key field automatically.

Complex fields aren't supported in a field mapping. Your source structure (nested or hierarchical structures) must exactly match the complex type in the index so that the default mappings work. For more information, see [Tutorial: Index nested JSON blobs](#) for an example. If you get an error similar to `"Field mapping specifies target field 'Address/city' that doesn't exist in the index"`, it's because target field mappings can't be a complex type.

Optionally, you might want just a few nodes in the complex structure. To get individual nodes, you can flatten incoming data into a string collection (see [outputFieldMappings](#) for this workaround).

Define a field mapping

This section explains the steps for setting up field mappings.

REST APIs

1. Use [Create Indexer](#) or [Create or Update Indexer](#) or an equivalent method in an Azure SDK. Here's an example of an indexer definition.

JSON

```
{  
  "name": "myindexer",  
  "description": null,  
  "dataSourceName": "mydatasource",  
  "targetIndexName": "myindex",  
  "schedule": { },  
  "parameters": { },  
  "fieldMappings": [],  
  "disabled": false,  
  "encryptionKey": { }  
}
```

2. Fill out the `fieldMappings` array to specify the mappings. A field mapping consists of three parts.

JSON

```
"fieldMappings": [  
  {  
    "sourceFieldName": "_city",  
    "targetFieldName": "city",  
    "mappingFunction": null  

```

 [Expand table](#)

Property	Description
sourceFieldName	Required. Represents a field in your data source.
targetFieldName	Optional. Represents a field in your search index. If omitted, the value of <code>sourceFieldName</code> is assumed for the target. Target fields must be top-level simple fields or collections. It can't be a complex type or collection. If you're handling a data type issue, a field's data type is specified in the index definition. The field mapping just needs to have the field's name.
mappingFunction	Optional. Consists of predefined functions that transform data.

Example: Name or type discrepancy

An explicit field mapping establishes a data path for cases where name and type aren't identical.

Azure AI Search uses case-insensitive comparison to resolve the field and function names in field mappings. This is convenient (you don't have to get all the casing right), but it means that your data source or index can't have fields that differ only by case.

JSON

```
PUT https://[service name].search.windows.net/indexers/myindexer?api-version=[api-version]
Content-Type: application/json
api-key: [admin key]
{
    "dataSourceName" : "mydatasource",
    "targetIndexName" : "myindex",
    "fieldMappings" : [ { "sourceFieldName" : "_city", "targetFieldName" :
"city" } ]
}
```

Example: One-to-many or forked data paths

This example maps a single source field to multiple target fields ("one-to-many" mappings). You can "fork" a field, copying the same source field content to two different index fields that will be analyzed or attributed differently in the index.

JSON

```
"fieldMappings" : [
    { "sourceFieldName" : "text", "targetFieldName" :
"textStandardEnglishAnalyzer" },
    { "sourceFieldName" : "text", "targetFieldName" : "textSoundexAnalyzer" }
]
```

You can use a similar approach for [skills-generated content](#).

Mapping functions and examples

A field mapping function transforms the contents of a field before it's stored in the index. The following mapping functions are currently supported:

- [base64Encode](#)

- [base64Decode](#)
- [extractTokenAtPosition](#)
- [fixedLengthEncode](#)
- [jsonArrayToStringCollection](#)
- [toJson](#)
- [urlEncode](#)
- [urlDecode](#)

Note that these functions are exclusively supported for parent indexes at this time. They aren't compatible with chunked index mapping, therefore, these functions can't be used for [index projections](#).

base64Encode function

Performs *URL-safe* Base64 encoding of the input string. Assumes that the input is UTF-8 encoded.

Example: Base-encoding a document key

Only URL-safe characters can appear in an Azure AI Search document key (so that you can address the document using the [Lookup API](#)). If the source field for your key contains URL-unsafe characters, such as `-` and `\`, use the `base64Encode` function to convert it at indexing time.

The following example specifies the `base64Encode` function on `metadata_storage_name` to handle unsupported characters.

HTTP

```
PUT /indexers?api-version=2025-09-01
{
  "dataSourceName" : "my-blob-datasource",
  "targetIndexName" : "my-search-index",
  "fieldMappings" : [
    {
      "sourceFieldName" : "metadata_storage_name",
      "targetFieldName" : "key",
      "mappingFunction" : {
        "name" : "base64Encode",
        "parameters" : { "useHttpServerUtilityUrlTokenEncode" : false }
      }
    }
  ]
}
```

A document key (both before and after conversion) can't be longer than 1,024 characters.

When you retrieve the encoded key at search time, use the `base64Decode` function to get the original key value, and use that to retrieve the source document.

Example: Make a base-encoded field "searchable"

There are times when you need to use an encoded version of a field like

`metadata_storage_path` as the key, but also need an unencoded version for full text search. To support both scenarios, you can map `metadata_storage_path` to two fields: one for the key (encoded), and a second for a path field that we can assume is attributed as `searchable` in the index schema.

HTTP

```
PUT /indexers/blob-indexer?api-version=2025-09-01
{
    "dataSourceName" : "blob-datasource",
    "targetIndexName" : "my-target-index",
    "schedule" : { "interval" : "PT2H" },
    "fieldMappings" : [
        { "sourceFieldName" : "metadata_storage_path", "targetFieldName" : "key",
        "mappingFunction" : { "name" : "base64Encode" } },
        { "sourceFieldName" : "metadata_storage_path", "targetFieldName" : "path"
    }
]
}
```

Example - preserve original values

The [blob storage indexer](#) automatically adds a field mapping from `metadata_storage_path`, the URI of the blob, to the index key field if no field mapping is specified. This value is Base64 encoded so it's safe to use as an Azure AI Search document key. The following example shows how to simultaneously map a *URL-safe* Base64 encoded version of `metadata_storage_path` to a `index_key` field and preserve the original value in a `metadata_storage_path` field:

JSON

```
"fieldMappings": [
    {
        "sourceFieldName": "metadata_storage_path",
        "targetFieldName": "metadata_storage_path"
    },
    {
        "sourceFieldName": "metadata_storage_path",
        "targetFieldName": "index_key",
    }
]
```

```
        "mappingFunction": {
            "name": "base64Encode"
        }
    }
]
```

If you don't include a parameters property for your mapping function, it defaults to the value `{"useHttpServerUtilityUrlTokenEncode" : true}`.

Azure AI Search supports two different Base64 encodings. You should use the same parameters when encoding and decoding the same field. For more information, see [base64 encoding options](#) to decide which parameters to use.

base64Decode function

Performs Base64 decoding of the input string. The input is assumed to be a *URL-safe* Base64-encoded string.

Example - decode blob metadata or URLs

Your source data might contain Base64-encoded strings, such as blob metadata strings or web URLs, that you want to make searchable as plain text. You can use the `base64Decode` function to turn the encoded data back into regular strings when populating your search index.

JSON

```
"fieldMappings" : [
    {
        "sourceFieldName" : "Base64EncodedMetadata",
        "targetFieldName" : "SearchableMetadata",
        "mappingFunction" : {
            "name" : "base64Decode",
            "parameters" : { "useHttpServerUtilityUrlTokenDecode" : false }
        }
    }
]
```

If you don't include a parameters property, it defaults to the value `{"useHttpServerUtilityUrlTokenEncode" : true}`.

Azure AI Search supports two different Base64 encodings. You should use the same parameters when encoding and decoding the same field. For more information, see [base64 encoding options](#) to decide which parameters to use.

base64 encoding options

Azure AI Search supports URL-safe base64 encoding and normal base64 encoding. A string that is base64 encoded during indexing should be decoded later with the same encoding options, or else the result won't match the original.

If the `useHttpServerUtilityUrlTokenEncode` or `useHttpServerUtilityUrlTokenDecode` parameters for encoding and decoding respectively are set to `true`, then `base64Encode` behaves like `HttpServerUtility.UrlTokenEncode` and `base64Decode` behaves like `HttpServerUtility.UrlTokenDecode`.

⚠ Warning

If `base64Encode` is used to produce key values, `useHttpServerUtilityUrlTokenEncode` must be set to true. Only URL-safe base64 encoding can be used for key values. See [Naming rules](#) for the full set of restrictions on characters in key values.

The .NET libraries in Azure AI Search assume the full .NET Framework, which provides built-in encoding. The `useHttpServerUtilityUrlTokenEncode` and `useHttpServerUtilityUrlTokenDecode` options apply this built-in functionality. If you're using .NET Core or another framework, we recommend setting those options to `false` and calling your framework's encoding and decoding functions directly.

The following table compares different base64 encodings of the string `00>00?00`. To determine the required processing (if any) for your base64 functions, apply your library encode function on the string `00>00?00` and compare the output with the expected output `MDA-MDA_MDA`.

 [Expand table](#)

Encoding	Base64 encode output	Extra processing after library encoding	Extra processing before library decoding
Base64 with padding	MDA+MDA/MDA=	Use URL-safe characters and remove padding	Use standard base64 characters and add padding
Base64 without padding	MDA+MDA/MDA	Use URL-safe characters	Use standard base64 characters
URL-safe base64 with padding	MDA-MDA_MDA=	Remove padding	Add padding
URL-safe base64 without padding	MDA-MDA_MDA	None	None

extractTokenAtPosition function

Splits a string field using the specified delimiter, and picks the token at the specified position in the resulting split.

This function uses the following parameters:

- `delimiter`: a string to use as the separator when splitting the input string.
- `position`: an integer zero-based position of the token to pick after the input string is split.

For example, if the input is `Jane Doe`, the `delimiter` is `" "`(space) and the `position` is 0, the result is `Jane`; if the `position` is 1, the result is `Doe`. If the position refers to a token that doesn't exist, an error is returned.

Example - extract a name

Your data source contains a `PersonName` field, and you want to index it as two separate `FirstName` and `LastName` fields. You can use this function to split the input using the space character as the delimiter.

JSON

```
"fieldMappings" : [
  {
    "sourceFieldName" : "PersonName",
    "targetFieldName" : "FirstName",
    "mappingFunction" : { "name" : "extractTokenAtPosition", "parameters" : {
      "delimiter" : " ", "position" : 0 } }
  },
  {
    "sourceFieldName" : "PersonName",
    "targetFieldName" : "LastName",
    "mappingFunction" : { "name" : "extractTokenAtPosition", "parameters" : {
      "delimiter" : " ", "position" : 1 } }
  }
]
```

jsonArrayToStringCollection function

Transforms a string formatted as a JSON array of strings into a string array that can be used to populate a `Collection(Edm.String)` field in the index.

For example, if the input string is `["red", "white", "blue"]`, then the target field of type `Collection(Edm.String)` will be populated with the three values `red`, `white`, and `blue`. For

input values that can't be parsed as JSON string arrays, an error is returned.

Example - populate collection from relational data

Azure SQL Database doesn't have a built-in data type that naturally maps to `Collection(Edm.String)` fields in Azure AI Search. To populate string collection fields, you can preprocess your source data as a JSON string array and then use the `jsonArrayToStringCollection` mapping function.

JSON

```
"fieldMappings" : [
  {
    "sourceFieldName" : "tags",
    "mappingFunction" : { "name" : "jsonArrayToStringCollection" }
  }
]
```

urlEncode function

This function can be used to encode a string so that it is "URL safe". When used with a string that contains characters that aren't allowed in a URL, this function will convert those "unsafe" characters into character-entity equivalents. This function uses the UTF-8 encoding format.

Example - document key lookup

`urlEncode` function can be used as an alternative to the `base64Encode` function, if only URL unsafe characters are to be converted, while keeping other characters as-is.

Say, the input string is `<hello>` - then the target field of type `(Edm.String)` will be populated with the value `%3chello%3e`

When you retrieve the encoded key at search time, you can then use the `urlDecode` function to get the original key value, and use that to retrieve the source document.

JSON

```
"fieldMappings" : [
  {
    "sourceFieldName" : "SourceKey",
    "targetFieldName" : "IndexKey",
    "mappingFunction" : {
      "name" : "urlEncode"
    }
}
```

```
    }  
]
```

urlDecode function

This function converts a URL-encoded string into a decoded string using UTF-8 encoding format.

Example - decode blob metadata

Some Azure storage clients automatically URL-encode blob metadata if it contains non-ASCII characters. However, if you want to make such metadata searchable (as plain text), you can use the `urlDecode` function to turn the encoded data back into regular strings when populating your search index.

JSON

```
"fieldMappings" : [  
  {  
    "sourceFieldName" : "UrlEncodedMetadata",  
    "targetFieldName" : "SearchableMetadata",  
    "mappingFunction" : {  
      "name" : "urlDecode"  
    }  
  }  
]
```

fixedLengthEncode function

This function converts a string of any length to a fixed-length string.

Example - map document keys that are too long

When errors occur that are related to document key length exceeding 1024 characters, this function can be applied to reduce the length of the document key.

JSON

```
"fieldMappings" : [  
  {  
    "sourceFieldName" : "metadata_storage_path",  
    "targetFieldName" : "your key field",  
    "mappingFunction" : {
```

```
        "name" : "fixedLengthEncode"
    }
]
```

toJson function

This function converts a string into a formatted JSON object. This can be used for scenarios where the data source, such as Azure SQL, doesn't natively support compound or hierarchical data types, and then map it to complex fields.

Example - map text content to a complex field

Assume there's a SQL row with a JSON string that needs to be mapped to a (correspondingly defined) complex field in the index, the `toJson` function can be used to achieve this. For instance, if a complex field in the index needs to be populated with the following data:

JSON

```
{
  "id": "5",
  "info": {
    "name": "Jane",
    "surname": "Smith",
    "skills": [
      "SQL",
      "C#",
      "Azure"
    ],
    "dob": "2005-11-04T12:00:00"
  }
}
```

It can be achieved by using the `toJson` mapping function on a JSON string column in a SQL row that looks like this: `{"id": 5, "info": {"name": "Jane", "surname": "Smith", "skills": ["SQL", "C#", "Azure"]}, "dob": "2005-11-04T12:00:00"}`.

The field mapping needs to be specified as shown below.

JSON

```
"fieldMappings" : [
{
  "sourceFieldName" : "content",
  "targetFieldName" : "complexField",
```

```
        "mappingFunction" : {  
            "name" : "toJson"  
        }  
    }  
]
```

Advanced field mapping scenarios

In scenarios where you have "one-to-many" document relationships, such as data chunking or splitting, follow these guidelines for mapping fields from parent documents to "child" documents (chunks):

1. Skipping parent document indexing

If you are skipping the indexing of parent documents (by setting `projectionMode` to `skipIndexingParentDocuments` in the skillset's `indexProjections`), use [index projections](#) to map fields from the parent documents to the "child" documents.

2. Indexing both parent and "child" documents

If you are indexing both parent documents and "child" documents:

- Use field mappings to map fields to the parent documents.
- Use [index projections](#) to map fields to the "child" documents.

3. Mapping function-transformed values to parent and/or "child" documents

If a field in the parent document requires a transformation (using the [mapping functions](#) such as encoding) and needs to be mapped to the parent and/or "child" documents:

- Apply the transformation using field mappings' [functions](#) in the indexer.
- Use [index projections](#) in the skillset to map the transformed field to the "child" documents.

Content metadata properties used in Azure AI Search

Article • 04/14/2025

Several indexer-supported data sources, including Azure Blob Storage, Azure Data Lake Storage Gen2, and SharePoint, contain standalone files or embedded objects of various content types. Many of those content types have metadata properties that can be useful to index. Just as you can create search fields for standard blob properties like `metadata_storage_name`, you can create fields in a search index for metadata properties that are specific to a document format.

Supported document formats

Azure AI Search supports blob indexing and SharePoint document indexing for the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Document format properties

The following table summarizes processing for each document format, and describes the metadata properties extracted by a blob indexer and the SharePoint Online indexer.

 Expand table

Document format / content type	Extracted metadata	Processing details
CSV (text/csv)	<code>metadata_content_type</code> <code>metadata_content_encoding</code>	Extract text NOTE: If you need to extract multiple document fields from a CSV blob, see Index CSV blobs
DOC (application/msword)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_character_count</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code> <code>metadata_page_count</code> <code>metadata_word_count</code>	Extract text, including embedded documents
DOCM (application/vnd.ms-word.document.macroenabled.12)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_character_count</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code> <code>metadata_page_count</code> <code>metadata_word_count</code>	Extract text, including embedded documents
DOCX (application/vnd.openxmlformats-officedocument.wordprocessingml.document)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_character_count</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code> <code>metadata_page_count</code> <code>metadata_word_count</code>	Extract text, including embedded documents
EML (message/rfc822)	<code>metadata_content_type</code> <code>metadata_message_from</code> <code>metadata_message_to</code> <code>metadata_message_cc</code> <code>metadata_creation_date</code> <code>metadata_subject</code>	Extract text, including attachments
EPUB (application/epub+zip)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_creation_date</code> <code>metadata_title</code> <code>metadata_description</code> <code>metadata_language</code> <code>metadata_keywords</code> <code>metadata_identifier</code> <code>metadata_publisher</code>	Extract text from all documents in the archive
GZ (application/gzip)	<code>metadata_content_type</code>	Extract text from all

Document format / content type	Extracted metadata	Processing details
		documents in the archive
HTML (text/html or application/xhtml+xml)	<code>metadata_content_encoding</code> <code>metadata_content_type</code> <code>metadata_language</code> <code>metadata_description</code> <code>metadata_keywords</code> <code>metadata_title</code>	Strip HTML elements and extract text
JSON (application/json)	<code>metadata_content_type</code> <code>metadata_content_encoding</code>	Extract text NOTE: If you need to extract multiple document fields from a JSON blob, see Index JSON blobs
KML (application/vnd.google-earth.kml+xml)	<code>metadata_content_type</code> <code>metadata_content_encoding</code> <code>metadata_language</code>	Strip XML elements and extract text
MSG (application/vnd.ms-outlook)	<code>metadata_content_type</code> <code>metadata_message_from</code> <code>metadata_message_from_email</code> <code>metadata_message_to</code> <code>metadata_message_to_email</code> <code>metadata_message_cc</code> <code>metadata_message_cc_email</code> <code>metadata_message_bcc</code> <code>metadata_message_bcc_email</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code> <code>metadata_subject</code>	Extract text, including text extracted from attachments. <code>metadata_message_to_email</code> , <code>metadata_message_cc_email</code> , and <code>metadata_message_bcc_email</code> are string collections. The rest of the fields are strings.
ODP (application/vnd.oasis.opendocument.presentation)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code> <code>metadata_title</code>	Extract text, including embedded documents
ODS (application/vnd.oasis.opendocument.spreadsheet)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code>	Extract text, including embedded documents
ODT (application/vnd.oasis.opendocument.text)	<code>metadata_content_type</code> <code>metadata_author</code> <code>metadata_character_count</code> <code>metadata_creation_date</code> <code>metadata_last_modified</code>	Extract text, including embedded documents

Document format / content type	Extracted metadata	Processing details
	metadata_page_count metadata_word_count	
PDF (application/pdf)	metadata_content_type metadata_language metadata_author metadata_title metadata_creation_date	Extract text, including embedded documents (excluding images)
Plain text (text/plain)	metadata_content_type metadata_content_encoding metadata_language	Extract text
PPT (application/vnd.ms-powerpoint)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified metadata_slide_count metadata_title	Extract text, including embedded documents
PPTM (application/vnd.ms-powerpoint.presentation.macroenabled.12)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified metadata_slide_count metadata_title	Extract text, including embedded documents
PPTX (application/vnd.openxmlformats-officedocument.presentationml.presentation)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified metadata_slide_count metadata_title	Extract text, including embedded documents
RTF (application/rtf)	metadata_content_type metadata_author metadata_character_count metadata_creation_date metadata_last_modified metadata_page_count metadata_word_count	Extract text
WORD 2003 XML (application/vnd.ms-wordml)	metadata_content_type metadata_author metadata_creation_date	Strip XML elements and extract text
WORD XML (application/vnd.ms-word2006ml)	metadata_content_type metadata_author metadata_character_count	Strip XML elements and extract text

Document format / content type	Extracted metadata	Processing details
	metadata_creation_date metadata_last_modified metadata_page_count metadata_word_count	
XLS (application/vnd.ms-excel)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified	Extract text, including embedded documents
XLSM (application/vnd.ms-excel.sheet.macroenabled.12)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified	Extract text, including embedded documents
XLSX (application/vnd.openxmlformats-officedocument.spreadsheetml.sheet)	metadata_content_type metadata_author metadata_creation_date metadata_last_modified	Extract text, including embedded documents
XML (application/xml)	metadata_content_type metadata_content_encoding metadata_language	Strip XML elements and extract text
ZIP (application/zip)	metadata_content_type	Extract text from all documents in the archive

Indexing blobs and files to produce multiple search documents

10/09/2025

Applies to: [Blob indexers](#), [File indexers](#)

By default, an indexer treats the contents of a blob or file as a single search document. If you want a more granular representation in a search index, you can set **parsingMode** values to create multiple search documents from one blob or file. The **parsingMode** values that result in many search documents include `delimitedText` (for [CSV](#)), and `jsonArray` or `jsonLines` (for [JSON](#)).

When you use any of these parsing modes, the new search documents that emerge must have unique document keys, and a problem arises in determining where that value comes from. The parent blob has at least one unique value in the form of `metadata_storage_path` property, but if it contributes that value to more than one search document, the key is no longer unique in the index.

To address this problem, the blob indexer generates an `AzureSearch_DocumentKey` that uniquely identifies each child search document created from the single blob parent. This article explains how this feature works.

One-to-many document key

A document key uniquely identifies each document in an index. When no parsing mode is specified, and if there's no [explicit field mapping](#) in the indexer definition for the search document key, the blob indexer automatically maps the `metadata_storage_path` property as the document key. This default mapping ensures that each blob appears as a distinct search document. It also eliminates the need for you to manually create this field mapping. Normally, fields with identical names and types are the only ones mapped automatically.

In a one-to-many search document scenario, an implicit document key based on `metadata_storage_path` property isn't possible. As a workaround, Azure AI Search can generate a document key for each individual entity extracted from a blob. The system generates a key called `AzureSearch_DocumentKey` and adds it to each search document. The indexer keeps track of the "many documents" created from each blob, and can target updates to the search index when source data changes over time.

By default, when no explicit field mappings for the key index field are specified, the `AzureSearch_DocumentKey` is mapped to it, using the `base64Encode` field-mapping function.

Example

Assume an index definition with the following fields:

- `id`
- `temperature`
- `pressure`
- `timestamp`

And your blob container has blobs with the following structure:

Blob1.json

JSON

```
{ "temperature": 100, "pressure": 100, "timestamp": "2024-02-13T00:00:00Z" }  
{ "temperature" : 33, "pressure" : 30, "timestamp": "2024-02-14T00:00:00Z" }
```

Blob2.json

JSON

```
{ "temperature": 1, "pressure": 1, "timestamp": "2023-01-12T00:00:00Z" }  
{ "temperature" : 120, "pressure" : 3, "timestamp": "2022-05-11T00:00:00Z" }
```

When you create an indexer and set the `parsingMode` to `jsonLines` - without specifying any explicit field mappings for the key field, the following mapping is applied implicitly.

HTTP

```
{  
  "sourceFieldName" : "AzureSearch_DocumentKey",  
  "targetFieldName": "id",  
  "mappingFunction": { "name" : "base64Encode" }  
}
```

This setup results in disambiguated document keys, similar to the following illustration (base64-encoded ID shortened for brevity).

[] Expand table

ID	temperature	pressure	timestamp
aHR0 ... YjEuanNvbjsx	100	100	2024-02-13T00:00:00Z

ID	temperature	pressure	timestamp
aHR0 ... YjEuanNvbjsy	33	30	2024-02-14T00:00:00Z
aHR0 ... YjluanNvbjsx	1	1	2023-01-12T00:00:00Z
aHR0 ... YjluanNvbjsy	120	3	2022-05-11T00:00:00Z

Custom field mapping for index key field

Assuming the same index definition as the previous example, suppose your blob container has blobs with the following structure:

Blob1.json

JSON

```
recordid, temperature, pressure, timestamp
1, 100, 100, "2024-02-13T00:00:00Z"
2, 33, 30, "2024-02-14T00:00:00Z"
```

Blob2.json

JSON

```
recordid, temperature, pressure, timestamp
1, 1, 1, "20123-01-12T00:00:00Z"
2, 120, 3, "2022-05-11T00:00:00Z"
```

When you create an indexer with `delimitedText` **parsingMode**, it might feel natural to set up a field-mapping function to the key field as follows:

HTTP

```
{
  "sourceFieldName" : "recordid",
  "targetFieldName": "id"
}
```

However, this mapping doesn't result in four documents showing up in the index because the `recordid` field isn't unique *across blobs*. Hence, we recommend you to make use of the implicit field mapping applied from the `AzureSearch_DocumentKey` property to the key index field for "one-to-many" parsing modes.

If you do want to set up an explicit field mapping, make sure that the `sourceField` is distinct for each individual entity **across all blobs**.

! Note

The approach used by `AzureSearch_DocumentKey` of ensuring uniqueness per extracted entity is subject to change and therefore you shouldn't rely on its value for your application's needs.

Specify the index key field in your data

Assuming the same index definition as the previous example and `parsingMode` is set to `jsonLines` without specifying any explicit field mappings so the mappings look like in the first example, suppose your blob container has blobs with the following structure:

Blob1.json

JSON

```
id, temperature, pressure, timestamp
1, 100, 100, "2024-02-13T00:00:00Z"
2, 33, 30, "2024-02-14T00:00:00Z"
```

Blob2.json

JSON

```
id, temperature, pressure, timestamp
1, 1, 1, "2023-01-12T00:00:00Z"
2, 120, 3, "2022-05-11T00:00:00Z"
```

Each document contains the `id` field, which is defined as the `key` field in the index. In this situation, the system generates a unique `AzureSearch_DocumentKey` for the document, but it isn't used as the "key." Instead, the value of the `id` field is mapped to the `key`` field.

Similar to the previous example, this mapping doesn't result in four documents showing up in the index because the `id` field isn't unique *across blobs*. When this situation occurs, any JSON entry that specifies an `id` causes a merge with the existing document instead of uploading a new one. The index then reflects the latest state of the entry with the specified `id`.

Limitations

When a document entry in the index is created from a line in a file, as explained in this article, deleting that line from the file doesn't automatically remove the corresponding entry from the index. To delete the document entry, you must manually submit a deletion request to the index using the [REST API deletion operation](#).

Next steps

If you aren't already familiar with the basic structure and workflow of blob indexing, you should review [Indexing Azure Blob Storage with Azure AI Search](#) first. For more information about parsing modes for different blob content types, review the following articles.

[Indexing CSV blobs](#)

[Indexing JSON blobs](#)

Index plain text blobs and files in Azure AI Search

10/09/2025

Applies to: [Blob indexers](#), [File indexers](#)

When using an indexer to extract searchable blob text or file content for full text search, you can assign a parsing mode to get better indexing outcomes. By default, the indexer parses a blob's `content` property as a single chunk of text. However, if all blobs and files contain plain text in the same encoding, you can significantly improve indexing performance by using the `text` parsing mode.

Recommendations for `text` parsing include either of the following characteristics:

- File type is `.txt`
- Files are of any type, but the content itself is text (for example, program source code, HTML, XML, and so forth). For files in a markup language, the syntax characters come through as static text.

Recall that all indexers serialize to JSON. By default, the content of the entire text file is indexed within one large field as `"content": "<file-contents>"`. New line and return instructions are embedded in the content field and expressed as `\r\n\`.

If you want a more refined or granular outcome, and if the file type is compatible, consider the following solutions:

- [delimitedText](#) parsing mode, if the source is CSV
- [jsonArray](#) or [jsonLines](#), if the source is JSON

An alternative third option for breaking content into multiple parts requires advanced features in the form of [AI enrichment](#). It adds analysis that identifies and assigns chunks of the file to different search fields. You might find a full or partial solution through [built-in skills](#) such as entity recognition or keyword extraction, but a more likely solution might be a custom learning model that understands your content, wrapped in a [custom skill](#).

Set up plain text indexing

To index plain text blobs, create or update an indexer definition with the `parsingMode` configuration property set to `text` on a [Create Indexer](#) request:

HTTP

```
PUT https://[service name].search.windows.net/indexers/[indexer name]?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    ... other parts of indexer definition
    "parameters" : { "configuration" : { "parsingMode" : "text" } }
}
```

By default, the `UTF-8` encoding is assumed. To specify a different encoding, use the `encoding` configuration property. The supported [list of encodings](#) is under [.NET 5 and later support](#) column.

HTTP

```
{
    ... other parts of indexer definition
    "parameters" : { "configuration" : { "parsingMode" : "text", "encoding" : "iso-8859-1" } }
}
```

Request example

Parsing modes are specified in the indexer definition.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "my-plaintext-indexer",
    "dataSourceName" : "my-blob-datasource",
    "targetIndexName" : "my-target-index",
    "parameters" : { "configuration" : { "parsingMode" : "delimitedText",
    "delimitedTextHeaders" : "id,datePublished,tags" } }
}
```

Change and delete detection using indexers for Azure Storage in Azure AI Search

10/09/2025

After an initial search index is created, you might want subsequent indexer jobs to only pick up new and changed documents. For indexed content that originates from Azure Storage, change detection occurs automatically because indexers keep track of the last update using the built-in timestamps on objects and files in Azure Storage.

Although change detection is a given, deletion detection isn't. An indexer doesn't track object deletion in data sources. To avoid having orphan search documents, you can implement a "soft delete" strategy that results in deleting search documents first, with physical deletion in Azure Storage following as a second step.

There are two ways to implement a soft delete strategy:

- [Native blob soft delete](#), applies to Blob Storage only
- [Soft delete using custom metadata](#)

The deletion detection strategy must be applied from the very first indexer run. If you didn't establish the deletion policy prior to the initial run, any documents that were deleted before the policy was implemented will remain in your index, even if you add the policy to the indexer later and reset it. If this has occurred, it's suggested that you create a new index using a new indexer, ensuring the deletion policy is in place from the beginning.

Prerequisites

- Use an Azure Storage indexer for [Blob Storage](#), [Table Storage](#), [File Storage](#), or [Data Lake Storage Gen2](#)
- Use consistent document keys and file structure. Changing document keys or directory names and paths (applies to ADLS Gen2) breaks the internal tracking information used by indexers to know which content was indexed, and when it was last indexed.

Note

ADLS Gen2 allows directories to be renamed. When a directory is renamed, the timestamps for the blobs in that directory don't get updated. As a result, the indexer won't reindex those blobs. If you need the blobs in a directory to be reindexed after a directory

rename because they now have new URLs, you need to update the `LastModified` timestamp for all the blobs in the directory so that the indexer knows to reindex them during a future run. The virtual directories in Azure Blob Storage can't be changed, so they don't have this issue.

Native blob soft delete

For this deletion detection approach, Azure AI Search depends on the [native blob soft delete](#) feature in Azure Blob Storage to determine whether blobs have transitioned to a soft deleted state. When blobs are detected in this state, a search indexer uses this information to remove the corresponding document from the index.

Requirements for native soft delete

- Blobs must be in an Azure Blob Storage container, including ADLS Gen2 Blob container. The Azure AI Search native blob soft delete policy isn't supported for Azure Files.
- [Enable soft delete for blobs](#).
- Document keys for the documents in your index must be mapped to either be a blob property or blob metadata, such as "metadata_storage_path".
- You can use the [REST API](#), or the indexer Data Source configuration in the Azure portal, to configure support for soft delete.
- [Blob versioning](#) must not be enabled in the storage account. Otherwise, native soft delete isn't supported by design.

Configure native soft delete

In Blob storage, when enabling soft delete per the requirements, set the retention policy to a value that's much higher than your indexer interval schedule. If there's an issue running the indexer, or if you have a large number of documents to index, there's plenty of time for the indexer to eventually process the soft deleted blobs. Azure AI Search indexers will only delete a document from the index if it processes the blob while it's in a soft deleted state.

In Azure AI Search, set a native blob soft deletion detection policy on the data source. You can do this either from the Azure portal or by using the [REST API](#). The following instructions explain how to set the delete detection policy in Azure portal or through REST APIs.

Azure portal

1. Sign in to the [Azure portal](#).
2. On the Azure AI Search service Overview page, go to **New Data Source**, a visual editor for specifying a data source definition.

The following screenshot shows where you can find this feature in the Azure portal.

The screenshot shows the Azure AI Search service Overview page for a search service named "azure-cognitive-search-service". The left sidebar includes links for Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, and Settings. The main content area has tabs for Get Started, Usage, Monitoring, Indexes, Indexers, and Data sources. The "Data sources" tab is selected, and a red box highlights the "+ New Data Source" button. Below it, there is a table with one row labeled "my-blob-data-source".

3. On the **New Data Source** form, fill out the required fields, select the **Track deletions** checkbox and choose **Native blob soft delete**. Then hit **Save** to enable the feature on Data Source creation.

The screenshot shows the "New Data Source" form for creating a data source. The "Settings" tab is selected. The "Data Source" dropdown is set to "Azure Blob Storage". The "Name" field is filled with "my-blob-data-source". The "Connection string" field contains "DefaultEndpointsProtocol=https;AccountName=[accountName];AccountKey=[accountKey]". Under "Managed identity authentication", the "None" option is selected. The "Container name" field is set to "mycontainer". The "Blob folder" field is set to "your/folder/here". The "Track deletions" checkbox is checked. Under "Data deletion detection policy", the "Native blob soft delete" radio button is selected. A red box highlights the "Native blob soft delete" radio button. The "Description" field is empty and labeled "(optional)".

Reindex undeleted blobs using native soft delete policies

If you restore a soft deleted blob in Blob storage, the indexer won't always reindex it. This is because the indexer uses the blob's `LastModified` timestamp to determine whether indexing is needed. When a soft deleted blob is undeleted, its `LastModified` timestamp doesn't get updated, so if the indexer has already processed blobs with more recent `LastModified` timestamps, it won't reindex the undeleted blob.

To make sure that an undeleted blob is reindexed, you'll need to update the blob's `LastModified` timestamp. One way to do this is by resaving the metadata of that blob. You don't need to change the metadata, but resaving the metadata will update the blob's `LastModified` timestamp so that the indexer knows to pick it up.

Soft delete strategy using custom metadata

This method uses custom metadata to indicate whether a search document should be removed from the index. It requires two separate actions: deleting the search document from the index, followed by file deletion in Azure Storage.

This feature is generally available.

There are steps to follow in both Azure Storage and Azure AI Search, but there are no other feature dependencies.

1. In Azure Storage, add a custom metadata key-value pair to the file to indicate the file is flagged for deletion. For example, you could name the property "IsDeleted", set to false. When you want to delete the file, change it to true.
2. In Azure AI Search, edit the data source definition to include a "dataDeletionDetectionPolicy" property. For example, the following policy considers a file to be deleted if it has a metadata property `IsDeleted` with the value `true`:

HTTP

```
PUT https://[service name].search.windows.net/datasources/file-datasource?  
api-version=2025-09-01  
{  
    "name" : "file-datasource",  
    "type" : "azurefile",  
    "credentials" : { "connectionString" : "<your storage connection string>" },  
    "container" : { "name" : "my-share", "query" : null },  
    "dataDeletionDetectionPolicy" : {  
        "@odata.type"  
        :"#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",  
        "softDeleteColumnName" : "IsDeleted",  
        "softDeleteMarkerValue" : "true"
```

```
    }  
}
```

3. Run the indexer. Once the indexer has processed the file and deleted the document from the search index, you can then delete the physical file in Azure Storage.

Reindex undeleted blobs and files

You can reverse a soft-delete if the original source file still physically exists in Azure Storage.

1. Change the `"softDeleteMarkerValue" : "false"` on the blob or file in Azure Storage.
2. Check the blob or file's `LastModified` timestamp to make it's newer than the last indexer run. You can force an update to the current date and time by resaving the existing metadata.
3. Run the indexer.

Index JSON blobs and files in Azure AI Search

10/09/2025

Applies to: [Blob indexers](#), [File indexers](#)

For blob indexing in Azure AI Search, this article shows you how to set properties for blobs or files consisting of JSON documents. JSON files in Azure Blob Storage or Azure Files commonly assume any of these forms:

- A single JSON document
- A JSON document containing an array of well-formed JSON elements
- A JSON document containing multiple entities, separated by a newline

The blob indexer provides a `parsingMode` parameter to optimize the output of the search document based on JSON structure. Parsing modes consist of the following options:

[] [Expand table](#)

parsingMode	JSON document	Description
<code>json</code>	One per blob	(default) Parses JSON blobs as a single chunk of text. Each JSON blob becomes a single search document.
<code>jsonArray</code>	Multiple per blob	Parses a JSON array in the blob, where each element of the array becomes a separate search document.
<code>jsonLines</code>	Multiple per blob	Parses a blob that contains multiple JSON entities (also an array), with individual elements separated by a newline. The indexer starts a new search document after each new line.

For both `jsonArray` and `jsonLines`, you should review [Indexing one blob to produce many search documents](#) to understand how the blob indexer handles disambiguation of the document key for multiple search documents produced from the same blob.

Within the indexer definition, you can optionally set [field mappings](#) to choose which properties of the source JSON document are used to populate your target search index. For example, when using the `jsonArray` parsing mode, if the array exists as a lower-level property, you can set a "documentRoot" property indicating where the array is placed within the blob.

! **Note**

When a JSON parsing mode is used, Azure AI Search assumes that all blobs use the same parser (either for `json`, `jsonArray` or `jsonLines`). If you have a mix of different file types in the same data source, consider using [file extension filters](#) to control which files are imported.

The following sections describe each mode in more detail. If you're unfamiliar with indexer clients and concepts, see [Create a search indexer](#). You should also be familiar with the details of [basic blob indexer configuration](#), which isn't repeated here.

Index single JSON documents (one per blob)

By default, blob indexers parse JSON blobs as a single chunk of text, one search document for each blob in a container. If the JSON is structured, the search document can reflect that structure, with individual elements represented as individual fields. For example, assume you have the following JSON document in Azure Blob Storage:

HTTP

```
{  
  "article" : {  
    "text" : "A hopefully useful article explaining how to parse JSON blobs",  
    "datePublished" : "2020-04-13",  
    "tags" : [ "search", "storage", "howto" ]  
  }  
}
```

The blob indexer parses the JSON document into a single search document, loading an index by matching "text", "datePublished", and "tags" from the source against identically named and typed target index fields. Given an index with "text", "datePublished", and "tags" fields, the blob indexer can infer the correct mapping without a field mapping present in the request.

Although the default behavior is one search document per JSON blob, setting the `json` parsing mode changes the internal field mappings for content, promoting fields inside `content` to actual fields in the search index. An example indexer definition for the `json` parsing mode might look like this:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01  
Content-Type: application/json  
api-key: [admin key]  
  
{  
  "name" : "my-json-indexer",
```

```
"dataSourceName" : "my-blob-datasource",
"targetIndexName" : "my-target-index",
"parameters" : { "configuration" : { "parsingMode" : "json" } }
}
```

ⓘ Note

As with all indexers, if fields don't clearly match, you should expect to explicitly specify individual [field mappings](#) unless you're using the implicit fields mappings available for blob content and metadata, as described in [basic blob indexer configuration](#). To override an existing index value, the source JSON must provide a non-null value. If the field in the source document is null, the indexer will retain the existing value. To explicitly clear a field, pass an empty string ("") instead. This prevents unintended deletions from the index.

json example (single hotel JSON files)

The [hotel JSON document data set](#) on GitHub is helpful for testing JSON parsing, where each blob represents a structured JSON file. You can upload the data files to Blob Storage and use an [import wizard](#) to quickly evaluate how this content is parsed into individual search documents.

The data set consists of five blobs, each containing a hotel document with an address collection and a rooms collection. The blob indexer detects both collections and reflects the structure of the input documents in the index schema.

Parse JSON arrays

Alternatively, you can use the JSON array option. This option is useful when blobs contain an array of well-formed JSON objects, and you want each element to become a separate search document. Using `jsonArrays`, the following JSON blob produces three separate documents, each with `"id"` and `"text"` fields.

```
text
```

```
[  
  { "id" : "1", "text" : "example 1" },  
  { "id" : "2", "text" : "example 2" },  
  { "id" : "3", "text" : "example 3" }  
]
```

The `parameters` property on the indexer contains parsing mode values. For a JSON array, the indexer definition should look similar to the following example.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    "name" : "my-json-indexer",
    "dataSourceName" : "my-blob-datasource",
    "targetIndexName" : "my-target-index",
    "parameters" : { "configuration" : { "parsingMode" : "jsonArray" } }
}
```

jsonArrays example

The [New York Philharmonic JSON data set](#) on GitHub is helpful for testing JSON array parsing. You can upload the data files to Blob storage and use an [import wizard](#) to quickly evaluate how this content is parsed into individual search documents.

The data set consists of eight blobs, each containing a JSON array of entities, for a total of 100 entities. The entities vary as to which fields are populated, but the end result is one search document per entity, from all arrays, in all blobs.

Parsing nested JSON arrays

For JSON arrays having nested elements, you can specify a `documentRoot` to indicate a multi-level structure. For example, if your blobs look like this:

HTTP

```
{
    "level1" : {
        "level2" : [
            { "id" : "1", "text" : "Use the documentRoot property" },
            { "id" : "2", "text" : "to pluck the array you want to index" },
            { "id" : "3", "text" : "even if it's nested inside the document" }
        ]
    }
}
```

Use this configuration to index the array contained in the `level2` property:

HTTP

```
{  
  "name" : "my-json-array-indexer",  
  ... other indexer properties  
  "parameters" : { "configuration" : { "parsingMode" : "jsonArray",  
"documentRoot" : "/level1/level2" } }  
}
```

Parse JSON entities separated by newlines

If your blob contains multiple JSON entities separated by a newline, and you want each element to become a separate search document, use `jsonLines`.

text

```
{ "id" : "1", "text" : "example 1" }  
{ "id" : "2", "text" : "example 2" }  
{ "id" : "3", "text" : "example 3" }
```

For JSON lines, the indexer definition should look similar to the following example.

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01  
Content-Type: application/json  
api-key: [admin key]  
  
{  
  "name" : "my-json-indexer",  
  "dataSourceName" : "my-blob-datasource",  
  "targetIndexName" : "my-target-index",  
  "parameters" : { "configuration" : { "parsingMode" : "jsonLines" } }  
}
```

Map JSON fields to search fields

Field mappings associate a source field with a destination field in situations where the field names and types aren't identical. But field mappings can also be used to match parts of a JSON document and "lift" them into top-level fields of the search document.

The following example illustrates this scenario. For more information about field mappings in general, see [field mappings](#).

HTTP

```
{  
  "article" : {  
    "text" : "A hopefully useful article explaining how to parse JSON blobs",  
    "datePublished" : "2016-04-13"  
    "tags" : [ "search", "storage", "howto" ]  
  }  
}
```

Assume a search index with the following fields: `text` of type `Edm.String`, `date` of type `Edm.DateTimeOffset`, and `tags` of type `Collection(Edm.String)`. Notice the discrepancy between "datePublished" in the source and `date` field in the index. To map your JSON into the desired shape, use the following field mappings:

HTTP

```
"fieldMappings" : [  
  { "sourceFieldName" : "/article/text", "targetFieldName" : "text" },  
  { "sourceFieldName" : "/article/datePublished", "targetFieldName" : "date" },  
  { "sourceFieldName" : "/article/tags", "targetFieldName" : "tags" }  
]
```

Source fields are specified using the [JSON Pointer](#) notation. You start with a forward slash to refer to the root of your JSON document, then pick the desired property (at arbitrary level of nesting) by using forward slash-separated path.

You can also refer to individual array elements by using a zero-based index. For example, to pick the first element of the "tags" array from the above example, use a field mapping like this:

HTTP

```
{ "sourceFieldName" : "/article/tags/0", "targetFieldName" : "firstTag" }
```

ⓘ Note

If "sourceFieldName" refers to a property that doesn't exist in the JSON blob, that mapping is skipped without an error. This behavior allows indexing to continue for JSON blobs that have a different schema (which is a common use case). Because there's no validation check, check the mappings carefully for typos so that you aren't losing documents for the wrong reason.

Index Markdown blobs and files in Azure AI Search

10/09/2025

! Note

This feature is currently in public preview. This preview is provided without a service-level agreement and isn't recommended for production workloads. Certain features might not be supported or might have constrained capabilities. For more information, see [Supplemental Terms of Use for Microsoft Azure Previews](#).

In Azure AI Search, indexers for Azure Blob Storage, Azure Files, and Microsoft OneLake support a `markdown` parsing mode for Markdown files. Markdown files can be indexed in two ways:

- One-to-many parsing mode, creating multiple search documents per Markdown file
- One-to-one parsing mode, creating one search document per Markdown file

💡 Tip

Continue on to the [Tutorial: Search Markdown data from Azure Blob Storage](#) after reviewing this article.

Prerequisites

- A supported data source: Azure Blob storage, Azure File storage, Microsoft OneLake.

For OneLake, make sure you meet all of the requirements of the [OneLake indexer](#).

Azure Storage for [blob indexers](#) and [file indexers](#) is a standard performance (general-purpose v2) instance that supports hot and cool access tiers.

Markdown parsing mode parameters

Parsing mode parameters are specified in an indexer definition when you create or update an indexer.

HTTP

```

POST https://[service name].search.windows.net/indexers?api-version=2025-08-01-preview
Content-Type: application/json
api-key: [admin key]

{
  "name": "my-markdown-indexer",
  "dataSourceName": "my-blob-datasource",
  "targetIndexName": "my-target-index",
  "parameters": {
    "configuration": {
      "parsingMode": "markdown",
      "markdownParsingSubmode": "oneToMany",
      "markdownHeaderDepth": "h6"
    }
  },
}

```

The blob indexer provides a `submode` parameter to determine the output of structure of the search documents. Markdown parsing mode provides the following submode options:

 Expand table

parsingMode	submode	Search document	Description
<code>markdown</code>	<code>oneToMany</code>	Multiple per blob	(default) Breaks the Markdown into multiple search documents, each representing a content (nonheader) section of the Markdown file. You can omit submode unless you want one-to-one parsing.
<code>markdown</code>	<code>oneToOne</code>	One per blob	Parses the Markdown into one search document, with sections mapped to specific headers in the Markdown file.

For `oneToMany` submode, you should review [Indexing one blob to produce many search documents](#) to understand how the blob indexer handles disambiguation of the document key for multiple search documents produced from the same blob.

Later sections describe each submode in more detail. If you're unfamiliar with indexer clients and concepts, see [Create a search indexer](#). You should also be familiar with the details of [basic blob indexer configuration](#), which isn't repeated here.

Optional Markdown parsing parameters

Parameters are case-sensitive.

Parameter name	Allowed Values	Description
markdownHeaderDepth	h1, h2, h3, h4, h5, h6(default)	This parameter determines the deepest header level that is considered when parsing, allowing for flexible handling of document structure (for example, when <code>markdownHeaderDepth</code> is set to <code>h1</code> , the parser only recognizes top-level headers that begin with "#", and all lower-level headers are treated as plain text). If not specified, it defaults to <code>h6</code> .

This setting can be changed after initial creation of the indexer, however the structure of the resulting search documents might change depending on the Markdown content.

Supported Markdown elements

Markdown parsing only splits content based on headers. All other elements such as lists, code blocks, tables, and so forth, are treated as plain text and passed into a content field.

Sample Markdown content

The following Markdown content is used for the examples on this page:

Markdown
<pre># Section 1 Content for section 1. ## Subsection 1.1 Content for subsection 1.1. # Section 2 Content for section 2.</pre>

Use one-to-many parsing mode

The one-to-many parsing mode parses Markdown files into multiple search documents, where each document corresponds to a specific content section of the Markdown file based on the header metadata at that point in the document. The Markdown is parsed based on headers into search documents, which contain the following content:

- `content`: A string that contains the raw Markdown found in a specific location, based on the header metadata at that point in the document.
- `sections`: An object that contains subfields for the header metadata up to the desired header level. For example, when `markdownHeaderDepth` is set to `h3`, contains string fields `h1`, `h2`, and `h3`. These fields are indexed by mirroring this structure in the index, or through field mappings in the format `/sections/h1`, `sections/h2`, etc. See index and indexer configurations in the following samples for in-context examples. The subfields contained are:
 - `h1` - A string containing the `h1` header value. Empty string if not set at this point in the document.
 - (Optional) `h2` - A string containing the `h2` header value. Empty string if not set at this point in the document.
 - (Optional) `h3` - A string containing the `h3` header value. Empty string if not set at this point in the document.
 - (Optional) `h4` - A string containing the `h4` header value. Empty string if not set at this point in the document.
 - (Optional) `h5` - A string containing the `h5` header value. Empty string if not set at this point in the document.
 - (Optional) `h6` - A string containing the `h6` header value. Empty string if not set at this point in the document.
- `ordinal_position`: An integer value indicating the position of the section within the document hierarchy. This field is used for ordering the sections in their original sequence as they appear in the document, beginning with an ordinal position of 1 and incrementing sequentially for each header.

Index schema for one-to-many parsing

An example index configuration might look something like this:

HTTP

```
{
  "name": "my-markdown-index",
  "fields": [
    {
      "name": "id",
      "type": "Edm.String",
      "key": true
    },
    {
      "name": "content",
      "type": "Edm.String",
    }
  ]
}
```

```
},
{
  "name": "ordinal_position",
  "type": "Edm.Int32"
},
{
  "name": "sections",
  "type": "Edm.ComplexType",
  "fields": [
    {
      "name": "h1",
      "type": "Edm.String"
    },
    {
      "name": "h2",
      "type": "Edm.String"
    }
  ]
}
}
```

Indexer definition for one-to-many parsing

If field names and data types align, the blob indexer can infer the mapping without an explicit field mapping present in the request, so an indexer configuration corresponding to the provided index configuration might look like this:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-08-01-preview
Content-Type: application/json
api-key: [admin key]

{
  "name": "my-markdown-indexer",
  "dataSourceName": "my-blob-datasource",
  "targetIndexName": "my-target-index",
  "parameters": {
    "configuration": { "parsingMode": "markdown" }
  },
}
```

⚠ Note

The `submode` doesn't need to be set explicitly here because `oneToMany` is the default.

Indexer output for one-to-many parsing

This Markdown file would result in three search documents after indexing, due to the three content sections. The search document resulting from the first content section of the provided Markdown document would contain the following values for `content`, `sections`, `h1`, and `h2`:

```
HTTP
{
  {
    "content": "Content for section 1.\r\n",
    "sections": {
      "h1": "Section 1",
      "h2": ""
    },
    "ordinal_position": 1
  },
  {
    "content": "Content for subsection 1.1.\r\n",
    "sections": {
      "h1": "Section 1",
      "h2": "Subsection 1.1"
    },
    "ordinal_position": 2
  },
  {
    "content": "Content for section 2.\r\n",
    "sections": {
      "h1": "Section 2",
      "h2": ""
    },
    "ordinal_position": 3
  }
}
```

Map one-to-many fields in a search index

Field mappings associate a source field with a destination field in situations where the field names and types aren't identical. But field mappings can also be used to match parts of a Markdown document and "lift" them into top-level fields of the search document.

The following example illustrates this scenario. For more information about field mappings in general, see [field mappings](#).

Assume a search index with the following fields: `raw_content` of type `Edm.String`, `h1_header` of type `Edm.String`, and `h2_header` of type `Edm.String`. To map your Markdown into the desired shape, use the following field mappings:

```
HTTP
```

```
"fieldMappings" : [
  { "sourceFieldName" : "/content", "targetFieldName" : "raw_content" },
  { "sourceFieldName" : "/sections/h1", "targetFieldName" : "h1_header" },
  { "sourceFieldName" : "/sections/h2", "targetFieldName" : "h2_header" },
]
```

The resulting search document in the index would look as follows:

HTTP

```
{
{
  "raw_content": "Content for section 1.\r\n",
  "h1_header": "Section 1",
  "h2_header": "",
},
{
  "raw_content": "Content for section 1.1.\r\n",
  "h1_header": "Section 1",
  "h2_header": "Subsection 1.1",
},
{
  "raw_content": "Content for section 2.\r\n",
  "h1_header": "Section 2",
  "h2_header": ""
}
```

Use one-to-one parsing mode

In the one-to-one parsing mode, the entire Markdown document is indexed as a single search document, preserving the hierarchy and structure of the original content. This mode is most useful when the files to be indexed share a common structure, so that you can use this common structure in the index to make the relevant fields searchable.

Within the indexer definition, set the `parsingMode` to `"markdown"` and use the optional `markdownHeaderDepth` parameter to define the maximum heading depth for chunking. If not specified, it defaults to `h6`, capturing all possible header depths.

The Markdown is parsed based on headers into search documents, which contain the following content:

- `document_content`: Contains the full Markdown text as a single string. This field serves as a raw representation of the input document.

- `sections`: An array of objects that contains the hierarchical representation of the sections within the Markdown document. Each section is represented as an object within this array and captures the structure of the document in a nested manner corresponding to the headers and their respective content. The fields are accessible through field mappings by referencing the path, for example `/sections/content`. The objects in this array have the following properties:
 - `header_level`: A string that indicates the level of the header (`h1`, `h2`, `h3`, etc.) in Markdown syntax. This field helps in understanding the hierarchy and structuring of the content.
 - `header_name`: A string containing the text of the header as it appears in the Markdown document. This field provides a label or title for the section.
 - `content`: A string containing text content that immediately follows the header, up to the next header. This field captures the detailed information or description associated with the header. If there's no content directly under a header, the value is an empty string.
 - `ordinal_position`: An integer value indicating the position of the section within the document hierarchy. This field is used for ordering the sections in their original sequence as they appear in the document, beginning with an ordinal position of 1 and incrementing sequentially for each content block.
 - `sections`: An array that contains objects representing subsections nested under the current section. This array follows the same structure as the top-level `sections` array, allowing for the representation of multiple levels of nested content. Each subsection object also includes `header_level`, `header_name`, `content`, and `ordinal_position` properties, enabling a recursive structure that represents and hierarchy of the Markdown content.

Here's the sample Markdown that we're using to explain the index schemas designed around each parsing mode.

```
Markdown

# Section 1
Content for section 1.

## Subsection 1.1
Content for subsection 1.1.

# Section 2
Content for section 2.
```

Index schema for one-to-one parsing

If you aren't utilizing field mappings, the shape of the index should reflect the shape of the Markdown content. Given the structure of sample Markdown with its two sections and single subsection, the index should look similar to the following example:

HTTP

```
{  
  "name": "my-markdown-index",  
  "fields": [  
    {  
      "name": "id",  
      "type": "Edm.String",  
      "key": true  
    },  
    {  
      "name": "document_content",  
      "type": "Edm.String"  
    },  
    {  
      "name": "sections",  
      "type": "Collection(Edm.ComplexType)",  
      "fields": [  
        {  
          "name": "header_level",  
          "type": "Edm.String"  
        },  
        {  
          "name": "header_name",  
          "type": "Edm.String"  
        },  
        {  
          "name": "content",  
          "type": "Edm.String"  
        },  
        {  
          "name": "ordinal_position",  
          "type": "Edm.Int32"  
        },  
        {  
          "name": "sections",  
          "type": "Collection(Edm.ComplexType)",  
          "fields": [  
            {  
              "name": "header_level",  
              "type": "Edm.String"  
            },  
            {  
              "name": "header_name",  
              "type": "Edm.String"  
            }  
          ]  
        }  
      ]  
    }  
  ]  
}
```

```
        "name": "content",
        "type": "Edm.String"
    },
    {
        "name": "ordinal_position",
        "type": "Edm.Int32"
    }
]
}
}
}
```

Indexer definition for one-to-one parsing

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-08-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name": "my-markdown-indexer",
    "dataSourceName": "my-blob-datasource",
    "targetIndexName": "my-target-index",
    "parameters": {
        "configuration": {
            "parsingMode": "markdown",
            "markdownParsingSubmode": "oneToOne",
        }
    }
}
```

Indexer output for one-to-one parsing

Because the Markdown we want to index only goes to a depth of `h2` ("##"), we need `sections` fields nested to a depth of 2 to match that. This configuration would result in the following data in the index:

HTTP

```
"document_content": "# Section 1\r\nContent for section 1.\r\n## Subsection 1.1\r\nContent for subsection 1.1.\r\n# Section 2\r\nContent for section 2.\r\n",
"sections": [
    {
        "header_level": "h1",
        "header_name": "Section 1",
        "content": "Content for section 1.",
        "ordinal_position": 1,
        "sections": [
            {
                "header_level": "h2",
                "header_name": "Subsection 1.1",
                "content": "Content for subsection 1.1."
            }
        ]
    }
]
```

```

"sections": [
  {
    "header_level": "h2",
    "header_name": "Subsection 1.1",
    "content": "Content for subsection 1.1.",
    "ordinal_position": 2,
  }
],
{
  "header_level": "h1",
  "header_name": "Section 2",
  "content": "Content for section 2.",
  "ordinal_position": 3,
  "sections": []
}
]
}

```

As you can see, the ordinal position increments based on the location of the content within the document.

It should also be noted that if header levels are skipped in the content, then structure of the resulting document reflects the headers that are present in the Markdown content, not necessarily containing nested sections for `h1` through `h6` consecutively. For example, when the document begins at `h2`, then the first element in the top-level sections array is `h2`.

Map one-to-one fields in a search index

If you would like to extract fields with custom names from the document, you can use field mappings to do so. Using the same Markdown sample as before, consider the following index configuration:

HTTP

```

{
  "name": "my-markdown-index",
  "fields": [
    {
      "name": "document_content",
      "type": "Edm.String",
    },
    {
      "name": "document_title",
      "type": "Edm.String",
    },
    {
      "name": "opening_subsection_title"
      "type": "Edm.String",
    }
  ]
}

```

```
        "name": "summary_content",
        "type": "Edm.String",
    }
]
}
```

Extracting specific fields from the parsed Markdown is handled similar to how the document paths are in `outputFieldMappings`, except the path begins with `/sections` instead of `/document`. So, for example, `/sections/0/content` would map to the content under the item at position 0 in the sections array.

An example of a strong use case might look something like this: all Markdown files have a document title in the first `h1`, a subsection title in the first `h2`, and a summary in the content of the final paragraph underneath the final `h1`. You could use the following field mappings to index only that content:

HTTP

```
"fieldMappings" : [
    { "sourceFieldName" : "/content", "targetFieldName" : "raw_content" },
    { "sourceFieldName" : "/sections/0/header_name", "targetFieldName" :
"document_title" },
    { "sourceFieldName" : "/sections/0/sections/header_name", "targetFieldName" :
"opening_subsection_title" },
    { "sourceFieldName" : "/sections/1/content", "targetFieldName" :
"summary_content" },
]
```

Here you would extract only the relevant pieces from that document. To most effectively use this functionality, documents you plan to index should share the same hierarchical header structure.

The resulting search document in the index would look as follows:

HTTP

```
{
    "content": "Content for section 1.\r\n",
    "document_title": "Section 1",
    "opening_subsection_title": "Subsection 1.1",
    "summary_content": "Content for section 2."
}
```

 **Note**

These examples specify how to use these parsing modes entirely with or without field mappings, but you can apply both in one scenario if it suits your needs.

Managing stale documents from Markdown re-indexing

When using one-to-many parsing mode, re-indexing a modified Markdown file can result in stale or duplicate documents if sections are removed. This behavior is specific to one-to-many mode and doesn't apply to one-to-one parsing.

Behavior overview

One-to-many parsing mode

In `oneToMany` mode, each Markdown section (based on headers) is indexed as a separate search document. When the file is re-indexed:

- **No automatic deletion:** The indexer overwrites existing documents with new ones, but it does not delete documents that no longer correspond to any content in the updated file.
- **Potential for duplicates:** This issue specifically arises only when more sections are deleted than inserted between indexing runs. In such cases, leftover documents from the previous version remain in the index, leading to stale entries that no longer reflect the current state of the source file.

One-to-one parsing mode

In `oneToOne` mode, the entire Markdown file is indexed as a single search document. When the file is re-indexed:

- **Overwrite behavior:** The existing document is replaced entirely with the new version.
- **No stale sections:** When the file is re-indexed, the existing document is replaced with the updated version and removed content is no longer included. The only exception is if the file path or blob URI changes, which could result in a new document being created alongside the old one.

Workaround options

To ensure the index reflects the current state of your Markdown files, consider one of the following approaches:

Option 1. Soft delete with metadata

This method uses a soft-delete to delete documents associated with a specific blob. For more information, see [Change and delete detection using indexers for Azure Storage in Azure AI Search](#).

Steps:

1. Mark the blob as deleted by setting a metadata field.
2. Let the indexer run. It deletes all documents in the index associated with that blob.
3. Remove the soft-delete marker and re-index the file.

Option 2. Use the delete API

Before re-indexing a modified Markdown file, explicitly delete the existing documents associated with that file using the [delete API](#). You can either:

- Manually identify individual stale documents by identifying duplicates in the index to be deleted. This may be feasible for small, well-understood changes but can be time-consuming.
- (Recommended) Remove all documents generated from the same parent file before re-indexing, ensuring inconsistencies are avoided.

Steps:

1. Identify the id of the documents associated with the file. Use a query like the following example to retrieve the document key IDs (for example, `id`, `chunk_id`, etc.) for all documents tied to a specific file. Replace `metadata_storage_path` with the appropriate field in your index that maps to the file path or blob URI. This field must be a key.

HTTP

```
GET https://[service name].search.windows.net/indexes/[index name]/docs?api-version=2025-05-01-preview
Content-Type: application/json
api-key: [admin key]
```

```
{
  "filter": "metadata_storage_path eq 'https://<storage-account>.blob.core.windows.net/<container-name>/<file-name>.md'",
  "select": "id"
}
```

2. Issue a delete request for the documents with the identified keys.

HTTP

```
POST https://[service name].search.windows.net/indexes/[index  
name]/docs/index?api-version=2025-05-01-preview  
Content-Type: application/json  
api-key: [admin key]  
  
{  
    "value": [  
        {  
            "@search.action": "delete",  
            "id": "aHR0c...jI1"  
        },  
        {  
            "@search.action": "delete",  
            "id": "aHR0...MQ2"  
        }  
    ]  
}
```

3. Re-index the updated file.

Indexer troubleshooting guidance for Azure AI Search

Occasionally, indexers run into problems that don't produce errors or that occur on other Azure services, such as during authentication or when connecting. This article focuses on troubleshooting indexer problems when there are no messages to guide you. It also provides troubleshooting for errors that come from non-search resources used during indexing.

(!) Note

If you have an Azure AI Search error to investigate, see [Troubleshooting common indexer errors and warnings](#) instead.

Best practices

These are some best practices and recommendations when working with indexers:

Indexers are designed to run on a schedule

- For reliable indexing, configure your indexers to run on a [regular schedule](#). Scheduled runs automatically pick up any documents missed in previous runs due to transient errors, network interruptions, or temporary service issues. This approach helps maintain data consistency and minimizes the need for manual intervention.
- For [large data sources](#), the initial enumeration and indexing can take hours or even days. Running your indexer on a schedule allows that progress continues and errors are retried automatically. Avoid relying solely on manual or on-demand indexer runs, as these do not provide the same reliability or transient error recovery.

Indexers provide best-effort indexing over time

- Built-in indexers are designed to process all documents without permanent errors over time, if not in the current run, then in subsequent scheduled runs. They offer a convenient, low/no-code way to index data for common scenarios, enabling faster development and easier maintenance. However, if they have AI enrichment capabilities, they are not optimized for very large-scale workloads. For guidance on handling large datasets, see [how to index large data sets](#).
- If your solution requires strict control over indexing timelines, use the Push APIs instead, such as the [Documents Index REST API](#) or the [IndexDocuments method \(Azure SDK for .NET\)](#). These options give you full control of the indexing pipeline.

- Indexers can occasionally fall out of schedule. While this is uncommon and auto-recovery mechanisms exist, recovery may take time. This behavior is expected.

Troubleshoot connections to restricted resources

For data sources under Azure network security, indexers are limited in how they make the connection. Currently, indexers can access restricted data sources [behind an IP firewall](#) or on a virtual network through a [private endpoint](#) using a shared private link.

Error connecting to Azure AI services on a private connection

If you get an error code 403 with the following message, you might have a problem with how the resource endpoint is specified in a skillset:

- "A Virtual Network is configured for this resource. Please use the correct endpoint for making requests. Check <https://aka.ms/cogservc-vnet> for more details."

This error occurs if you have [configured a shared private link](#) for connections to Azure AI services multi-service, and the endpoint is missing a custom subdomain. A custom subdomain is the first part of the endpoint (for example, `http://my-custom-subdomain.cognitiveservices.azure.com`). A custom domain might be missing if you created the resource in Azure AI Foundry.

If the Azure AI services multi-service account isn't in the same region as Azure AI Search, [use a keyless connection](#) when attaching a billable Azure AI resource.

Firewall rules

Azure Storage, Azure Cosmos DB and Azure SQL provide a configurable firewall. There's no specific error message when the firewall blocks the request. Typically, firewall errors are generic. Some common errors include:

- The remote server returned an error: (403) Forbidden
- This request is not authorized to perform this operation
- Credentials provided in the connection string are invalid or have expired

There are two options for allowing indexers to access these resources in such an instance:

- Configure an inbound rule for the IP address of your search service and the IP address range of [AzureCognitiveSearch service tag](#). Details for configuring IP address range restrictions for each data source type can be found from the following links:
 - [Azure Storage](#)

- Azure Cosmos DB
 - Azure SQL
- As a last resort or as a temporary measure, disable the firewall by allowing access from All Networks.

Limitation: IP address range restrictions only work if your search service and your storage account are in different regions.

In addition to data retrieval, indexers also send outbound requests through skillsets and [custom skills](#). For custom skills based on an Azure function, be aware that Azure functions also have [IP address restrictions](#). The list of IP addresses to allow through for custom skill execution include the IP address of your search service and the IP address range of `AzureCognitiveSearch` service tag.

Network security group (NSG) rules

When an indexer accesses data on a SQL managed instance, or when an Azure VM is used as the web service URI for a [custom skill](#), the network security group determines whether requests are allowed in.

For external resources residing on a virtual network, [configure inbound NSG rules](#) for the `AzureCognitiveSearch` service tag.

For more information about connecting to a virtual machine, see [Configure a connection to SQL Server on an Azure VM](#).

Network errors

Usually, network errors are generic. Some common errors include:

- A network-related or instance-specific error occurred while establishing a connection to the server
- The server was not found or was not accessible
- Verify that the instance name is correct and that the source is configured to allow remote connections

When you receive any of those errors:

- Make sure your source is accessible by trying to connect to it directly and not through the search service
- Check your resource in the Azure portal for any current errors or outages
- Check for any network outages in [Azure Status](#) ↗

- Verify you're using a public DNS for name resolution and not an [Azure Private DNS](#)

Azure SQL Database serverless indexing (error code 40613)

If your SQL database is on a [serverless compute tier](#), make sure that the database is running (and not paused) when the indexer connects to it.

If the database is paused, the first sign in from your search service is expected to auto-resume the database, but instead returns an error stating that the database is unavailable, giving error code 40613. After the database is running, retry the sign in to establish connectivity.

Microsoft Entra Conditional Access policies

When you create a SharePoint indexer, there's a step requiring you to sign in to your Microsoft Entra app after providing a device code. If you receive a message that says "Your sign-in was successful but your admin requires the device requesting access to be managed", the indexer is probably blocked from the SharePoint document library by a [Conditional Access](#) policy.

To update the policy and allow indexer access to the document library:

1. Open the Azure portal and search for **Microsoft Entra Conditional Access**.
2. Select **Policies** on the left menu. If you don't have access to view this page, you need to either find someone who has access or get access.
3. Determine which policy is blocking the SharePoint indexer from accessing the document library. The policy that might be blocking the indexer includes the user account that you used to authenticate during the indexer creation step in the **Users and groups** section. The policy also might have **Conditions** that:
 - Restrict **Windows** platforms.
 - Restrict **Mobile apps and desktop clients**.
 - Have **Device state** configured to **Yes**.
4. Once you've confirmed which policy is blocking the indexer, make an exemption for the indexer. Start by retrieving the search service IP address.

First, obtain the fully qualified domain name (FQDN) of your search service. The FQDN looks like `<your-search-service-name>.search.windows.net`. You can find the FQDN in the Azure portal.

The screenshot shows the Azure portal interface for a search service named 'contoso-search-svc'. The left sidebar lists various service management options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Settings, Semantic Search (Preview), Knowledge Center, Keys, Scale, Search traffic analytics, Identity, and Properties. The main content area is titled 'Overview' and displays the following information:

- Resource group:** (move)
- Status:** Running
- Location:** West US 2
- Subscription:** (move)
- Pricing tier:** Standard
- Replicas:** 1 (No SLA)
- Partitions:** 1
- Search units:** 1

Below this, there's a 'Tags' section with a link to 'Edit' and a note to 'Click here to add tags'.

At the bottom of the main content area, there are tabs for Get Started, Usage, Monitoring, Indexes, Indexers, Data sources, Skillsets, and more.

Now that you have the FQDN, get the IP address of the search service by performing a `nslookup` (or a `ping`) of the FQDN. In the following example, you would add "150.0.0.1" to an inbound rule on the Azure Storage firewall. It might take up to 15 minutes after the firewall settings have been updated for the search service indexer to be able to access the Azure Storage account.

```
Azure PowerShell

nslookup contoso.search.windows.net
Server: server.example.org
Address: 10.50.10.50

Non-authoritative answer:
Name: <name>
Address: 150.0.0.1
Aliases: contoso.search.windows.net
```

5. Get the IP address ranges for the indexer execution environment for your region.

Extra IP addresses are used for requests that originate from the indexer's [multitenant execution environment](#). You can get this IP address range from the service tag.

The IP address ranges for the `AzureCognitiveSearch` service tag can be either obtained via the [discovery API](#) or the [downloadable JSON file](#).

For this exercise, assuming the search service is the Azure Public cloud, the [Azure Public JSON file](#) should be downloaded.

Azure IP Ranges and Service Tags – Public Cloud

Important! Selecting a language below will dynamically change the complete page content to that language.

Language:

English

[Download](#)

Azure IP Ranges and Service Tags – Public Cloud

 [Details](#)

 [System Requirements](#)

 [Install Instructions](#)

From the JSON file, assuming the search service is in West Central US, the list of IP addresses for the multitenant indexer execution environment are listed below.

JSON

```
{  
  "name": "AzureCognitiveSearch.WestCentralUS",  
  "id": "AzureCognitiveSearch.WestCentralUS",  
  "properties": {  
    "changeNumber": 1,  
    "region": "westcentralus",  
    "platform": "Azure",  
    "systemService": "AzureCognitiveSearch",  
    "addressPrefixes": [  
      "52.150.139.0/26",  
      "52.253.133.74/32"  
    ]  
  }  
}
```

6. Back on the Conditional Access page in Azure portal, select **Named locations** from the menu on the left, then select **+ IP ranges location**. Give your new named location a name and add the IP ranges for your search service and indexer execution environments that you collected in the last two steps. 1

- For your search service IP address, you might need to add "/32" to the end of the IP address since it only accepts valid IP ranges.
- Remember that for the indexer execution environment IP ranges, you only need to add the IP ranges for the region that your search service is in.

7. Exclude the new Named location from the policy:
 - a. Select **Policies** on the left menu.
 - b. Select the policy that is blocking the indexer.
 - c. Select **Conditions**.
 - d. Select **Locations**.
 - e. Select **Exclude** then add the new Named location.
 - f. **Save** the changes.
8. Wait a few minutes for the policy to update and enforce the new policy rules.
9. Attempt to create the indexer again:
 - a. Send an update request for the data source object that you created.
 - b. Resend the indexer create request. Use the new code to sign in, then send another indexer creation request.

Indexing unsupported document types

If you're indexing content from Azure Blob Storage, and the container includes blobs of an [unsupported content type](#), the indexer skips that document. In other cases, there might be problems with individual documents.

In this situation, you can [set configuration options](#) to allow indexer processing to continue if there are problems with individual documents.

HTTP

```
PUT https://[service name].search.windows.net/indexers/[indexer name]?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
    ... other parts of indexer definition
    "parameters" : { "configuration" : { "failOnUnsupportedContentType" : false,
    "failOnUnprocessableDocument" : false } }
}
```

Missing documents

Indexers extract documents or rows from an external [data source](#) and create *search documents*, which are then indexed by the search service. Occasionally, a document that exists in data source fails to appear in a search index. This unexpected result can occur due to the following reasons:

- The document was updated after the indexer was run. If your indexer is on a [schedule](#), it eventually reruns and picks up the document.
- The indexer timed out before the document could be ingested. There are [maximum processing time limits](#) after which no documents are processed. You can check indexer status in the Azure portal or by calling [Get Indexer Status \(REST API\)](#).
- [Field mappings](#) or [AI enrichment](#) have changed the document and its articulation in the search index is different from what you expect.
- Change tracking values are erroneous or prerequisites are missing. If your high watermark value is a date set to a future time, then any documents that have an earlier date are skipped by the indexer. You can determine your indexer's change tracking state using the 'initialTrackingState' and 'finalTrackingState' fields in the [indexer status](#). Indexers for Azure SQL and MySQL must have an index on the high water mark column of the source table, or queries used by the indexer might time out.

Tip

If documents are missing, check the [query](#) you're using to make sure it isn't excluding the document in question. To query for a specific document, use the [Lookup Document REST API](#).

Missing content from Blob Storage

The blob indexer [finds and extracts text from blobs in a container](#). Some problems with extracting text include:

- The document only contains scanned images. PDF blobs that have non-text content, such as scanned images (JPGs), don't produce results in a standard blob indexing pipeline. If you have image content with text elements, you can use [OCR or image analysis](#) to find and extract the text.
- The blob indexer is configured to only index metadata. To extract content, the blob indexer must be configured to [extract both content and metadata](#):

HTTP

```
PUT https://[service name].search.windows.net/indexers/[indexer name]?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]

{
  ... other parts of indexer definition
```

```
"parameters" : { "configuration" : { "dataToExtract" : "contentAndMetadata" } }
```

Missing content from Azure Cosmos DB

Azure AI Search has an implicit dependency on Azure Cosmos DB indexing. If you turn off automatic indexing in Azure Cosmos DB, Azure AI Search returns a successful state, but fails to index container contents. For instructions on how to check settings and turn on indexing, see [Manage indexing in Azure Cosmos DB](#).

Document count discrepancy between the data source and index

An indexer might show a different document count than either the data source, the index itself, or count in your code. Here are some possible reasons why this behavior can occur:

- The index can lag in showing the real document count, especially in the Azure portal.
- The indexer has a Deleted Document Policy. The deleted documents get counted by the indexer if the documents are indexed before they get deleted.
- If the ID column in the data source isn't unique. This applies to data sources that have the concept of columns, such as Azure Cosmos DB.
- If the data source definition has a different query than the one you're using to estimate the number of records. In example, in your database, you're querying the database record count, while in the data source definition query, you might be selecting just a subset of records to index.
- The counts are being checked at different intervals for each component of the pipeline: data source, indexer and index.
- The data source has a file that's mapped to many documents. This condition can occur when [indexing blobs](#) and "parsingMode" is set to `jsonArray` and `jsonLines`.

Documents processed multiple times

Indexers use a conservative buffering strategy to ensure that every new and changed document in the data source is picked up during indexing. In certain situations, these buffers can overlap, causing an indexer to index a document two or more times resulting in the processed documents count to be more than actual number of documents in the data source. This behavior does **not** affect the data stored in the index, such as duplicating documents, only that it can take longer to reach eventual consistency. This condition is especially prevalent if any of the following criteria are true:

- On-demand indexer requests are issued in quick succession
- The data source's topology includes multiple replicas and partitions (one such example is discussed [here](#))
- The data source is an Azure SQL database and the column chosen as "high water mark" is of type `datetime2`

Indexers aren't intended to be invoked multiple times in quick succession. If you need updates quickly, the supported approach is to push updates to the index while simultaneously updating the data source. For on-demand processing, we recommend that you pace your requests in five-minute intervals or more, and run the indexer on a schedule.

Example of duplicate document processing with 30 second buffer

Conditions under which a document is processed twice is explained in the following timeline that notes each action and counter action. The following timeline illustrates the issue:

 Expand table

Timeline (hh:mm:ss)	Event	Indexer	Comment
	High Water Mark		
00:01:00	Write <code>doc1</code> to data source with eventual consistency	null	Document timestamp is 00:01:00.
00:01:05	Write <code>doc2</code> to data source with eventual consistency	null	Document timestamp is 00:01:05.
00:01:10	Indexer starts	null	
00:01:11	Indexer queries for all changes before 00:01:10; the replica that the indexer queries happens to be only aware of <code>doc2</code> ; only <code>doc2</code> is retrieved	null	Indexer requests all changes before starting timestamp but actually receives a subset. This behavior necessitates the look back buffer period.
00:01:12	Indexer processes <code>doc2</code> for the first time	null	
00:01:13	Indexer ends	00:01:10	High water mark is updated to starting timestamp of current indexer execution.
00:01:20	Indexer starts	00:01:10	

Timeline (hh:mm:ss)	Event	Indexer High Water Mark	Comment
00:01:21	Indexer queries for all changes between 00:00:40 and 00:01:20; the replica that the indexer queries happens to be aware of both <code>doc1</code> and <code>doc2</code> ; retrieves <code>doc1</code> and <code>doc2</code>	00:01:10	Indexer requests for all changes between current high water mark minus the 30 second buffer, and starting timestamp of current indexer execution.
00:01:22	Indexer processes <code>doc1</code> for the first time	00:01:10	
00:01:23	Indexer processes <code>doc2</code> for the second time	00:01:10	
00:01:24	Indexer ends	00:01:20	High water mark is updated to starting timestamp of current indexer execution.
00:01:32	Indexer starts	00:01:20	
00:01:33	Indexer queries for all changes between 00:00:50 and 00:01:32; retrieves <code>doc1</code> and <code>doc2</code>	00:01:20	Indexer requests for all changes between current high water mark minus the 30 second buffer, and starting timestamp of current indexer execution.
00:01:34	Indexer processes <code>doc1</code> for the second time	00:01:20	
00:01:35	Indexer processes <code>doc2</code> for the third time	00:01:20	
00:01:36	Indexer ends	00:01:32	High water mark is updated to starting timestamp of current indexer execution.
00:01:40	Indexer starts	00:01:32	
00:01:41	Indexer queries for all changes between 00:01:02 and 00:01:40; retrieves <code>doc2</code>	00:01:32	Indexer requests for all changes between current high water mark minus the 30 second buffer, and starting timestamp of current indexer execution.
00:01:42	Indexer processes <code>doc2</code> for the fourth time	00:01:32	
00:01:43	Indexer ends	00:01:40	Notice this indexer execution started more than 30 seconds after the last write to the data source and also processed <code>doc2</code> . This is

Timeline (hh:mm:ss)	Event	Indexer	Comment
		High Water Mark	the expected behavior because if all indexer executions before 00:01:35 are eliminated, this becomes the first and only execution to process <code>doc1</code> and <code>doc2</code> .

In practice, this scenario only happens when on-demand indexers are manually invoked within minutes of each other, for certain data sources. It can result in mismatched numbers (like the indexer processed 345 documents total according to the indexer execution stats, but there are 340 documents in the data source and index) or potentially increased billing if you're running the same skills for the same document multiple times. Running an indexer using a schedule is the preferred recommendation.

Parallel indexing

When multiple indexers are operating simultaneously, it's typical for some to enter a queue, waiting for available resources to begin execution. The number of indexers that can run concurrently depends on several factors. If the indexers aren't linked with [skillsets](#), the capacity to run in parallel relies on the number of [replicas and partitions](#) set up in the AI Search service.

On the other hand, if an indexer is associated with a skillset, it operates within the AI Search's internal clusters. The ability to run concurrently in this case is determined by the complexity of the skillset and whether other skillsets are running simultaneously. Built-in indexers are designed to reliably extract data from the source, so no data is missed if running on a schedule. However, it's expected that the indexer processes of parallelization and scaling out require some time to complete.

Indexing documents with sensitivity labels

If you have [sensitivity labels set on documents](#), you might not be able to index them. If you're getting errors, remove the labels prior to indexing.

Troubleshooting common indexer errors and warnings in Azure AI Search

10/14/2025

This article provides information and solutions to common errors and warnings you might encounter during indexing and AI enrichment in Azure AI Search.

Indexing stops when the error count exceeds '[maxFailedItems](#)'.

If you want indexers to ignore these errors (and skip over "failed documents"), consider updating the `maxFailedItems` and `maxFailedItemsPerBatch` as described [here](#).

➊ Note

Each failed document along with its document key (when available) will show up as an error in the indexer execution status. You can utilize the [index api](#) to manually upload the documents at a later point if you have set the indexer to tolerate failures.

The error information in this article can help you resolve errors, allowing indexing to continue.

Warnings don't stop indexing, but they do indicate conditions that could result in unexpected outcomes. Whether you take action or not depends on the data and your scenario.

Where can you find specific indexer errors?

To verify an indexer status and identify errors in the Azure portal, follow the steps below:

1. Sign in to the [Azure portal](#) and [find your search service](#).
2. On the left, expand **Search Management > Indexers** and select an indexer.
3. Under **Execution History**, select the status. All statuses, including Success, have details about the execution.
4. If there's an error, hover over the error message. A pane appears on the right side of your screen displaying detailed information about the error.

Transient errors

For various reasons, such as transient network communication interruptions, timeouts from long-running processes, or specific document nuances, it's common to encounter transient

errors or warnings during indexer runs. However, these errors are temporary and should be resolved in subsequent indexer runs.

To manage these errors effectively, we recommend [putting your indexer on a schedule](#), for instance, to run every five minutes, where the next run commences five minutes after completing the first run, adhering to the [maximum runtime limit](#) on your service. Regularly scheduled runs help rectify transient errors or warnings.

If an error persists over multiple indexer runs, it's likely not a transient issue. In such cases, refer to the list below for potential solutions.

Error properties

 [Expand table](#)

Property	Description	Example
Key	The ID of the document impacted by the error or warning.	Azure Storage example, where the default ID is the metadata storage path: <code>https://<storageaccount>.blob.core.windows.net/jfk-1k/docid-32112954.pdf</code>
Name	The operation causing the error or warning. This is generated by the following structure: <code>[category]. [subcategory]. [resourceType]. [resourceName]</code>	<code>DocumentExtraction.azureblob.myBlobContainerName</code> <code>Enrichment.WebApiSkill.mySkillName</code> <code>Projection.SearchIndex.OutputFieldMapping.myOutputFieldName</code> <code>Projection.SearchIndex.MergeOrUpload.myIndexName</code> <code>Projection.KnowledgeStore.Table.myTableName</code>
Message	A high-level description of the error or warning.	<code>Could not execute skill because the Web Api request failed.</code>

Property	Description	Example
Details	Specific information that might be helpful in diagnosing the issue, such as the WebApi response if executing a custom skill failed.	<code>link-cryptonyms-list - Error processing the request record : System.ArgumentNullException: Value cannot be null. Parameter name: source at System.Linq.Enumerable.All[TSource](IEnumerable`1 source, Func`2 predicate) at Microsoft.CognitiveSearch.WebApiSkills.JfkWebApiSkills. ...rest of stack trace...</code>
DocumentationLink	A link to relevant documentation with detailed information to debug and resolve the issue. This link will often point to one of the below sections on this page.	https://go.microsoft.com/fwlink/?linkid=2106475

Error: Could not read document

Indexer was unable to read the document from the data source. This can happen due to:

[Expand table](#)

Reason	Details/Example	Resolution
Inconsistent field types across different documents	<code>Type of value has a mismatch with column type. Couldn't store '{47.6,-122.1}' in authors column. Expected type is JArray. Error converting data type nvarchar to float. Conversion failed when converting the nvarchar value '12 months' to data type int. Arithmetic overflow error converting expression to data type int.</code>	Ensure that the type of each field is the same across different documents. For example, if the first document 'startTime' field is a DateTime, and in the second document it's a string, this error is hit.
Errors from the data source's underlying service	From Azure Cosmos DB: <code>{"Errors": ["Request rate is large"]}</code>	Check your storage instance to ensure it's healthy. You might need to adjust your scaling or partitioning.

Reason	Details/Example	Resolution
Transient issues	A transport-level error has occurred when receiving results from the server. (provider: TCP Provider, error: 0 - An existing connection was forcibly closed by the remote host)	Occasionally there are unexpected connectivity issues. Try running the document through your indexer again later.

Error: Could not extract content or metadata from your document

Indexer with a Blob data source was unable to extract the content or metadata from the document (for example, a PDF file). This can happen due to:

[+] [Expand table](#)

Reason	Details/Example	Resolution
Blob is over the size limit	Document is '150441598' bytes, which exceeds the maximum size '134217728' bytes for document extraction for your current service tier.	Blob indexing errors
Blob has unsupported content type	Document has unsupported content type 'image/png'	Blob indexing errors
Blob is encrypted	Document could not be processed - it may be encrypted or password protected.	You can skip the blob with blob settings .
Transient issues	Error processing blob: The request was aborted: The request was canceled. Document timed out during processing.	Occasionally there are unexpected connectivity issues. Try running the document through your indexer again later.

Error: Could not parse document

Indexer read the document from the data source, but there was an issue converting the document content into the specified field mapping schema. This can happen due to:

[+] [Expand table](#)

Reason	Details/Example	Resolution
The document key is missing	Document key cannot be missing or empty	Ensure all documents have valid document keys. The document key is determined by setting the 'key' property as part of the index definition . Indexers emit this error when the property flagged as the 'key' can't be found on a particular document.
The document key is invalid	Invalid document key. Keys can only contain letters, digits, underscore (_), dash (-), or equal sign (=).	Ensure all documents have valid document keys. Review Indexing Blob Storage for more details. If you're using the blob indexer, and your document key is the <code>metadata_storage_path</code> field, make sure that the indexer definition has a base64Encode mapping function with <code>parameters</code> equal to <code>null</code> , instead of the path in plain text.
The document key is invalid	Document key cannot be longer than 1024 characters	Modify the document key to meet the validation requirements.
Couldn't apply field mapping to a field	Could not apply mapping function 'functionName' to field 'fieldName'. Array cannot be null. Parameter name: bytes	Double check the field mappings defined on the indexer, and compare with the data of the specified field of the failed document. It might be necessary to modify the field mappings or the document data.
Couldn't read field value	Could not read the value of column 'fieldName' at index 'fieldIndex'. A transport-level error has occurred when receiving results from the server. (provider: TCP Provider, error: 0 - An existing connection was forcibly closed by the remote host.)	These errors are typically due to unexpected connectivity issues with the data source's underlying service. Try running the document through your indexer again later.

Error: Could not map output field 'xyz' to search index due to deserialization problem while applying mapping function 'abc'

The output mapping might have failed because the output data is in the wrong format for the mapping function you're using. For example, applying `Base64Encode` mapping function on binary data would generate this error. To resolve the issue, either rerun indexer without

specifying mapping function or ensure that the mapping function is compatible with the output field data type. See [Output field mapping](#) for details.

Error: Could not execute skill

The indexer wasn't able to run a skill in the skillset.

 [Expand table](#)

Reason	Details/Example	Resolution
Transient connectivity issues	A transient error occurred. Try again later.	Occasionally there are unexpected connectivity issues. Try running the document through your indexer again later.
Potential product bug	An unexpected error occurred.	This indicates an unknown class of failure and can indicate a product bug. File a support ticket to get help.
A skill has encountered an error during execution	(From Merge Skill) One or more offset values were invalid and couldn't be parsed. Items were inserted at the end of the text	Use the information in the error message to fix the issue. This kind of failure requires action to resolve.

Error: Could not execute skill because the Web API request failed

The skill execution failed because the call to the Web API failed. Typically, this class of failure occurs when custom skills are used, in which case you need to debug your custom code to resolve the issue. If instead the failure is from a built-in skill, refer to the error message for help with fixing the issue.

While debugging this issue, be sure to pay attention to any [skill input warnings](#) for this skill. Your Web API endpoint might be failing because the indexer is passing it unexpected input.

Error: Could not execute skill because Web API skill response is invalid

The skill execution failed because the call to the Web API returned an invalid response. Typically, this class of failure occurs when custom skills are used, in which case you need to

debug your custom code to resolve the issue. If instead the failure is from a built-in skill, file a [support ticket](#) to get assistance.

Error: Type of value has a mismatch with column type. Couldn't store in 'xyz' column. Expected type is 'abc'

If your data source has a field with a different data type than the field you're trying to map in your index, you might encounter this error. Check your data source field data types and make sure they're [mapped correctly to your index data types](#).

Error: Skill did not execute within the time limit

There are two cases under which you might encounter this error message, each of which should be treated differently. Follow the instructions below depending on what skill returned this error for you.

Built-in Azure AI services skills

Many of the built-in cognitive skills, such as language detection, entity recognition, or OCR, are backed by an Azure AI services API endpoint. Sometimes there are transient issues with these endpoints and a request will time out. For transient issues, there's no remedy except to wait and try again. As a mitigation, consider setting your indexer to [run on a schedule](#). Scheduled indexing picks up where it left off. Assuming transient issues are resolved, indexing and cognitive skill processing should be able to continue on the next scheduled run.

If you continue to see this error on the same document for a built-in cognitive skill, file a [support ticket](#) to get assistance, as this isn't expected.

Custom skills

If you encounter a timeout error with a custom skill, there are a couple of things you can try. First, review your custom skill and ensure that it's not getting stuck in an infinite loop and that it's returning a result consistently. Once you have confirmed that a result is returned, check the duration of execution. If you didn't explicitly set a `timeout` value on your custom skill definition, then the default `timeout` is 30 seconds. If 30 seconds isn't long enough for your skill to

execute, you can specify a higher `timeout` value on your custom skill definition. Here's an example of a custom skill definition where the timeout is set to 90 seconds:

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Custom.WebApiSkill",  
    "uri": "<your custom skill uri>",  
    "batchSize": 1,  
    "timeout": "PT90S",  
    "context": "/document",  
    "inputs": [  
        {  
            "name": "input",  
            "source": "/document/content"  
        }  
    ],  
    "outputs": [  
        {  
            "name": "output",  
            "targetName": "output"  
        }  
    ]  
}
```

The maximum value that you can set for the `timeout` parameter is 230 seconds. If your custom skill is unable to execute consistently within 230 seconds, you might consider reducing the `batchSize` of your custom skill so that it has fewer documents to process within a single execution. If you have already set your `batchSize` to 1, you need to rewrite the skill to be able to execute in under 230 seconds, or otherwise split it into multiple custom skills so that the execution time for any single custom skill is a maximum of 230 seconds. Review the [custom skill documentation](#) for more information.

Error: Could not 'MergeOrUpload' | 'Delete' document to the search index

The document was read and processed, but the indexer couldn't add it to the search index. This can happen due to:

[+] Expand table

Reason	Details/Example	Resolution
A field contains a term that is too large	A term in your document is larger than the 32-KB limit	You can avoid this restriction by ensuring the field isn't configured as

Reason	Details/Example	Resolution
		filterable, facetable, or sortable.
Document is too large to be indexed	A document is larger than the maximum API request size	How to index large data sets
Document contains too many objects in collection	A collection in your document exceeds the maximum elements across all complex collections limit . The document with key '1000052' has '4303' objects in collections (JSON arrays). At most '3000' objects are allowed to be in collections across the entire document. Remove objects from collections and try indexing the document again.	We recommend reducing the size of the complex collection in the document to below the limit and avoid high storage utilization.
Trouble connecting to the target index (that persists after retries) because the service is under other load, such as querying or indexing.	Failed to establish connection to update index. Search service is under heavy load.	Scale up your search service
Search service is being patched for service update, or is in the middle of a topology reconfiguration.	Failed to establish connection to update index. Search service is currently down/Search service is undergoing a transition.	Configure service with at least three replicas for 99.9% availability per SLA documentation
Failure in the underlying compute/networking resource (rare)	Failed to establish connection to update index. An unknown failure occurred.	Configure indexers to run on a schedule to pick up from a failed state.
An indexing request made to the target index wasn't acknowledged within a timeout period due to network issues.	Couldn't establish connection to the search index in a timely manner.	Configure indexers to run on a schedule to pick up from a failed state. Additionally, try lowering the indexer batch size if this error condition persists.

Error: Could not index document because some of the document's data was not valid

The document was read and processed by the indexer, but due to a mismatch in the configuration of the index fields and the data extracted and processed by the indexer, it couldn't be added to the search index. This can happen due to:

Reason	Details/Example
Data type of one or more fields extracted by the indexer is incompatible with the data model of the corresponding target index field.	The data field '_data_' in the document with key '888' has an invalid value 'of type 'Edm.String''. The expected type was 'Collection(Edm.String)'.
Failed to extract any JSON entity from a string value.	Could not parse value 'of type 'Edm.String'' of field '_data_' as a JSON object. Error:'After parsing a value an unexpected character was encountered: '''. Path '_path_', line 1, position 3162.'
Failed to extract a collection of JSON entities from a string value.	Could not parse value 'of type 'Edm.String'' of field '_data_' as a JSON array. Error:'After parsing a value an unexpected character was encountered: '''. Path '[0]', line 1, position 27.'
An unknown type was discovered in the source document.	Unknown type '_unknown_' cannot be indexed
An incompatible notation for geography points was used in the source document.	WKT POINT string literals are not supported. Use GeoJson point literals instead

In all these cases, refer to [Supported Data types](#) and [Data type map for indexers](#) to make sure that you build the index schema correctly and have set up appropriate [indexer field mappings](#). The error message includes details that can help track down the source of the mismatch.

Error: Integrated change tracking policy cannot be used because table has a composite primary key

This applies to SQL tables, and usually happens when the key is either defined as a composite key or, when the table has defined a unique clustered index (as in a SQL index, not an Azure Search index). The main reason is that the key attribute is modified to be a composite primary key in a [unique clustered index](#). In that case, make sure that your SQL table doesn't have a unique clustered index, or that you map the key field to a field that is guaranteed not to have duplicate values.

Error: Could not process document within indexer max run time

This error occurs when the indexer is unable to finish processing a single document from the data source within the allowed execution time. [Maximum running time](#) is shorter when skillsets are used. When this error occurs, if you have maxFailedItems set to a value other than 0, the indexer bypasses the document on future runs so that indexing can progress. If you can't afford to skip any document, or if you're seeing this error consistently, consider breaking documents into smaller documents so that partial progress can be made within a single indexer execution.

Error: Could not project document

This error occurs when the indexer is attempting to [project data into a knowledge store](#) and there was a failure on the attempt. This failure could be consistent and fixable, or it could be a transient failure with the projection output sink that you might need to wait and retry in order to resolve. Here's a set of known failure states and possible resolutions.

[] [Expand table](#)

Reason	Details/Example	Resolution
Couldn't update projection blob <code>'blobUri'</code> in container <code>'containerName'</code>	The specified container doesn't exist.	The indexer checks if the specified container has been previously created and will create it if necessary, but it only performs this check once per indexer run. This error means that something deleted the container after this step. To resolve this error, try this: leave your storage account information alone, wait for the indexer to finish, and then rerun the indexer.
Couldn't update projection blob <code>'blobUri'</code> in container <code>'containerName'</code>	Unable to write data to the transport connection: An existing connection was forcibly closed by the remote host.	This is expected to be a transient failure with Azure Storage and thus should be resolved by rerunning the indexer. If you encounter this error consistently, file a support ticket so it can be investigated further.
Couldn't update row <code>'projectionRow'</code> in table <code>'tableName'</code>	The server is busy.	This is expected to be a transient failure with Azure Storage and thus should be resolved by rerunning the indexer. If you encounter this error consistently, file a support ticket so it can be investigated further.

Error: The cognitive service for skill '<skill-name>' has been throttled

Skill execution failed because the call to Azure AI services was throttled. Typically, this class of failure occurs when too many skills are executing in parallel. If you're using the Microsoft.Search.Documents client library to run the indexer, you can use the [SearchIndexingBufferedSender](#) to get automatic retry on failed steps. Otherwise, you can reset and rerun the indexer.

Error: Expected IndexAction metadata

An 'Expected IndexAction metadata' error means when the indexer attempted to read the document to identify what action should be taken, it didn't find any corresponding metadata on the document. Typically, this error occurs when the indexer has an annotation cache added or removed without resetting the indexer. To address this, you should [reset and rerun the indexer](#).

Warning: Skill input was invalid

An input to the skill was missing, it has the wrong type, or otherwise, invalid. You might see the following information:

- Could not execute skill
- Skill executed but may have unexpected results

Cognitive skills have required inputs and optional inputs. For example, the [Key phrase extraction skill](#) has two required inputs `text`, `languageCode`, and no optional inputs. Custom skill inputs are all considered optional inputs.

If necessary inputs are missing or if the input isn't the right type, the skill gets skipped and generates a warning. Skipped skills don't generate outputs. If downstream skills consume the outputs of the skipped skill, they can generate other warnings.

If an optional input is missing, the skill still runs, but it might produce unexpected output due to the missing input.

In both cases, this warning is due to the shape of your data. For example, if you have a document containing information about people with the fields `firstName`, `middleName`, and `lastName`, you might have some documents that don't have an entry for `middleName`. If you pass `middleName` as an input to a skill in the pipeline, then it's expected that this skill input is missing some of the time. You need to evaluate your data and scenario to determine whether or not any action is required as a result of this warning.

If you want to provide a default value for a missing input, you can use the [Conditional skill](#) to generate a default value and then use the output of the [Conditional skill](#) as the skill input.

JSON

```
{ "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill", "context": "/document", "inputs": [ { "name": "condition", "source": "= $(/document/language) == null" }, { "name": "whenTrue", "source": "= 'en'" }, { "name": "whenFalse", "source": "= $(/document/language)" } ], "outputs": [ { "name": "output", "targetName": "languageWithDefault" } ] }
```

[] [Expand table](#)

Reason	Details/Example	Resolution
Skill input is the wrong type	"Required skill input was not of the expected type <code>String</code> . Name: <code>text</code> , Source: <code>/document/merged_content</code> ." "Required skill input wasn't of the expected format. Name: <code>text</code> , Source: <code>/document/merged_content</code> ." "Cannot iterate over non-array <code>/document/normalized_images/0/imageCelebrities/0/detail/celebrities</code> ." "Unable to select <code>0</code> in non-array <code>/document/normalized_images/0/imageCelebrities/0/detail/celebrities</code> "	Certain skills expect inputs of particular types, for example Sentiment skill expects <code>text</code> to be a string. If the input specifies a nonstring value, then the skill doesn't execute and generates no outputs. Ensure your data set has input values uniform in type, or use a Custom Web API skill to preprocess the input. If you're iterating the skill over an array, check the skill

Reason	Details/Example	Resolution
		context and input have * in the correct positions. Usually both the context and input source should end with * for arrays.
Skill input is missing	Required skill input is missing. Name: text, Source: /document/merged_content Missing value /document/normalized_images/0/imageTags. Unable to select 0 in array /document/pages of length 0.	If this warning occurs for all documents, there could be a typo in the input paths. Check the property name casing. Check for an extra or missing * in the path. Verify that the documents from the data source provide the required inputs.
Skill language code input is invalid	Skill input languageCode has the following language codes X,Y,Z, at least one of which is invalid.	See more details below.

Warning: Skill input 'languageCode' has the following language codes 'X,Y,Z', at least one of which is invalid.

One or more of the values passed into the optional languageCode input of a downstream skill isn't supported. This can occur if you're passing the output of the [LanguageDetectionSkill](#) to subsequent skills, and the output consists of more languages than are supported in those downstream skills.

Note that you can also get a warning similar to this one if an invalid `countryHint` input gets passed to the `LanguageDetectionSkill`. If that happens, validate that the field you're using from your data source for that input contains valid ISO 3166-1 alpha-2 two letter country codes. If some are valid and some are invalid, continue with the following guidance but replace `languageCode` with `countryHint` and `defaultLanguageCode` with `defaultCountryHint` to match your use case.

If you know that your data set is all in one language, you should remove the `LanguageDetectionSkill` and the `languageCode` skill input and use the `defaultLanguageCode` skill parameter for that skill instead, assuming the language is supported for that skill.

If you know that your data set contains multiple languages and thus you need the `LanguageDetectionSkill` and `languageCode` input, consider adding a `ConditionalSkill` to filter out the text with languages that aren't supported before passing in the text to the downstream skill. Here's an example of what this might look like for the `EntityRecognitionSkill`:

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Util.ConditionalSkill",  
    "context": "/document",  
    "inputs": [  
        { "name": "condition", "source": "= $(/document/language) == 'de' ||  
        $(/document/language) == 'en' || $(/document/language) == 'es' ||  
        $(/document/language) == 'fr' || $(/document/language) == 'it'" },  
        { "name": "whenTrue", "source": "/document/content" },  
        { "name": "whenFalse", "source": "= null" }  
    "outputs": [ { "name": "output", "targetName":  
    "supportedByEntityRecognitionSkill" } ]  
}
```

Here are some references for the currently supported languages for each of the skills that can produce this error message:

- [EntityRecognitionSkill supported languages](#)
- [EntityLinkingSkill supported languages](#)
- [KeyPhraseExtractionSkill supported languages](#)
- [LanguageDetectionSkill supported languages](#)
- [PIIDetectionSkill supported languages](#)
- [SentimentSkill supported languages](#)
- [Translator supported languages](#)
- [Text SplitSkill supported languages](#): da, de, en, es, fi, fr, it, ko, pt

Warning: Skill input was truncated

Cognitive skills limit the length of text that can be analyzed at one time. If the text input exceeds the limit, the text is truncated before it's enriched. The skill executes, but not over all of your data.

In the example `LanguageDetectionSkill` below, the `'text'` input field might trigger this warning if the input is over the character limit. Input limits can be found in the [skills reference documentation](#).

JSON

```
{  
    "@odata.type": "#Microsoft.Skills.Text.LanguageDetectionSkill",  
    "inputs": [  
        {  
            "name": "text",  
            "source": "/document/text"  
        }  
    ],  
    "outputs": [...]  
}
```

If you want to ensure that all text is analyzed, consider using the [Split skill](#).

Warning: Web API skill response contains warnings

The indexer ran the skill in the skillset, but the response from the Web API request indicates there are warnings. Review the warnings to understand how your data is impacted and whether further action is required.

Warning: The current indexer configuration does not support incremental progress

This warning only occurs for Azure Cosmos DB data sources.

Incremental progress during indexing ensures that if indexer execution is interrupted by transient failures or execution time limit, the indexer can pick up where it left off next time it runs, instead of having to reindex the entire collection from scratch. This is especially important when indexing large collections.

The ability to resume an unfinished indexing job is predicated on having documents ordered by the `_ts` column. The indexer uses the timestamp to determine which document to pick up

next. If the `_ts` column is missing or if the indexer can't determine if a custom query is ordered by it, the indexer starts at beginning and you'll see this warning.

It's possible to override this behavior, enabling incremental progress and suppressing this warning by using the `assumeOrderByHighWaterMarkColumn` configuration property.

For more information, see [Incremental progress and custom queries](#).

Warning: Some data was lost during projection.

Row 'X' in table 'Y' has string property 'Z' which was too long.

The [Table Storage service](#) has limits on how large [entity properties](#) can be. Strings can have 32,000 characters or less. If a row with a string property longer than 32,000 characters is being projected, only the first 32,000 characters are preserved. To work around this issue, avoid projecting rows with string properties longer than 32,000 characters.

Warning: Truncated extracted text to X characters

Indexers limit how much text can be extracted from any one document. This limit depends on the pricing tier: 32,000 characters for Free tier, 64,000 for Basic, 4 million for Standard, 8 million for Standard S2, and 16 million for Standard S3. Text that was truncated won't be indexed. To avoid this warning, try breaking apart documents with large amounts of text into multiple, smaller documents.

For more information, see [Indexer limits](#).

Warning: Could not map output field 'X' to search index

Output field mappings that reference non-existent/null data will produce warnings for each document and result in an empty index field. To work around this issue, double-check your output field-mapping source paths for possible typos, or set a default value using the [Conditional skill](#). See [Output field mapping](#) for details.

Reason	Details/Example	Resolution
Can't iterate over non-array	"Cannot iterate over non-array /document/normalized_images/0/imageCelebrities/0/detail/celebrities."	This error occurs when the output isn't an array. If you think the output should be an array, check the indicated output source field path for errors. For example, you might have a missing or extra <code>*</code> in the source field name. It's also possible that the input to this skill is null, resulting in an empty array. Find similar details in Skill Input was Invalid section.
Unable to select <code>0</code> in non-array	"Unable to select <code>0</code> in non-array /document/pages."	This could happen if the skills output doesn't produce an array and the output source field name has array index or <code>*</code> in its path. Double check the paths provided in the output source field names and the field value for the indicated field name. Find similar details in Skill Input was Invalid section.

Warning: The data change detection policy is configured to use key column 'X'

Data change detection policies have specific requirements for the columns they use to detect change. One of these requirements is that this column is updated every time the source item is changed. Another requirement is that the new value for this column is greater than the previous value. Key columns don't fulfill this requirement because they don't change on every update. To work around this issue, select a different column for the change detection policy.

Warning: Document text appears to be UTF-16 encoded, but is missing a byte order mark

The [indexer parsing modes](#) need to know how text is encoded before parsing it. The two most common ways of encoding text are UTF-16 and UTF-8. UTF-8 is a variable-length encoding where each character is between 1 byte and 4 bytes long. UTF-16 is a fixed-length encoding where each character is 2 bytes long. UTF-16 has two different variants, `big endian` and `little endian`. Text encoding is determined by a `byte order mark`, a series of bytes before the text.

[] [Expand table](#)

Encoding	Byte Order Mark
UTF-16 Big Endian	0xFE 0xFF
UTF-16 Little Endian	0xFF 0xFE
UTF-8	0xEF 0xBB 0xBF

If no byte order mark is present, the text is assumed to be encoded as UTF-8.

To work around this warning, determine what the text encoding for this blob is and add the appropriate byte order mark.

Warning: Azure Cosmos DB collection 'X' has a Lazy indexing policy. Some data may be lost

Collections with [Lazy](#) indexing policies can't be queried consistently, resulting in your indexer missing data. To work around this warning, change your indexing policy to Consistent.

Warning: The document contains very long words (longer than 64 characters). These words may

result in truncated and/or unreliable model predictions.

This warning is passed from the Language service of Azure AI services. In some cases, it's safe to ignore this warning, for example if the long string is just a long URL. Be aware that when a word is longer than 64 characters, it's truncated to 64 characters which can affect model predictions.

Error: Cannot write more bytes to the buffer than the configured maximum buffer size

Indexers have [document size limits](#). Make sure that the documents in your data source are smaller than the supported size limit, as documented for your service tier.

Error: Failed to compare value 'X' of type M to value 'Y' of type N.

This error usually happens in Azure SQL indexers when the source column type used for [dataChangeDetectionPolicy](#) doesn't match what the indexer expects, especially if [convertHighWaterMarkToRowVersion](#) is turned on.

For example, if the column used for change detection is of type datetime, but the indexer expects a rowversion type because [convertHighWaterMarkToRowVersion](#) is enabled, the mismatch will cause an error.

Check the data type for the 'High Water Mark' column in the source and update the indexer configuration accordingly. Once verified and updated, reset and rerun the indexer to process the column values.

Error: Access denied to Virtual Network/Firewall rules.

This error typically occurs due to one of the following:

- Firewall restrictions on Azure resources required by your indexer, depending on your configuration. These resources may include: the [data source](#), Azure Storage account (used for [debug sessions](#), [incremental enrichment](#) or [knowledge store](#)), Azure Function (used for [web API custom skills](#)) or AI Services / AI Foundry deployments used during [AI enrichment](#).

- Private endpoint configurations that block access from the indexer to those resources.

Ensure that the indexer has access to your setup components by reviewing your resource configurations to confirm they allow traffic to all required services:

- [Firewall and IP restriction settings](#)
- [Shared private link setup](#)

Error: Credentials provided in the connection string are invalid or have expired.

This error occurs when the Azure AI Search indexer cannot authenticate using the provided connection string or it has issues accessing the storage account to verify the credentials.

[\[\]](#) [Expand table](#)

Possible Cause	Details/Example	Resolution
Expired or rotated key	A connection string contains an outdated key that no longer works.	Go to the resource that is being contacted (for example, Azure Storage or Azure SQL) and copy the latest access keys if using key-based authentication, then update the data source or connection string accordingly.
Managed identity not enabled or access not granted	The AI Search service managed identity is enabled but lacks the required access roles.	- Enable system or user-assigned managed identity on the search Service. - Assign appropriate role(s) to the identity (for example, <code>Storage Blob Data Reader</code> for blob containers). Each data source has its own permission requirements.
Network/firewall blocks identity access	The resource contacted is configured to restrict network access.	Configure network settings to allow Azure AI Search access.
Key authorization has been disabled	Shared key access removed on the source, but the Search service data source configuration still uses key-based authentication.	Use managed identity authentication and ensure role-based permissions are in place. From an Azure Storage perspective, this means that shared key authorization functionality is blocked , either from the storage account itself, or enforced through enterprise-level Azure Policies.

Data sources gallery

Find a data connector from Microsoft or a partner that works with [an indexer](#) to simplify data ingestion into a search index.

! Note

The connectors mentioned in this article represent one method for indexing data in Azure AI Search. You also have the option of developing your own connector using the [Push REST API or An Azure SDK](#).

Generally available data sources by Azure AI Search

Pull in content from other Azure services using indexers and the following data source connectors.

Azure Blob Storage

By [Azure AI Search](#)

Extract blob metadata and content, serialized into JSON documents, and imported into a search index as search documents. Set properties in both data source and indexer definitions to optimize for various blob content types. Change detection is supported automatically.

[More details](#)

Azure Table Storage

By [Azure AI Search](#)

Extract rows from an Azure Table, serialized into JSON documents, and imported into a search index as search documents.

[More details](#)

Azure Data Lake Storage Gen2

By [Azure AI Search](#)

Connect to Azure Storage through Azure Data Lake Storage Gen2 to extract content from a hierarchy of directories and nested subdirectories.

[More details](#)

Azure Cosmos DB for NoSQL

By [Azure AI Search](#)

Connect to Azure Cosmos DB through the SQL API to extract items from a container, serialized into JSON documents, and imported into a search index as search documents. Configure change tracking to refresh the search index with the latest changes in your database.

[More details](#)

Azure SQL Database

By [Azure AI Search](#)

Extract field values from a single table or view, serialized into JSON documents, and imported into a search index as search documents. Configure change tracking to refresh the search index with the latest changes in your database.

[More details](#)

Microsoft OneLake files

By [Azure AI Search](#)

Connect to a OneLake lakehouse to extract supported files content from a hierarchy of directories and nested subdirectories.

[More details](#)

Logic app connectors

Pull in content using [logic app workflows](#) and the following supported data sources. Note that the Logic Apps artifacts mentioned below, they have a pre-built workflow, however, you can use [any connectors listed under Logic Apps](#) that pull data from sources and create your own indexing pipeline workflow that pushes data to [Azure AI Search](#) via a Logic App connector.

SharePoint

By [Logic Apps](#)

SharePoint helps organizations share and collaborate with colleagues, partners, and customers. You can connect to SharePoint in Microsoft 365 or to an on-premises SharePoint 2016 or 2019

farm using the On-Premises Data Gateway to manage documents and list items.

[More details](#)

OneDrive

By [Logic Apps](#)

Connect to OneDrive to manage your files. You can perform various actions such as upload, update, get, and delete on files in OneDrive.

[More details](#)

OneDrive for Business

By [Logic Apps](#)

OneDrive for Business is a cloud storage, file hosting service that allows users to sync files and later access them from a web browser or mobile device. Connect to OneDrive for Business to manage your files. You can perform various actions such as upload, update, get, and delete files.

[More details](#)

Azure File Storage

By [Logic Apps](#)

Microsoft Azure Storage provides a massively scalable, durable, and highly available storage for data on the cloud, and serves as the data storage solution for modern applications. Connect to File Storage to perform various operations such as create, update, get and delete on files in your Azure Storage account.

[More details](#)

Azure Queues

By [Logic Apps](#)

Azure Queue storage provides cloud messaging between application components. Queue storage also supports managing asynchronous tasks and building process work flows.

[More details](#)

Service Bus

By [Logic Apps](#)

Connect to Azure Service Bus to send and receive messages. You can perform actions such as send to queue, send to topic, receive from queue, receive from subscription, etc.

[More details](#)

Preview data sources by Azure AI Search

New data sources are issued as preview features. [Sign up](#) to get started.

Azure Files

By [Azure AI Search](#)

Connect to Azure Storage through Azure Files share to extract content serialized into JSON documents, and imported into a search index as search documents.

[More details](#)

Azure Cosmos DB for Apache Gremlin

By [Azure AI Search](#)

Connect to Azure Cosmos DB for Apache Gremlin to extract items from a container, serialized into JSON documents, and imported into a search index as search documents. Configure change tracking to refresh the search index with the latest changes in your database.

[More details](#)

Azure Cosmos DB for MongoDB

By [Azure AI Search](#)

Connect to Azure Cosmos DB for MongoDB to extract items from a container, serialized into JSON documents, and imported into a search index as search documents. Configure change tracking to refresh the search index with the latest changes in your database.

[More details](#)

SharePoint

By [Azure AI Search](#)

Connect to a SharePoint site and index documents from one or more document libraries, for accounts and search services in the same tenant. Text and normalized images are extracted by default. Optionally, you can configure a skillset for more content transformation and enrichment, or configure change tracking to refresh a search index with new or changed content in SharePoint.

[More details](#)

Azure MySQL

By [Azure AI Search](#)

Connect to MySQL database on Azure to extract rows in a table, serialized into JSON documents, and imported into a search index as search documents. On subsequent runs, assuming High Water Mark change detection policy is configured, the indexer takes all changes, uploads, and delete and reflect those changes in your search index.

[More details](#)

Data sources from our partners

The following Microsoft partners offer custom third-party data connectors. Each partner implements and supports these connectors, which aren't part of Azure AI Search built-in indexers. Before you use a custom connector, review the partner's licensing and usage instructions.

- [ServiceNow ↗](#)

Search over Azure Blob Storage content

10/06/2025

Searching across the variety of content types stored in Azure Blob Storage can be a difficult problem to solve, but [Azure AI Search](#) provides deep integration at the content layer, extracting and inferring textual information, which can then be queried in a search index.

In this article, review the basic workflow for extracting content and metadata from blobs and sending it to a [search index](#) in Azure AI Search. The resulting index can be queried using full text search or vector search. Optionally, you can send processed blob content to a [knowledge store](#) for non-search scenarios.

 **Note**

Already familiar with the workflow and composition? [Configure a blob indexer](#) is your next step.

What it means to add search over blob data

Azure AI Search is a standalone search service that supports indexing and query workloads over user-defined indexes that contain your private searchable content hosted in the cloud. Co-locating your searchable content with the query engine in the cloud is necessary for performance, returning results at a speed users have come to expect from search queries.

Azure AI Search integrates with Azure Blob Storage at the indexing layer, importing your blob content as search documents that are indexed into *inverted indexes* and other query structures that support free-form text queries, vector queries, and filter expressions. Because your blob content is indexed into a search index, you can use the full range of query features in Azure AI Search to find information in your blob content.

Inputs are your blobs, in a single container, in Azure Blob Storage. Blobs can be almost any kind of text data. If your blobs contain images, you can add [AI enrichment](#) to create and extract text and features from images.

Output is always an Azure AI Search index, used for fast text search, retrieval, and exploration in client applications. In between is the indexing pipeline architecture itself. The pipeline is based on the *indexer* feature, discussed further on in this article.

Once the index is created and populated, it exists independently of your blob container, but you can rerun indexing operations to refresh your index based on changed documents.

Timestamp information on individual blobs is used for change detection. You can opt for either scheduled execution or on-demand indexing as the refresh mechanism.

Resources used in a blob-search solution

You need Azure AI Search, Azure Blob Storage, and a client. Azure AI Search is typically one of several components in a solution, where your application code issues query API requests and handles the response. You might also write application code to handle indexing, although for proof-of-concept testing and impromptu tasks, it's common to use the Azure portal as the search client.

Within Blob Storage, you'll need a container that provides source content. You can set file inclusion and exclusion criteria, and specify which parts of a blob are indexed in Azure AI Search.

You can start directly in your Storage Account portal page.

1. In the left navigation page under **Data management**, select **Azure AI Search** to select or create a search service.
2. Use an [import wizard](#) to extract and optionally create searchable content from your blobs.

The workflow creates an indexer, data source, index, and option skillset on your Azure AI Search service.

The screenshot shows the Microsoft Azure portal interface for a storage account named 'contoso-storage'. The left sidebar lists various management options like Data management, Storage tasks, and Azure AI Search. The main area is titled 'contoso-storage | Azure AI Search' and contains a form for creating a new search service. The 'Data management' section is selected. The form fields include:

- Select a search service: *Connect to your data
- Add cognitive skills (Optional)
- Customize target index
- Create an indexer
- Data Source: Azure Blob Storage
- Data source name: demo-ds
- Data to extract: Content and metadata
- Parsing mode: Default
- Connection string: DefaultEndpointsProtocol=https;AccountName=heidisteenstor... (with a note to choose an existing connection)
- Managed identity authentication: None (selected)
- Container name: (empty field)
- Blob folder: your/folder/here
- Description: (optional)

At the bottom, there are 'Previous: Select a search service' and 'Next: Add cognitive skills (Optional)' buttons, along with a 'Give feedback' link.

3. Use [Search explorer](#) in the search portal page to query your content.

The wizard is the best place to start, but you'll discover more flexible options when you [configure a blob indexer](#) yourself. You can use a [REST client](#). [Tutorial: Index and search semi-structured data \(JSON blobs\)](#) walks you through the steps of calling the REST API.

How blobs are indexed

By default, most blobs are indexed as a single search document in the index, including blobs with structured content, such as JSON or CSV, which are indexed as a single chunk of text. However, for JSON or CSV documents that have an internal structure (delimiters), you can assign parsing modes to generate individual search documents for each line or element:

- [Indexing JSON blobs](#)
- [Indexing CSV blobs](#)
- [Indexing Markdown blobs](#)
- [Indexing plain text blobs](#)

A compound or embedded document (such as a ZIP archive, a Word document with embedded Outlook email containing attachments, or an .MSG file with attachments) is also indexed as a single document. For example, all images extracted from the attachments of an .MSG file will be returned in the normalized_images field. If you have images, consider adding [AI enrichment](#) to get more search utility from that content.

Textual content of a document is extracted into a string field named "content". You can also extract standard and user-defined metadata.

 **Note**

Azure AI Search imposes [indexer limits](#) on how much text it extracts depending on the pricing tier. A warning will appear in the indexer status response if documents are truncated.

Use a blob indexer for content extraction

An *indexer* is a data-source-aware subservice in Azure AI Search, equipped with internal logic for sampling data, reading and retrieving data and metadata, and serializing data from native formats into JSON documents for subsequent import.

Blobs in Azure Storage are indexed using the [blob indexer](#). You can invoke this indexer by using the [Azure AI Search](#) command in Azure Storage, an [import wizard](#) in the Azure portal, a REST API, or the .NET SDK. In code, you use this indexer by setting the type, and by providing connection information that includes an Azure Storage account along with a blob container.

You can subset your blobs by creating a virtual directory, which you can then pass as a parameter, or by filtering on a file type extension.

An indexer "[cracks a document](#)", opening a blob to inspect content. After connecting to the data source, it's the first step in the pipeline. For blob data, this is where PDF, Office docs, and other content types are detected. Document cracking with text extraction is no charge. If your blobs contain image content, images are ignored unless you [add AI enrichment](#). Standard indexing applies only to text content.

The Azure blob indexer comes with configuration parameters and supports change tracking if the underlying data provides sufficient information. You can learn more about the core functionality in [Index data from Azure Blob Storage](#).

Supported access tiers

Blob storage [access tiers](#) include hot, cool, cold, and archive. Indexers can retrieve blobs on hot, cool, and cold access tiers.

Supported content types

By running a blob indexer over a container, you can extract text and metadata from the following content types with a single query:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCX, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Controlling which blobs are indexed

You can control which blobs are indexed, and which are skipped, by the blob's file type or by setting properties on the blob themselves, causing the indexer to skip over them.

Include specific file extensions by setting `"indexedFileNameExtensions"` to a comma-separated list of file extensions (with a leading dot). Exclude specific file extensions by setting `"excludedFileNameExtensions"` to the extensions that should be skipped. If the same extension is in both lists, it's excluded from indexing.

HTTP

```
PUT /indexers/[indexer name]?api-version=2025-09-01
{
  "parameters" : {
    "configuration" : {
      "indexedFileNameExtensions" : ".pdf, .docx",
      "excludedFileNameExtensions" : ".png, .jpeg"
    }
  }
}
```

Add "skip" metadata the blob

The indexer configuration parameters apply to all blobs in the container or folder. Sometimes, you want to control how *individual blobs* are indexed.

Add the following metadata properties and values to blobs in Blob Storage. When the indexer encounters this property, it skips the blob or its content in the indexing run.

 Expand table

Property name	Property value	Explanation
<code>"AzureSearch_Skip"</code>	<code>"true"</code>	Instructs the blob indexer to completely skip the blob. Neither metadata nor content extraction is attempted. This is useful when a particular blob fails repeatedly and interrupts the indexing process.
<code>"AzureSearch_SkipContent"</code>	<code>"true"</code>	This is equivalent to the <code>"dataToExtract" : "allMetadata"</code> setting described above scoped to a particular blob.

Indexing blob metadata

A common scenario that makes it easy to sort through blobs of any content type is to [index both custom metadata and system properties](#) for each blob. In this way, information for all

blobs is indexed regardless of document type, stored in an index in your search service. Using your new index, you can then proceed to sort, filter, and facet across all Blob storage content.

! Note

Blob Index tags are natively indexed by the Blob storage service and exposed for querying. If your blobs' key/value attributes require indexing and filtering capabilities, Blob Index tags should be used instead of metadata.

To learn more about Blob Index, see [Manage and find data on Azure Blob Storage with Blob Index](#).

Search blob content in a search index

The output of an indexer is a search index, used for interactive exploration using free text and filtered queries in a client app. For initial exploration and verification of content, we recommend starting with [Search Explorer](#) in the Azure portal to examine document structure. In Search explorer, you can use:

- [Simple query syntax](#)
- [Full query syntax](#)
- [Filter expression syntax](#)

A more permanent solution is to gather query inputs and present the response as search results in a client application. The following C# tutorial explains how to build a search application: [Add search to an ASP.NET Core \(MVC\) application](#).

Next steps

- [Upload, download, and list blobs with the Azure portal \(Azure Blob storage\)](#)
- [Set up a blob indexer \(Azure AI Search\)](#)
- [Index large data sets](#)

Index data from Azure Data Lake Storage Gen2

10/09/2025

In this article, learn how to configure an [indexer](#) that imports content from Azure Data Lake Storage (ADLS) Gen2 and makes it searchable in Azure AI Search. Inputs to the indexer are your blobs, in a single container. Output is a search index with searchable content and metadata stored in individual fields.

This article supplements [Create an indexer](#) with information that's specific to indexing from ADLS Gen2. It uses the REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

For a code sample in C#, see [Index Data Lake Gen2 using Microsoft Entra ID](#) on GitHub.

! Note

ADLS Gen2 supports an [access control model](#) with Azure role-based access control (Azure RBAC) and POSIX-like access control lists (ACLs) at the blob level. Azure AI Search can now recognize document-level permissions in ADLS Gen2 blobs during indexing and transfers those permissions to indexed content in the search index. For more information about ACL ingestion and RBAC scope during indexing, see [Indexing Access Control Lists and Azure Role-Based Access Control scope using Indexers](#).

Prerequisites

- ADLS Gen2 with [hierarchical namespace](#) enabled. ADLS Gen2 is available through Azure Storage. When setting up a storage account, you have the option of enabling [hierarchical namespace](#), organizing files into a hierarchy of directories and nested subdirectories. By enabling a hierarchical namespace, you enable ADLS Gen2.
- [Access tiers](#) for ADLS Gen2 include hot, cool, and archive. Only hot and cool can be accessed by search indexers.
- Blobs containing text. If you have binary data, you can include [AI enrichment](#) for image analysis. Blob content can't exceed the [indexer limits](#) for your search service tier.
- Read permissions on Azure Storage. A "full access" connection string includes a key that grants access to the content, but if you're using Azure roles instead, make sure the [search](#)

service managed identity has **Storage Blob Data Reader** permissions.

- Use a [REST client](#) to formulate REST calls similar to the ones shown in this article.

Limitations

- Unlike blob indexers, ADLS Gen2 indexers can't use container-level SAS tokens for enumerating and indexing content from a storage account. This is because the indexer makes a check to determine if the storage account has hierarchical namespaces enabled by calling the [Filesystem - Get properties API](#). For storage accounts where hierarchical namespaces are not enabled, customers are instead recommended to utilize [blob indexers](#) to ensure performant enumeration of blobs.
- If the property `metadata_storage_path` is mapped to be the index key field, blobs are not guaranteed to get reindexed upon a directory rename. If you desire to reindex the blobs that are part of the renamed directories, update the `LastModified` timestamps for all of them.

Supported document formats

The ADLS Gen2 indexer can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Determine which blobs to index

Before you set up indexing, review your source data to determine whether any changes should be made up front. An indexer can index content from one container at a time. By default, all blobs in the container are processed. You have several options for more selective processing:

- Place blobs in a virtual folder. An indexer [data source definition](#) includes a "query" parameter that can take a virtual folder. If you specify a virtual folder, only those blobs in the folder are indexed.
- Include or exclude blobs by file type. The [supported document formats list](#) can help you determine which blobs to exclude. For example, you might want to exclude image or audio files that don't provide searchable text. This capability is controlled through [configuration settings](#) in the indexer.
- Include or exclude arbitrary blobs. If you want to skip a specific blob for whatever reason, you can add the following metadata properties and values to blobs in Blob Storage. When an indexer encounters this property, it skips the blob or its content in the indexing run.

 [Expand table](#)

Property name	Property value	Explanation
"AzureSearch_Skip"	"true"	Instructs the blob indexer to completely skip the blob. Neither metadata nor content extraction is attempted. This is useful when a particular blob fails repeatedly and interrupts the indexing process.
"AzureSearch_SkipContent"	"true"	Skips content and extracts just the metadata. this is equivalent to the <code>"dataToExtract" : "allMetadata"</code> setting described in configuration settings , just scoped to a particular blob.

If you don't set up inclusion or exclusion criteria, the indexer will report an ineligible blob as an error and move on. If enough errors occur, processing might stop. You can specify error tolerance in the indexer [configuration settings](#).

An indexer typically creates one search document per blob, where the text content and metadata are captured as searchable fields in an index. If blobs are whole files, you can potentially parse them into [multiple search documents](#). For example, you can parse rows in a [CSV file](#) to create one search document per row.

Indexing blob metadata

Blob metadata can also be indexed, and that's helpful if you think any of the standard or custom metadata properties will be useful in filters and queries.

User-specified metadata properties are extracted verbatim. To receive the values, you must define field in the search index of type `Edm.String`, with same name as the metadata key of the blob. For example, if a blob has a metadata key of `Sensitivity` with value `High`, you should define a field named `Sensitivity` in your search index and it will be populated with the value `High`.

Standard blob metadata properties can be extracted into similarly named and typed fields, as listed below. The blob indexer automatically creates internal field mappings for these blob metadata properties, converting the original hyphenated name ("metadata-storage-name") to an underscored equivalent name ("metadata_storage_name").

You still have to add the underscored fields to the index definition, but you can omit field mappings because the indexer will make the association automatically.

- **metadata_storage_name** (`Edm.String`) - the file name of the blob. For example, if you have a blob /my-container/my-folder/subfolder/resume.pdf, the value of this field is `resume.pdf`.
- **metadata_storage_path** (`Edm.String`) - the full URI of the blob, including the storage account. For example, `https://myaccount.blob.core.windows.net/my-container/my-folder/subfolder/resume.pdf`
- **metadata_storage_content_type** (`Edm.String`) - content type as specified by the code you used to upload the blob. For example, `application/octet-stream`.
- **metadata_storage_last_modified** (`Edm.DateTimeOffset`) - last modified timestamp for the blob. Azure AI Search uses this timestamp to identify changed blobs, to avoid reindexing everything after the initial indexing.
- **metadata_storage_size** (`Edm.Int64`) - blob size in bytes.
- **metadata_storage_content_md5** (`Edm.String`) - MD5 hash of the blob content, if available.
- **metadata_storage_sas_token** (`Edm.String`) - A temporary SAS token that can be used by [custom skills](#) to get access to the blob. This token shouldn't be stored for later use as it might expire.

Lastly, any metadata properties specific to the document format of the blobs you're indexing can also be represented in the index schema. For more information about content-specific

metadata, see [Content metadata properties](#).

It's important to point out that you don't need to define fields for all of the above properties in your search index - just capture the properties you need for your application.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is defined as an independent resource so that it can be used by multiple indexers.

1. [Create or update a data source](#) to set its definition:

JSON

```
{  
  "name" : "my-adlsgen2-datasource",  
  "type" : "adlsgen2",  
  "credentials" : { "connectionString" :  
    "DefaultEndpointsProtocol=https;AccountName=<account name>;AccountKey=<account key>" },  
  "container" : { "name" : "my-container", "query" : "<optional-virtual-directory-name>" }  
}
```

2. Set "type" to `adlsgen2` (required).

3. Set `credentials` to an Azure Storage connection string. The next section describes the supported formats.

4. Set `container` to the blob container, and use "query" to specify any subfolders.

A data source definition can also include [soft deletion policies](#), if you want the indexer to delete a search document when the source document is flagged for deletion.

Supported credentials and connection strings

Indexers can connect to a blob container using the following connections.

 [Expand table](#)

Full access storage account connection string

```
{ "connectionString" : "DefaultEndpointsProtocol=https;AccountName=<your storage account>;AccountKey=<your account key>" }
```

Full access storage account connection string

You can get the connection string from the Storage account page in Azure portal by selecting **Access keys** in the left pane. Make sure to select a full connection string and not just a key.

 Expand table

Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;" }
```

This connection string doesn't require an account key, but you must have previously configured a search service to [connect using a managed identity](#).

 Expand table

Storage account shared access signature** (SAS) connection string

```
{ "connectionString" : "BlobEndpoint=https://<your account>.blob.core.windows.net/;SharedAccessSignature=?sv=2016-05-31&sig=<the signature>&spr=https&se=<the validity end time>&srt=co&ss=b&sp=r1;" }
```

The SAS should have the list and read permissions on containers and objects (blobs in this case).

Note

If you use SAS credentials, you will need to update the data source credentials periodically with renewed signatures to prevent their expiration. If SAS credentials expire, the indexer will fail with an error message similar to "Credentials provided in the connection string are invalid or have expired".

Add search fields to an index

In a [search index](#), add fields to accept the content and metadata of your Azure blobs.

1. [Create or update an index](#) to define search fields that will store blob content and metadata:

HTTP

```
{
  "name" : "my-search-index",
  "fields": [
```

```

        { "name": "ID", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false },
        { "name": "metadata_storage_name", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_size", "type": "Edm.Int64", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_content_type", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true }
    ]
}

```

2. Create a document key field ("key": true). For blob content, the best candidates are metadata properties.

- `metadata_storage_path` (default) full path to the object or file. The key field ("ID" in this example) will be populated with values from `metadata_storage_path` because it's the default.
- `metadata_storage_name`, usable only if names are unique. If you want this field as the key, move `"key": true` to this field definition.
- A custom metadata property that you add to blobs. This option requires that your blob upload process adds that metadata property to all blobs. Since the key is a required property, any blobs that are missing a value will fail to be indexed. If you use a custom metadata property as a key, avoid making changes to that property. Indexers will add duplicate documents for the same blob if the key property changes.

Metadata properties often include characters, such as `/` and `-`, that are invalid for document keys. The indexer automatically encodes the key metadata property, with no configuration or field mapping required.

3. Add a "content" field to store extracted text from each file through the blob's "content" property. You aren't required to use this name, but doing so lets you take advantage of implicit field mappings.
4. Add fields for standard metadata properties. The indexer can read custom metadata properties, [standard metadata](#) properties, and [content-specific metadata](#) properties.

Configure and run the ADLS Gen2 indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

You can also specify which parts of a blob to index.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
{  
  "name" : "my-adlsgen2-indexer",  
  "dataSourceName" : "my-adlsgen2-datasource",  
  "targetIndexName" : "my-search-index",  
  "parameters": {  
    "batchSize": null,  
    "maxFailedItems": null,  
    "maxFailedItemsPerBatch": null,  
    "configuration": {  
      "indexedFileNameExtensions" : ".pdf,.docx",  
      "excludedFileNameExtensions" : ".png,.jpeg",  
      "dataToExtract": "contentAndMetadata",  
      "parsingMode": "default"  
    }  
  },  
  "schedule" : { },  
  "fieldMappings" : [ ]  
}
```

2. Set "batchSize" if the default (10 documents) is either under utilizing or overwhelming available resources. Default batch sizes are data source specific. Blob indexing sets batch size at 10 documents in recognition of the larger average document size.
3. Under "configuration", control which blobs are indexed based on file type, or leave unspecified to retrieve all blobs.

For "indexedFileNameExtensions", provide a comma-separated list of file extensions (with a leading dot). Do the same for "excludedFileNameExtensions" to indicate which extensions should be skipped. If the same extension is in both lists, it will be excluded from indexing.

4. Under "configuration", set "dataToExtract" to control which parts of the blobs are indexed:

- "contentAndMetadata" specifies that all metadata and textual content extracted from the blob are indexed. This is the default value.
- "storageMetadata" specifies that only the [standard blob properties and user-specified metadata](#) are indexed.
- "allMetadata" specifies that standard blob properties and any [metadata for found content types](#) are extracted from the blob content and indexed.

5. Under "configuration", set "parsingMode" if blobs should be mapped to [multiple search documents](#), or if they consist of [plain text](#), [JSON documents](#), or [CSV files](#).

6. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.

In blob indexing, you can often omit field mappings because the indexer has built-in support for mapping the "content" and metadata properties to similarly named and typed fields in an index. For metadata properties, the indexer will automatically replace hyphens - with underscores in the search index.

7. See [Create an indexer](#) for more information about other properties. For the full list of parameter descriptions, see [Create Indexer \(REST\)](#) in the REST API.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, send a [Get Indexer Status](#) request:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-version=2025-09-01
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
    "status": "running",
    "lastResult": {
        "status": "success",
        "errorMessage": null,
        "startTime": "2024-02-21T00:23:24.957Z",
        "endTime": "2024-02-21T00:36:47.752Z",
        "errors": [],
        "itemsProcessed": 1599501,
        "itemsFailed": 0,
        "initialTrackingState": null,
        "finalTrackingState": null
    },
    "executionHistory":
```

```

[
  {
    "status": "success",
    "errorMessage": null,
    "startTime": "2024-02-21T00:23:24.957Z",
    "endTime": "2024-02-21T00:36:47.752Z",
    "errors": [],
    "itemsProcessed": 1599501,
    "itemsFailed": 0,
    "initialTrackingState": null,
    "finalTrackingState": null
  },
  ... earlier history items
]
}

```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Handle errors

Errors that commonly occur during indexing include unsupported content types, missing content, or oversized blobs.

By default, the blob indexer stops as soon as it encounters a blob with an unsupported content type (for example, an audio file). You could use the "excludedFileNameExtensions" parameter to skip certain content types. However, you might want indexing to proceed even if errors occur, and then debug individual documents later. For more information about indexer errors, see [Indexer troubleshooting guidance](#) and [Indexer errors and warnings](#).

There are five indexer properties that control the indexer's response when errors occur.

HTTP

```

PUT /indexers/[indexer name]?api-version=2025-09-01
{
  "parameters" : {
    "maxFailedItems" : 10,
    "maxFailedItemsPerBatch" : 10,
    "configuration" : {
      "failOnUnsupportedContentType" : false,
      "failOnUnprocessableDocument" : false,
      "indexStorageMetadataOnlyForOversizedDocuments": false
    }
  }
}

```

Parameter	Valid values	Description
"maxFailedItems"	-1, null or 0, positive integer	Continue indexing if errors happen at any point of processing, either while parsing blobs or while adding documents to an index. Set these properties to the number of acceptable failures. A value of -1 allows processing no matter how many errors occur. Otherwise, the value is a positive integer.
"maxFailedItemsPerBatch"	-1, null or 0, positive integer	Same as above, but used for batch indexing.
"failOnUnsupportedContentType"	true or false	If the indexer is unable to determine the content type, specify whether to continue or fail the job.
"failOnUnprocessableDocument"	true or false	If the indexer is unable to process a document of an otherwise supported content type, specify whether to continue or fail the job.
"indexStorageMetadataOnlyForOversizedDocuments"	true or false	Oversized blobs are treated as errors by default. If you set this parameter to true, the indexer will try to index its metadata even if the content cannot be indexed. For limits on blob size, see service Limits .

Next steps

You can now [run the indexer](#), [monitor status](#), or [schedule indexer execution](#). The following articles apply to indexers that pull content from Azure Storage:

- [Change detection and deletion detection](#)
- [Index large data sets](#)
- [C# Sample: Index Data Lake Gen2 using Microsoft Entra ID](#)

Index data from Azure Blob Storage

10/09/2025

In this article, learn how to configure an [indexer](#) that imports content from Azure Blob Storage and makes it searchable in Azure AI Search. Inputs to the indexer are your blobs, in a single container. Output is a search index with searchable content and metadata stored in individual fields.

To configure and run the indexer, you can use:

- [Search Service REST API](#), any version.
- An Azure SDK package, any version.
- [Import data wizard](#) in the Azure portal.
- [Import data \(new\) wizard](#) in the Azure portal.

This article uses the REST APIs to illustrate each step.

ⓘ Note

Azure AI Search can now ingest RBAC scope during indexing and transfers those permissions to indexed content in the search index. For more information about RBAC scope during indexing, see [Indexing Azure Role-Based Access Control scope using Indexers](#).

Prerequisites

- [Azure Blob Storage](#), Standard performance (general-purpose v2).
- [Access tiers](#) include hot, cool, cold, and archive. Indexers can retrieve blobs on hot, cool, and cold access tiers.
- Blobs providing text content and metadata. If blobs contain binary content or unstructured text, consider adding [AI enrichment](#) for image and natural language processing. Blob content can't exceed the [indexer limits](#) for your search service tier.
- A supported network configuration and data access. At a minimum, you need read permissions in Azure Storage. A storage connection string that includes an access key gives you read access to storage content. If instead you're using Microsoft Entra logins and roles, make sure the [search service's managed identity](#) has [Storage Blob Data Reader](#) permissions.

By default, both search and storage accept requests from public IP addresses. If network security isn't an immediate concern, you can index blob data using just the connection string and read permissions. When you're ready to add network protections, see [Indexer access to content protected by Azure network security features](#) for guidance about data access.

- Use a [REST client](#) to formulate REST calls similar to the ones shown in this article.

Supported tasks

You can use this indexer for the following tasks:

- **Data indexing and incremental indexing:** The indexer can index files and associated metadata from blob containers and folders. It detects new and updated files and metadata through built-in change detection. You can configure data refresh on a schedule or on demand.
- **Deletion detection:** The indexer can [detect deletions through native soft delete or through custom metadata](#).
- **Applied AI through skillsets:** [Skillsets](#) are fully supported by the indexer. This includes key features like [integrated vectorization](#) that adds data chunking and embedding steps.
- **Parsing modes:** The indexer supports [JSON parsing modes](#) if you want to parse JSON arrays or lines into individual search documents. It also supports [Markdown parsing mode](#).
- **Compatibility with other features:** The indexer is designed to work seamlessly with other indexer features, such as [debug sessions](#), [indexer cache for incremental enrichments](#), and [knowledge store](#).

Supported document formats

The blob indexer can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP

- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Determine which blobs to index

Before you set up indexing, review your source data to determine whether any changes should be made up front. An indexer can index content from one container at a time. By default, all blobs in the container are processed. You have several options for more selective processing:

- Place blobs in a virtual folder. An indexer [data source definition](#) includes a "query" parameter that can take a virtual folder. If you specify a virtual folder, only those blobs in the folder are indexed.
- Include or exclude blobs by file type. The [supported document formats list](#) can help you determine which blobs to exclude. For example, you might want to exclude image or audio files that don't provide searchable text. This capability is controlled through [configuration settings](#) in the indexer.
- Include or exclude arbitrary blobs. If you want to skip a specific blob for whatever reason, you can add the following metadata properties and values to blobs in Blob Storage. When an indexer encounters this property, it skips the blob or its content in the indexing run.

[] [Expand table](#)

Property name	Property value	Explanation
"AzureSearch_Skip"	"true"	Instructs the blob indexer to completely skip the blob. Neither metadata nor content extraction is attempted. This is useful when a particular blob fails repeatedly and interrupts the indexing process.
"AzureSearch_SkipContent"	"true"	Skips content and extracts just the metadata. this is equivalent to the "dataToExtract" : "allMetadata" setting described in configuration settings , just scoped to a particular blob.

If you don't set up inclusion or exclusion criteria, the indexer reports an ineligible blob as an error and move on. If enough errors occur, processing might stop. You can specify error tolerance in the indexer [configuration settings](#).

An indexer typically creates one search document per blob, where the text content and metadata are captured as searchable fields in an index. If blobs are whole files, you can potentially parse them into [multiple search documents](#). For example, you can parse rows in a [CSV file](#) to create one search document per row.

A compound or embedded document (such as a ZIP archive, a Word document with embedded Outlook email containing attachments, or an .MSG file with attachments) is also indexed as a single document. For example, all images extracted from the attachments of an .MSG file will be returned in the normalized_images field. If you have images, consider adding [AI enrichment](#) to get more search utility from that content.

Textual content of a document is extracted into a string field named "content". You can also extract standard and user-defined metadata.

Indexing blob metadata

Blob metadata can also be indexed, and that's helpful if you think any of the standard or custom metadata properties are useful in filters and queries.

User-specified metadata properties are extracted verbatim. To receive the values, you must define field in the search index of type `Edm.String`, with same name as the metadata key of the blob. For example, if a blob has a metadata key of `Sensitivity` with value `High`, you should define a field named `Sensitivity` in your search index and it will be populated with the value `High`.

Standard blob metadata properties can be extracted into similarly named and typed fields, as listed below. The blob indexer automatically creates internal field mappings for these blob metadata properties, converting the original hyphenated name ("metadata-storage-name") to an underscored equivalent name ("metadata_storage_name").

You still have to add the underscored fields to the index definition, but you can omit field mappings because the indexer makes the association automatically.

- **metadata_storage_name** (`Edm.String`) - the file name of the blob. For example, if you have a blob /my-container/my-folder/subfolder/resume.pdf, the value of this field is `resume.pdf`.
- **metadata_storage_path** (`Edm.String`) - the full URI of the blob, including the storage account. For example, `https://myaccount.blob.core.windows.net/my-container/my-folder/subfolder/resume.pdf`
- **metadata_storage_content_type** (`Edm.String`) - content type as specified by the code you used to upload the blob. For example, `application/octet-stream`.

- **metadata_storage_last_modified** (`Edm.DateTimeOffset`) - last modified timestamp for the blob. Azure AI Search uses this timestamp to identify changed blobs, to avoid reindexing everything after the initial indexing.
- **metadata_storage_size** (`Edm.Int64`) - blob size in bytes.
- **metadata_storage_content_md5** (`Edm.String`) - MD5 hash of the blob content, if available.
- **metadata_storage_sas_token** (`Edm.String`) - A temporary SAS token that can be used by [custom skills](#) to get access to the blob. This token shouldn't be stored for later use as it might expire.

Lastly, any metadata properties specific to the document format of the blobs you're indexing can also be represented in the index schema. For more information about content-specific metadata, see [Content metadata properties](#).

It's important to point out that you don't need to define fields for all of the above properties in your search index - just capture the properties you need for your application.

Currently, indexing [blob index tags](#) isn't supported by this indexer.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is defined as an independent resource so that it can be used by multiple indexers.

1. [Create or update a data source](#) to set its definition:

```
JSON

{
  "name" : "my-blob-datasource",
  "type" : "azureblob",
  "credentials" : { "connectionString" :
  "DefaultEndpointsProtocol=https;AccountName=<account name>;AccountKey=
  <account key>" },
  "container" : { "name" : "my-container", "query" : "<optional-virtual-
  directory-name>" }
}
```

2. Set "type" to `"azureblob"` (required).

3. Set "credentials" to an Azure Storage connection string. The next section describes the supported formats.

4. Set "container" to the blob container, and use "query" to specify any subfolders.

A data source definition can also include [soft deletion policies](#), if you want the indexer to delete a search document when the source document is flagged for deletion.

Supported credentials and connection strings

Indexers can connect to a blob container using the following connections.

[\[+\] Expand table](#)

Full access storage account connection string

```
{ "connectionString" : "DefaultEndpointsProtocol=https;AccountName=<your storage account>;AccountKey=<your account key>;" }
```

You can get the connection string from the Storage account page in Azure portal by selecting **Access keys** in the left pane. Make sure to select a full connection string and not just a key.

[\[+\] Expand table](#)

Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;" }
```

This connection string doesn't require an account key, but you must have previously configured a search service to [connect using a managed identity](#).

[\[+\] Expand table](#)

Storage account shared access signature** (SAS) connection string

```
{ "connectionString" : "BlobEndpoint=https://<your account>.blob.core.windows.net/;SharedAccessSignature=?sv=2016-05-31&sig=<the signature>&spr=https&se=<the validity end time>&srt=co&ss=b&sp=r;" }
```

The SAS should have the list and read permissions on containers and objects (blobs in this case).

[\[+\] Expand table](#)

Container shared access signature

```
{ "connectionString" : "ContainerSharedAccessUri=https://<your storage account>.blob.core.windows.net/<container name>?sv=2016-05-31&sr=c&sig=<the signature>&se=<the validity end time>&sp=r;" }
```

The SAS should have the list and read permissions on the container. For more information, see [Using Shared Access Signatures](#).

! Note

If you use SAS credentials, you will need to update the data source credentials periodically with renewed signatures to prevent their expiration. If SAS credentials expire, the indexer will fail with an error message similar to "Credentials provided in the connection string are invalid or have expired".

Add search fields to an index

In a [search index](#), add fields to accept the content and metadata of your Azure blobs.

1. [Create or update an index](#) to define search fields that will store blob content and metadata:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-09-01
{
    "name" : "my-search-index",
    "fields": [
        { "name": "ID", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false },
        { "name": "metadata_storage_name", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_size", "type": "Edm.Int64", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_content_type", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true }
    ]
}
```

2. Create a document key field ("key": true). For blob content, the best candidates are metadata properties.

- `metadata_storage_path` (default) full path to the object or file. The key field ("ID" in this example) will be populated with values from `metadata_storage_path` because it's the default.
- `metadata_storage_name`, usable only if names are unique. If you want this field as the key, move `"key": true` to this field definition.
- A custom metadata property that you add to blobs. This option requires that your blob upload process adds that metadata property to all blobs. Since the key is a required property, any blobs that are missing a value will fail to be indexed. If you use a custom metadata property as a key, avoid making changes to that property. Indexers will add duplicate documents for the same blob if the key property changes.

Metadata properties often include characters, such as `/` and `-`, which are invalid for document keys. However, the indexer automatically encodes the key metadata property, with no configuration or field mapping required.

3. Add a "content" field to store extracted text from each file through the blob's "content" property. You aren't required to use this name, but doing so lets you take advantage of implicit field mappings.
4. Add fields for standard metadata properties. The indexer can read custom metadata properties, [standard metadata](#) properties, and [content-specific metadata](#) properties.

Configure and run the blob indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors. You can also specify which parts of a blob to index.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
{
  "name" : "my-blob-indexer",
  "dataSourceName" : "my-blob-datasource",
  "targetIndexName" : "my-search-index",
  "parameters": {
    "batchSize": null,
    "maxFailedItems": null,
```

```

    "maxFailedItemsPerBatch": null,
    "configuration": {
        "indexedFileNameExtensions" : ".pdf,.docx",
        "excludedFileNameExtensions" : ".png,.jpeg",
        "dataToExtract": "contentAndMetadata",
        "parsingMode": "default"
    }
},
"schedule" : { },
"fieldMappings" : [ ]
}

```

2. Set `batchSize` if the default (10 documents) is either underutilizing or overwhelming available resources. Default batch sizes are data source specific. Blob indexing sets batch size at 10 documents in recognition of the larger average document size.
3. Under "configuration", control which blobs are indexed based on file type, or leave unspecified to retrieve all blobs.

For `"indexedFileNameExtensions"`, provide a comma-separated list of file extensions (with a leading dot). Do the same for `"excludedFileNameExtensions"` to indicate which extensions should be skipped. If the same extension is in both lists, it will be excluded from indexing.

4. Under "configuration", set "dataToExtract" to control which parts of the blobs are indexed:
 - "contentAndMetadata" specifies that all metadata and textual content extracted from the blob are indexed. This is the default value.
 - "storageMetadata" specifies that only the [standard blob properties and user-specified metadata](#) are indexed.
 - "allMetadata" specifies that standard blob properties and any [metadata for found content types](#) are extracted from the blob content and indexed.
5. Under "configuration", set "parsingMode". The default parsing mode is one search document per blob. If blobs are plain text, you can get better performance by switching to [plain text](#) parsing. If you need more granular parsing that maps blobs to [multiple search documents](#), specify a different mode. One-to-many parsing is supported for blobs consisting of:
 - [JSON documents](#)
 - [CSV files](#)
6. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.

In blob indexing, you can often omit field mappings because the indexer has built-in support for mapping the "content" and metadata properties to similarly named and typed fields in an index. For metadata properties, the indexer will automatically replace hyphens - with underscores in the search index.

7. See [Create an indexer](#) for more information about other properties. For the full list of parameter descriptions, see [REST API](#).

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Indexing data from multiple Azure Blob containers to a single index

Keep in mind that an indexer can only index data from a single container. If your requirement is to index data from multiple containers and consolidate it into a single AI Search index, this can be achieved by configuring multiple indexers, all directed to the same index. Please be aware of the [maximum number of indexers available per SKU](#).

To illustrate, let's consider an example of two indexers, pulling data from two distinct data sources, named `my-blob-datasource1` and `my-blob-datasource2`. Each data source points to a separate Azure Blob container, but both direct to the same index named `my-search-index`.

First indexer definition example:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
{
    "name" : "my-blob-indexer1",
    "dataSourceName" : "my-blob-datasource1",
    "targetIndexName" : "my-search-index",
    "parameters": {
        "batchSize": null,
        "maxFailedItems": null,
        "maxFailedItemsPerBatch": null,
        "configuration": {
            "indexedFileNameExtensions" : ".pdf,.docx",
            "excludedFileNameExtensions" : ".png,.jpeg",
            "dataToExtract": "contentAndMetadata",
            "parsingMode": "default"
        }
    },
    "schedule" : { },
    "fieldMappings" : [ ]
}
```

Second indexer definition that runs in parallel example:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
{
  "name" : "my-blob-indexer2",
  "dataSourceName" : "my-blob-datasource2",
  "targetIndexName" : "my-search-index",
  "parameters": {
    "batchSize": null,
    "maxFailedItems": null,
    "maxFailedItemsPerBatch": null,
    "configuration": {
      "indexedFileNameExtensions" : ".pdf,.docx",
      "excludedFileNameExtensions" : ".png,.jpeg",
      "dataToExtract": "contentAndMetadata",
      "parsingMode": "default"
    }
  },
  "schedule" : { },
  "fieldMappings" : [ ]
}
```

Check indexer status

To monitor the indexer status and execution history, send a [Get Indexer Status](#) request:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-
version=2025-09-01
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
  "status":"running",
  "lastResult": {
    "status":"success",
    "errorMessage":null,
    "startTime":"2022-02-21T00:23:24.957Z",
    "endTime":"2022-02-21T00:36:47.752Z",
    "errors":[],
    "itemsProcessed":1599501,
```

```
        "itemsFailed":0,
        "initialTrackingState":null,
        "finalTrackingState":null
    },
    "executionHistory":
    [
        {
            "status":"success",
            "errorMessage":null,
            "startTime":"2022-02-21T00:23:24.957Z",
            "endTime":"2022-02-21T00:36:47.752Z",
            "errors":[],
            "itemsProcessed":1599501,
            "itemsFailed":0,
            "initialTrackingState":null,
            "finalTrackingState":null
        },
        ... earlier history items
    ]
}
```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Handle errors

Errors that commonly occur during indexing include unsupported content types, missing content, or oversized blobs.

By default, the blob indexer stops as soon as it encounters a blob with an unsupported content type (for example, an audio file). You could use the "excludedFileNameExtensions" parameter to skip certain content types. However, you might want to indexing to proceed even if errors occur, and then debug individual documents later. For more information about indexer errors, see [Indexer troubleshooting guidance](#) and [Indexer errors and warnings](#).

There are five indexer properties that control the indexer's response when errors occur.

HTTP

```
PUT /indexers/[indexer name]?api-version=2025-09-01
{
    "parameters" : {
        "maxFailedItems" : 10,
        "maxFailedItemsPerBatch" : 10,
        "configuration" : {
            "failOnUnsupportedContentType" : false,
            "failOnUnprocessableDocument" : false,
            "indexStorageMetadataOnlyForOversizedDocuments": false
        }
}
```

```
    }  
}
```

 Expand table

Parameter	Valid values	Description
"maxFailedItems"	-1, null or 0, positive integer	Continue indexing if errors happen at any point of processing, either while parsing blobs or while adding documents to an index. Set these properties to the number of acceptable failures. A value of -1 allows processing no matter how many errors occur. Otherwise, the value is a positive integer.
"maxFailedItemsPerBatch"	-1, null or 0, positive integer	Same as above, but used for batch indexing.
"failOnUnsupportedContentType"	true or false	If the indexer is unable to determine the content type, specify whether to continue or fail the job.
"failOnUnprocessableDocument"	true or false	If the indexer is unable to process a document of an otherwise supported content type, specify whether to continue or fail the job.
"indexStorageMetadataOnlyForOversizedDocuments"	true or false	Oversized blobs are treated as errors by default. If you set this parameter to true, the indexer will try to index its metadata even if the content can't be indexed. For limits on blob size, see service Limits .

Index data from Azure Files

05/08/2025

ⓘ Important

Azure Files indexer is currently in public preview under [Supplemental Terms of Use](#). Use a [preview REST API](#) to create the indexer data source.

In this article, learn how to configure an [indexer](#) that imports content from Azure Files and makes it searchable in Azure AI Search. Inputs to the indexer are your files in a single share. Output is a search index with searchable content and metadata stored in individual fields.

To configure and run the indexer, you can use:

- [Search Service preview REST APIs](#), any preview version.
- An Azure SDK package, any version.
- [Import data wizard](#) in the Azure portal.
- [Import and vectorize data wizard](#) in the Azure portal.

Prerequisites

- [Azure Files](#), Transaction Optimized tier.
- An [SMB file share](#) providing the source content. [NFS shares](#) are not supported.
- Files containing text. If you have binary data, you can include [AI enrichment](#) for image analysis.
- Read permissions on Azure Storage. A "full access" connection string includes a key that grants access to the content.
- Use a [REST client](#) to formulate REST calls similar to the ones shown in this article.

Supported tasks

You can use this indexer for the following tasks:

- **Data indexing and incremental indexing:** The indexer can index files and associated metadata from tables. It detects new and updated files and metadata through built-in change detection. You can configure data refresh on a schedule or on demand.
- **Deletion detection:** The indexer can [detect deletions through custom metadata](#).

- **Applied AI through skillsets:** [Skillsets](#) are fully supported by the indexer. This includes key features like [integrated vectorization](#) that adds data chunking and embedding steps.
- **Parsing modes:** The indexer supports [JSON parsing modes](#) if you want to parse JSON arrays or lines into individual search documents. It also supports [Markdown parsing mode](#).
- **Compatibility with other features:** The indexer is designed to work seamlessly with other indexer features, such as [debug sessions](#), [indexer cache for incremental enrichments](#), and [knowledge store](#).

Supported document formats

The Azure Files indexer can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

How Azure Files are indexed

By default, most files are indexed as a single search document in the index, including files with structured content, such as JSON or CSV, which are indexed as a single chunk of text.

A compound or embedded document (such as a ZIP archive, a Word document with embedded Outlook email containing attachments, or an .MSG file with attachments) is also indexed as a single document. For example, all images extracted from the attachments of an .MSG file will be returned in the normalized_images field. If you have images, consider adding [AI enrichment](#) to get more search utility from that content.

Textual content of a document is extracted into a string field named "content". You can also extract standard and user-defined metadata.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is defined as an independent resource so that it can be used by multiple indexers.

You can use 2020-06-30-preview or later for "type": "azurefile". We recommend the latest preview API.

1. [Create a data source](#) to set its definition, using a preview API for "type": "azurefile".

```
HTTP  
  
POST /datasources?api-version=2024-05-01-preview  
{  
    "name" : "my-file-datasource",  
    "type" : "azurefile",  
    "credentials" : { "connectionString" :  
        "DefaultEndpointsProtocol=https;AccountName=<account name>;AccountKey=<account key>;" },  
    "container" : { "name" : "my-file-share", "query" : "<optional-directory-name>" }  
}
```

2. Set "type" to "azurefile" (required).
3. Set "credentials" to an Azure Storage connection string. The next section describes the supported formats.
4. Set "container" to the root file share, and use "query" to specify any subfolders.

A data source definition can also include [soft deletion policies](#), if you want the indexer to delete a search document when the source document is flagged for deletion.

Supported credentials and connection strings

Indexers can connect to a file share using the following connections.

[] Expand table

Full access storage account connection string

```
{ "connectionString" : "DefaultEndpointsProtocol=https;AccountName=<your storage account>;AccountKey=<your account key>;" }
```

You can get the connection string from the Storage account page in Azure portal by selecting **Access keys** in the left pane. Make sure to select a full connection string and not just a key.

Add search fields to an index

In the [search index](#), add fields to accept the content and metadata of your Azure files.

1. [Create or update an index](#) to define search fields that will store file content and metadata.

HTTP

```
POST /indexes?api-version=2024-07-01
{
    "name" : "my-search-index",
    "fields": [
        { "name": "ID", "type": "Edm.String", "key": true, "searchable": false },
        { "name": "content", "type": "Edm.String", "searchable": true, "filterable": false },
        { "name": "metadata_storage_name", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_path", "type": "Edm.String", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_size", "type": "Edm.Int64", "searchable": false, "filterable": true, "sortable": true },
        { "name": "metadata_storage_content_type", "type": "Edm.String", "searchable": true, "filterable": true, "sortable": true }
    ]
}
```

2. Create a document key field ("key": true). For blob content, the best candidates are metadata properties. Metadata properties often include characters, such as / and -, that are invalid for document keys. The indexer automatically encodes the key metadata property, with no configuration or field mapping required.

- `metadata_storage_path` (default) full path to the object or file
- `metadata_storage_name` usable only if names are unique
- A custom metadata property that you add to blobs. This option requires that your blob upload process adds that metadata property to all blobs. Since the key is a required property, any blobs that are missing a value will fail to be indexed. If you

use a custom metadata property as a key, avoid making changes to that property. Indexers will add duplicate documents for the same blob if the key property changes.

3. Add a "content" field to store extracted text from each file through the blob's "content" property. You aren't required to use this name, but doing so lets you take advantage of implicit field mappings.
4. Add fields for standard metadata properties. In file indexing, the standard metadata properties are the same as blob metadata properties. The Azure Files indexer automatically creates internal field mappings for these properties that converts hyphenated property names to underscored property names. You still have to add the fields you want to use the index definition, but you can omit creating field mappings in the data source.

- **metadata_storage_name** (`Edm.String`) - the file name. For example, if you have a file `/my-share/my-folder/subfolder/resume.pdf`, the value of this field is `resume.pdf`.
- **metadata_storage_path** (`Edm.String`) - the full URI of the file, including the storage account. For example, `https://myaccount.file.core.windows.net/my-share/my-folder/subfolder/resume.pdf`
- **metadata_storage_content_type** (`Edm.String`) - content type as specified by the code you used to upload the file. For example, `application/octet-stream`.
- **metadata_storage_last_modified** (`Edm.DateTimeOffset`) - last modified timestamp for the file. Azure AI Search uses this timestamp to identify changed files, to avoid reindexing everything after the initial indexing.
- **metadata_storage_size** (`Edm.Int64`) - file size in bytes.
- **metadata_storage_content_md5** (`Edm.String`) - MD5 hash of the file content, if available.
- **metadata_storage_sas_token** (`Edm.String`) - A temporary SAS token that can be used by [custom skills](#) to get access to the file. This token shouldn't be stored for later use as it might expire.

Configure and run the Azure Files indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
POST /indexers?api-version=2024-07-01
{
    "name" : "my-file-indexer",
    "dataSourceName" : "my-file-datasource",
    "targetIndexName" : "my-search-index",
    "parameters": {
        "batchSize": null,
        "maxFailedItems": null,
        "maxFailedItemsPerBatch": null,
        "configuration": {
            "indexedFileNameExtensions" : ".pdf,.docx",
            "excludedFileNameExtensions" : ".png,.jpeg"
        }
    },
    "schedule" : { },
    "fieldMappings" : [ ]
}
```

2. In the optional "configuration" section, provide any inclusion or exclusion criteria. If left unspecified, all files in the file share are retrieved.

If both `indexedFileNameExtensions` and `excludedFileNameExtensions` parameters are present, Azure AI Search first looks at `indexedFileNameExtensions`, then at `excludedFileNameExtensions`. If the same file extension is present in both lists, it will be excluded from indexing.

3. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.

In file indexing, you can often omit field mappings because the indexer has built-in support for mapping the "content" and metadata properties to similarly named and typed fields in an index. For metadata properties, the indexer will automatically replace hyphens `-` with underscores in the search index.

4. See [Create an indexer](#) for more information about other properties.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, send a [Get Indexer Status](#) request:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-version=2024-07-01
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
    "status": "running",
    "lastResult": {
        "status": "success",
        "errorMessage": null,
        "startTime": "2022-02-21T00:23:24.957Z",
        "endTime": "2022-02-21T00:36:47.752Z",
        "errors": [],
        "itemsProcessed": 1599501,
        "itemsFailed": 0,
        "initialTrackingState": null,
        "finalTrackingState": null
    },
    "executionHistory":
    [
        {
            "status": "success",
            "errorMessage": null,
            "startTime": "2022-02-21T00:23:24.957Z",
            "endTime": "2022-02-21T00:36:47.752Z",
            "errors": [],
            "itemsProcessed": 1599501,
            "itemsFailed": 0,
            "initialTrackingState": null,
            "finalTrackingState": null
        },
        ...
        ... earlier history items
    ]
}
```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Next steps

You can now [run the indexer](#), [monitor status](#), or [schedule indexer execution](#). The following articles apply to indexers that pull content from Azure Storage:

- Change detection and deletion detection
- Index large data sets

Index data from Azure Table Storage

10/09/2025

In this article, learn how to configure an [indexer](#) that imports content from Azure Table Storage and makes it searchable in Azure AI Search. Inputs to the indexer are your entities, in a single table. Output is a search index with searchable content and metadata stored in individual fields.

This article supplements [Create an indexer](#) with information that's specific to indexing from Azure Table Storage. It uses the Azure portal and REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

Prerequisites

- [Azure Table Storage](#)
- Tables containing text. If you have binary data, consider [AI enrichment](#) for image analysis.
- Read permissions on Azure Storage. A "full access" connection string includes a key that gives access to the content, but if you're using Azure roles, make sure the [search service managed identity](#) has [Storage Table Data Reader](#) permissions.

To work through the examples in this article, you need the Azure portal or a [REST client](#). If you're using Azure portal, make sure that access to all public networks is enabled. Other approaches for creating an Azure Table indexer include Azure SDKs.

Try with sample data

Use these instructions to create a table in Azure Storage for testing purposes.

1. Sign in to the Azure portal, navigate to your storage account, and create a table named *hotels*.
2. [Install Azure Storage Explorer](#).
3. [Download HotelsData_toAzureSearch.csv](#) from GitHub. This file is a subset of the built-in hotels sample dataset. It omits the rooms collection, translated descriptions, and geography coordinates.
4. In Azure Storage Explorer, sign in to Azure, select your subscription, and then select your storage account.

5. Open **Tables** and select *hotels*.
6. Select **Import** on the command bar, and then select the *HotelsData_toAzureSearch.csv* file.
7. Accept the defaults. Select **Import** to load the data.

You should have 50 hotel records in the table with an autogenerated partitionKey, rowKey, and timestamp. You can now use this content for indexing in the Azure portal, REST client, or an Azure SDK.

The Description field provides the most verbose content. You should target this field for full text search and optional vector queries.

Use the Azure portal

You can use either the **Import data** wizard or the **Import data (new)** wizard to automate indexing from an SQL database table or view. The data source configuration is similar for both wizards.

1. [Start the wizard](#).
2. On **Connect to your data**, select or verify that the data source type is either *Azure Table Storage* or that the data selection fields prompt for tables.

The data source name refers to the data source connection object in Azure AI Search. If you use the vector wizard, your data source name is autogenerated using a custom prefix specified at the end of the wizard workflow.

3. Specify the storage account and table name. The query is optional. It's useful if you have specific columns you want to import.
4. Specify an authentication method, either a managed identity or built-in API key. If you don't specify a managed identity connection, the Azure portal uses the key.

If you [configure Azure AI Search to use a managed identity](#), and you create a role assignment on Azure Storage that grants **Reader and Data Access** permissions to the identity, your indexer can connect to table storage using Microsoft Entra ID and roles.

5. For the **Import data (new)** wizard, you can specify options for deletion detection.

Deletion detection requires that you have a preexisting field in the table that can be used as a soft-delete flag. It should be a Boolean field (you could name it *IsDeleted*). Specify `true` as the soft-delete value. In the search index, add a corresponding search field called *IsDeleted* set to retrievable and filterable.

6. Continue with the remaining steps to complete the wizard:

- [Import data wizard](#)
- [Import data \(new\) wizard](#)

Use the REST APIs

This section demonstrates the REST API calls that create a data source, index, and indexer.

Define the data source

The data source definition specifies the source data to index, credentials, and policies for change detection. A data source is an independent resource that can be used by multiple indexers.

1. [Create or update a data source](#) to set its definition:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
{
    "name": "my-table-storage-ds",
    "description": null,
    "type": "azuretable",
    "subtype": null,
    "credentials": {
        "connectionString": "DefaultEndpointsProtocol=https;AccountName=<account name>"
    },
    "container": {
        "name": "my-table-in-azure-storage",
        "query": ""
    },
    "dataChangeDetectionPolicy": null,
    "dataDeletionDetectionPolicy": null,
    "encryptionKey": null,
    "identity": null
}
```

2. Set "type" to `"azuretable"` (required).

3. Set "credentials" to an Azure Storage connection string. The next section describes the supported formats.

4. Set "container" to the name of the table.

5. Optionally, set "query" to a filter on PartitionKey. Setting this property is a best practice that improves performance. If "query" is null, the indexer executes a full table scan, which can result in poor performance if the tables are large.

A data source definition can also include [soft deletion policies](#), if you want the indexer to delete a search document when the source document is flagged for deletion.

Supported credentials and connection strings

Indexers can connect to a table using the following connections.

[Expand table](#)

Full access storage account connection string

```
{ "connectionString" : "DefaultEndpointsProtocol=https;AccountName=<your storage account>;AccountKey=<your account key>;" }
```

You can get the connection string from the Storage account page in Azure portal by selecting **Access keys** in the left pane. Make sure to select a full connection string and not just a key.

[Expand table](#)

Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.Storage/storageAccounts/<your storage account name>/;" }
```

This connection string doesn't require an account key, but you must have previously configured a search service to [connect using a managed identity](#).

[Expand table](#)

Storage account shared access signature** (SAS) connection string

```
{ "connectionString" : "BlobEndpoint=https://<your account>.blob.core.windows.net/;SharedAccessSignature=?sv=2016-05-31&sig=<the signature>&spr=https&se=<the validity end time>&srt=co&ss=b&sp=r;" }
```

The SAS should have the list and read permissions on tables and entities.

[Expand table](#)

Container shared access signature

```
{ "connectionString" : "ContainerSharedAccessUri=https://<your storage account>.blob.core.windows.net/<container name>?sv=2016-05-31&sr=c&sig=<the signature>&se=<the validity end time>&sp=r;" }
```

The SAS should have the list and read permissions on the container. For more information, see [Using Shared Access Signatures](#).

! Note

If you use SAS credentials, you'll need to update the data source credentials periodically with renewed signatures to prevent their expiration. When SAS credentials expire, the indexer will fail with an error message similar to "Credentials provided in the connection string are invalid or have expired".

Partition for improved performance

By default, Azure AI Search uses the following internal query filter to keep track of which source entities have been updated since the last run: `Timestamp >= HighWaterMarkValue`. Because Azure tables don't have a secondary index on the `Timestamp` field, this type of query requires a full table scan and is therefore slow for large tables.

To avoid a full scan, you can use table partitions to narrow the scope of each indexer job.

- If your data can naturally be partitioned into several partition ranges, create a data source and a corresponding indexer for each partition range. Each indexer now has to process only a specific partition range, resulting in better query performance. If the data that needs to be indexed has a small number of fixed partitions, even better: each indexer only does a partition scan.

For example, to create a data source for processing a partition range with keys from `000` to `100`, use a query like this: `"container" : { "name" : "my-table", "query" : "PartitionKey ge '000' and PartitionKey lt '100'" }`

- If your data is partitioned by time (for example, if you create a new partition every day or week), consider the following approach:
 - In the data source definition, specify a query similar to the following example: `(PartitionKey ge <TimeStamp>) and (other filters)`.
 - Monitor indexer progress by using [Get Indexer Status API](#), and periodically update the `<TimeStamp>` condition of the query based on the latest successful high-water-mark

value.

- With this approach, if you need to trigger a full reindex, reset the data source query in addition to [resetting the indexer](#).

Add search fields to an index

In a [search index](#), add fields to accept the content and metadata of your table entities.

- [Create or update an index](#) to define search fields that will store content from entities:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-09-01
{
  "name" : "my-search-index",
  "fields": [
    { "name": "Key", "type": "Edm.String", "key": true, "searchable": false },
    { "name": "SomeColumnInMyTable", "type": "Edm.String", "searchable": true }
  ]
}
```

- Create a document key field ("key": true), but allow the indexer to populate it automatically. A table indexer populates the key field with concatenated partition and row keys from the table. For example, if a row's PartitionKey is `1` and RowKey is `1_123`, then the key value is `11_123`. If the partition key is null, just the row key is used.

If you're using the Import data wizard to create the index, the Azure portal infers a "Key" field for the search index and uses an implicit field mapping to connect the source and destination fields. You don't have to add the field yourself, and you don't need to set up a field mapping.

If you're using the REST APIs and you want implicit field mappings, create and name the document key field "Key" in the search index definition as shown in the previous step (`{ "name": "Key", "type": "Edm.String", "key": true, "searchable": false }`). The indexer populates the Key field automatically, with no field mappings required.

If you don't want a field named "Key" in your search index, add an explicit field mapping in the indexer definition with the field name you want, setting the source field to "Key":

JSON

```
"fieldMappings" : [
  {
```

```

        "sourceFieldName" : "Key",
        "targetFieldName" : "MyDocumentKeyFieldName"
    }
]

```

3. Now add any other entity fields that you want in your index. For example, if an entity looks like the following example, your search index should have fields for HotelName, Description, and Category to receive those values.

PartitionKey	RowKey	Timestamp	HotelName	Description	Category
	20	2022-01-14T20:19:10.29...	Travel Resort	The Best Gaming Resort ...	Budget
	23	2022-01-14T20:20:36.88...	Days Hotel	Mix and mingle in the h...	Boutique
	3	2022-01-14T20:21:20.61...	Triple Landscape Hotel	The Hotel stands out for...	Resort and Spa
	31	2022-01-14T20:20:01.02...	Santa Fe Stay	Nestled on six beautiful...	Resort and Spa

Using the same names and compatible [data types](#) minimizes the need for [field mappings](#). When names and types are the same, the indexer can determine the data path automatically.

Configure and run the table indexer

Once you have an index and data source, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```

POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
{
    "name" : "my-table-indexer",
    "dataSourceName" : "my-table-storage-ds",
    "targetIndexName" : "my-search-index",
    "disabled": null,
    "schedule": null,
    "parameters" : {
        "batchSize" : null,
        "maxFailedItems" : null,
        "maxFailedItemsPerBatch" : null,
        "configuration" : { }
    },
    "fieldMappings" : [ ],
    "cache": null,
    "encryptionKey": null
}

```

2. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index. The Target field is the name of the field in the search index.

```
JSON

"fieldMappings" : [
  {
    "sourceFieldName" : "Description",
    "targetFieldName" : "HotelDescription"
  }
]
```

3. See [Create an indexer](#) for more information about other properties.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, check the indexer execution history in the Azure portal, or send a [Get Indexer Status](#) REST API request

Portal

1. On the search service page, open **Search management > Indexers**.
2. Select an indexer to access configuration and execution history.
3. Select a specific indexer job to view details, warnings, and errors.

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Next steps

Learn more about how to [run the indexer](#), [monitor status](#), or [schedule indexer execution](#). The following articles apply to indexers that pull content from Azure Storage:

- [Tutorial: Index encrypted blobs in Azure Storage](#)

Change and delete detection using indexers for Azure Storage in Azure AI Search

10/09/2025

After an initial search index is created, you might want subsequent indexer jobs to only pick up new and changed documents. For indexed content that originates from Azure Storage, change detection occurs automatically because indexers keep track of the last update using the built-in timestamps on objects and files in Azure Storage.

Although change detection is a given, deletion detection isn't. An indexer doesn't track object deletion in data sources. To avoid having orphan search documents, you can implement a "soft delete" strategy that results in deleting search documents first, with physical deletion in Azure Storage following as a second step.

There are two ways to implement a soft delete strategy:

- [Native blob soft delete](#), applies to Blob Storage only
- [Soft delete using custom metadata](#)

The deletion detection strategy must be applied from the very first indexer run. If you didn't establish the deletion policy prior to the initial run, any documents that were deleted before the policy was implemented will remain in your index, even if you add the policy to the indexer later and reset it. If this has occurred, it's suggested that you create a new index using a new indexer, ensuring the deletion policy is in place from the beginning.

Prerequisites

- Use an Azure Storage indexer for [Blob Storage](#), [Table Storage](#), [File Storage](#), or [Data Lake Storage Gen2](#)
- Use consistent document keys and file structure. Changing document keys or directory names and paths (applies to ADLS Gen2) breaks the internal tracking information used by indexers to know which content was indexed, and when it was last indexed.

Note

ADLS Gen2 allows directories to be renamed. When a directory is renamed, the timestamps for the blobs in that directory don't get updated. As a result, the indexer won't reindex those blobs. If you need the blobs in a directory to be reindexed after a directory

rename because they now have new URLs, you need to update the `LastModified` timestamp for all the blobs in the directory so that the indexer knows to reindex them during a future run. The virtual directories in Azure Blob Storage can't be changed, so they don't have this issue.

Native blob soft delete

For this deletion detection approach, Azure AI Search depends on the [native blob soft delete](#) feature in Azure Blob Storage to determine whether blobs have transitioned to a soft deleted state. When blobs are detected in this state, a search indexer uses this information to remove the corresponding document from the index.

Requirements for native soft delete

- Blobs must be in an Azure Blob Storage container, including ADLS Gen2 Blob container. The Azure AI Search native blob soft delete policy isn't supported for Azure Files.
- [Enable soft delete for blobs](#).
- Document keys for the documents in your index must be mapped to either be a blob property or blob metadata, such as "metadata_storage_path".
- You can use the [REST API](#), or the indexer Data Source configuration in the Azure portal, to configure support for soft delete.
- [Blob versioning](#) must not be enabled in the storage account. Otherwise, native soft delete isn't supported by design.

Configure native soft delete

In Blob storage, when enabling soft delete per the requirements, set the retention policy to a value that's much higher than your indexer interval schedule. If there's an issue running the indexer, or if you have a large number of documents to index, there's plenty of time for the indexer to eventually process the soft deleted blobs. Azure AI Search indexers will only delete a document from the index if it processes the blob while it's in a soft deleted state.

In Azure AI Search, set a native blob soft deletion detection policy on the data source. You can do this either from the Azure portal or by using the [REST API](#). The following instructions explain how to set the delete detection policy in Azure portal or through REST APIs.

Azure portal

1. Sign in to the [Azure portal](#).
2. On the Azure AI Search service Overview page, go to **New Data Source**, a visual editor for specifying a data source definition.

The following screenshot shows where you can find this feature in the Azure portal.

The screenshot shows the Azure AI Search service Overview page for a search service named "azure-cognitive-search-service". The left sidebar includes links for Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, and Settings. The main content area has tabs for Get Started, Usage, Monitoring, Indexes, Indexers, and Data sources. The "Data sources" tab is selected, and a red box highlights the "+ New Data Source" button. Below it, there's a table with one row labeled "my-blob-data-source".

3. On the **New Data Source** form, fill out the required fields, select the **Track deletions** checkbox and choose **Native blob soft delete**. Then hit **Save** to enable the feature on Data Source creation.

The screenshot shows the "New Data Source" configuration form. The "Settings" tab is selected. The "Data Source" dropdown is set to "Azure Blob Storage". The "Name" field contains "my-blob-data-source". The "Connection string" field contains "DefaultEndpointsProtocol=https;AccountName=[accountName];AccountKey=[accountKey]". Under "Managed identity authentication", "None" is selected. The "Container name" field is "mycontainer". The "Blob folder" field is "your/folder/here". The "Track deletions" checkbox is checked (highlighted by a red box). Under "Data deletion detection policy", the "Native blob soft delete" radio button is selected (highlighted by a red box). The "Description" field is "(optional)".

Reindex undeleted blobs using native soft delete policies

If you restore a soft deleted blob in Blob storage, the indexer won't always reindex it. This is because the indexer uses the blob's `LastModified` timestamp to determine whether indexing is needed. When a soft deleted blob is undeleted, its `LastModified` timestamp doesn't get updated, so if the indexer has already processed blobs with more recent `LastModified` timestamps, it won't reindex the undeleted blob.

To make sure that an undeleted blob is reindexed, you'll need to update the blob's `LastModified` timestamp. One way to do this is by resaving the metadata of that blob. You don't need to change the metadata, but resaving the metadata will update the blob's `LastModified` timestamp so that the indexer knows to pick it up.

Soft delete strategy using custom metadata

This method uses custom metadata to indicate whether a search document should be removed from the index. It requires two separate actions: deleting the search document from the index, followed by file deletion in Azure Storage.

This feature is generally available.

There are steps to follow in both Azure Storage and Azure AI Search, but there are no other feature dependencies.

1. In Azure Storage, add a custom metadata key-value pair to the file to indicate the file is flagged for deletion. For example, you could name the property "IsDeleted", set to false. When you want to delete the file, change it to true.
2. In Azure AI Search, edit the data source definition to include a "dataDeletionDetectionPolicy" property. For example, the following policy considers a file to be deleted if it has a metadata property `IsDeleted` with the value `true`:

HTTP

```
PUT https://[service name].search.windows.net/datasources/file-datasource?  
api-version=2025-09-01  
{  
    "name" : "file-datasource",  
    "type" : "azurefile",  
    "credentials" : { "connectionString" : "<your storage connection string>" },  
    "container" : { "name" : "my-share", "query" : null },  
    "dataDeletionDetectionPolicy" : {  
        "@odata.type"  
        :"#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",  
        "softDeleteColumnName" : "IsDeleted",  
        "softDeleteMarkerValue" : "true"
```

```
    }  
}
```

3. Run the indexer. Once the indexer has processed the file and deleted the document from the search index, you can then delete the physical file in Azure Storage.

Reindex undeleted blobs and files

You can reverse a soft-delete if the original source file still physically exists in Azure Storage.

1. Change the `"softDeleteMarkerValue" : "false"` on the blob or file in Azure Storage.
2. Check the blob or file's `LastModified` timestamp to make it's newer than the last indexer run. You can force an update to the current date and time by resaving the existing metadata.
3. Run the indexer.

Index data from Azure Cosmos DB for NoSQL for queries in Azure AI Search

10/09/2025

In this article, learn how to configure an [indexer](#) that imports content from [Azure Cosmos DB for NoSQL](#) and makes it searchable in Azure AI Search.

This article supplements [Create an indexer](#) with information that's specific to Cosmos DB. It uses the Azure portal and REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

Because terminology can be confusing, it's worth noting that [Azure Cosmos DB indexing](#) and [Azure AI Search indexing](#) are different operations. Indexing in Azure AI Search creates and loads a search index on your search service.

Prerequisites

- An [Azure Cosmos DB account, database, container, and items](#). Use the same region for both Azure AI Search and Azure Cosmos DB for lower latency and to avoid bandwidth charges.
- An [automatic indexing policy](#) on the Azure Cosmos DB collection, set to [Consistent](#). This is the default configuration. Lazy indexing isn't recommended and can result in missing data.
- Read permissions. A "full access" connection string includes a key that grants access to the content, but if you're using identities (Microsoft Entra ID), make sure the [search service managed identity](#) is assigned as both [Cosmos DB Account Reader Role](#) and [Cosmos DB Built-in Data Reader Role](#).

To work through the examples in this article, you need the Azure portal or a [REST client](#). If you're using Azure portal, make sure that access to all public networks is enabled. Other approaches for creating a Cosmos DB indexer include Azure SDKs.

Try with sample data

Use these instructions to create a container and database in Cosmos DB for testing purposes.

1. [Download HotelsData_toCosmosDB.json](#) ↗ from GitHub to create a container in Cosmos DB that contains a subset of the sample hotels data set.

- Sign in to the Azure portal and [create an account, database, and container](#) on Cosmos DB.
- In Cosmos DB, select **Data Explorer** for the new container, provide the following values.

 Expand table

Property	Value
Database	Create new
Database ID	hotelsdb
Share throughput across containers	Don't select
Container ID	hotels
Partition key	/HotelId
Container throughput (autoscale)	Autoscale
Container Max RU/s	1000

- In **Data Explorer**, expand *hotelsdb* and *hotels*, and then select **Items**.
- Select **Upload Item** and then select *HotelsData_toCosmosDB.json* file that you downloaded from GitHub.
- Right-click **Items** and select **New SQL query**. The default query is `SELECT * FROM c`.
- Select **Execute query** to run the query and view results. You should have 50 hotel documents.

Now that you have a container, you can use the Azure portal, REST client, or an Azure SDK to index your data.

The Description field provides the most verbose content. You should target this field for full text search and optional vector queries.

Use the Azure portal

You can use either the **Import data** wizard or the **Import data (new)** wizard to automate indexing from an SQL database table or view. The data source configuration is similar for both wizards.

- [Start the wizard](#).

2. On **Connect to your data**, select or verify that the data source type is either *Azure Cosmos DB* or a *NoSQL account*.

The data source name refers to the data source connection object in Azure AI Search. If you use the vector wizard, your data source name is autogenerated using a custom prefix specified at the end of the wizard workflow.

3. Specify the database name and collection. The query is optional. It's useful if you have hierarchical data and you want to import a specific slice.

4. Specify an authentication method, either a managed identity or built-in API key. If you don't specify a managed identity connection, the Azure portal uses the key.

If you [configure Azure AI Search to use a managed identity](#), and you create a [role assignment on Cosmos DB](#) that grants **Cosmos DB Account Reader** and **Cosmos DB Built-in Data Reader** permissions to the identity, your indexer can connect to Cosmos DB using Microsoft Entra ID and roles.

5. For the **Import data (new)** wizard, you can specify options for change and deletion tracking.

[Change detection](#) is supported by default through a `_ts` field (timestamp). If you upload content using the approach described in [Try with sample data](#), the collection is created with a `_ts` field.

[Deletion detection](#) requires that you have a preexisting top-level field in the collection that can be used as a soft-delete flag. It should be a Boolean field (you could name it `IsDeleted`). Specify `true` as the soft-deleted value. In the search index, add a corresponding search field called `IsDeleted` set to retrievable and filterable.

6. Continue with the remaining steps to complete the wizard:

- [Import data wizard](#)
- [Import data \(new\) wizard](#)

Use the REST APIs

This section demonstrates the REST API calls that create a data source, index, and indexer.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is an independent resource that can be used by multiple

indexers.

1. [Create or update a data source](#) to set its definition:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: [Search service admin key]
{
  "name": "[my-cosmosdb-ds]",
  "type": "cosmosdb",
  "credentials": {
    "connectionString": "AccountEndpoint=https://[cosmos-account-name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-database-name]"
  },
  "container": {
    "name": "[my-cosmos-db-collection]",
    "query": null
  },
  "dataChangeDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
    "highWaterMarkColumnName": "_ts"
  },
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

2. Set "type" to `"cosmosdb"` (required). If you're using an older Search API version 2017-11-11, the syntax for "type" is `"documentdb"`. Otherwise, for 2019-05-06 and later, use `"cosmosdb"`.
3. Set "credentials" to a connection string. The next section describes the supported formats.
4. Set "container" to the collection. The "name" property is required and it specifies the ID of the database collection to be indexed. The "query" property is optional. Use it to [flatten an arbitrary JSON document](#) into a flat schema that Azure AI Search can index.
5. [Set "dataChangeDetectionPolicy"](#) if data is volatile and you want the indexer to pick up just the new and updated items on subsequent runs.
6. [Set "dataDeletionDetectionPolicy"](#) if you want to remove search documents from a search index when the source item is deleted.

Supported credentials and connection strings

Indexers can connect to a collection using the following connections.

Avoid port numbers in the endpoint URL. If you include the port number, the connection fails.

[] [Expand table](#)

Full access connection string

```
{ "connectionString" : "AccountEndpoint=https://<Cosmos DB account name>.documents.azure.com;AccountKey=<Cosmos DB auth key>;Database=<Cosmos DB database id>" }
```

You can get the connection string from the Azure Cosmos DB account page in the Azure portal by selecting **Keys** in the left pane. Make sure to select a full connection string and not just a key.

[] [Expand table](#)

(Modern approach) Managed identity connection string for NoSQL accounts

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.DocumentDB/databaseAccounts/<your cosmos db account name>/;(ApiKind=[api-kind]);/(IdentityAuthType=AccessToken)" }
```

This connection string, supported only for Azure Cosmos DB for NoSQL accounts, ensures that the search service will never use account keys (even in the background) when attempting to access data from Cosmos DB. This is recommended, as it works even if the NoSQL account has account keys disabled. For more information, see [Setting up an indexer connection to an Azure Cosmos DB database using a managed identity](#)

[] [Expand table](#)

(Legacy approach) Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.DocumentDB/databaseAccounts/<your cosmos db account name>/;(ApiKind=[api-kind]);/(IdentityAuthType=AccountKey)" }
```

This connection string doesn't require an account key to be specified directly, but the search service will utilize the managed identity to fetch the account keys in the background. Though this is supported for all Cosmos DB account types, it isn't recommended for the NoSQL account type. Such a connection string won't work if account keys are disabled for the Cosmos DB account. If the `IdentityAuthType` property is omitted, the search service will still default to fetching the account key in the background. For connections targeting the [SQL API](#), you can omit `ApiKind` from the connection string. For more information about `ApiKind`, `IdentityAuthType` see [Setting up an indexer connection to an Azure Cosmos DB database using a managed identity](#)

Using queries to shape indexed data

In the "query" property under "container", you can specify a SQL query to flatten nested properties or arrays, project JSON properties, and filter the data to be indexed.

Example document:

HTTP

```
{  
    "userId": 10001,  
    "contact": {  
        "firstName": "andy",  
        "lastName": "hoh"  
    },  
    "company": "microsoft",  
    "tags": ["azure", "cosmosdb", "search"]  
}
```

Filter query:

SQL

```
SELECT * FROM c WHERE c.company = "microsoft" and c._ts >= @HighWaterMark ORDER BY c._ts
```

Flattening query:

SQL

```
SELECT c.id, c.userId, c.contact.firstName, c.contact.lastName, c.company, c._ts  
FROM c WHERE c._ts >= @HighWaterMark ORDER BY c._ts
```

Projection query:

SQL

```
SELECT VALUE { "id":c.id, "Name":c.contact.firstName, "Company":c.company,  
"_ts":c._ts } FROM c WHERE c._ts >= @HighWaterMark ORDER BY c._ts
```

Array flattening query:

SQL

```
SELECT c.id, c.userId, tag, c._ts FROM c JOIN tag IN c.tags WHERE c._ts >=  
@HighWaterMark ORDER BY c._ts
```

Unsupported queries (DISTINCT and GROUP BY)

Queries using the [DISTINCT keyword](#) or [GROUP BY clause](#) aren't supported. Azure AI Search relies on [SQL query pagination](#) to fully enumerate the results of the query. Neither the DISTINCT keyword or GROUP BY clauses are compatible with the [continuation tokens](#) used to paginate results.

Examples of unsupported queries:

SQL

```
SELECT DISTINCT c.id, c.userId, c._ts FROM c WHERE c._ts >= @HighWaterMark ORDER BY c._ts

SELECT DISTINCT VALUE c.name FROM c ORDER BY c.name

SELECT TOP 4 COUNT(1) AS foodGroupCount, f.foodGroup FROM Food f GROUP BY f.foodGroup
```

Although Azure Cosmos DB has a workaround to support [SQL query pagination with the DISTINCT keyword by using the ORDER BY clause](#), it isn't compatible with Azure AI Search. The query returns a single JSON value, whereas Azure AI Search expects a JSON object.

SQL

```
-- The following query returns a single JSON value and isn't supported by Azure AI Search
SELECT DISTINCT VALUE c.name FROM c ORDER BY c.name
```

Add search fields to an index

In a [search index](#), add fields to accept the source JSON documents or the output of your custom query projection. Ensure that the search index schema is compatible with source data. For content in Azure Cosmos DB, your search index schema should correspond to the [Azure Cosmos DB items](#) in your data source.

1. [Create or update an index](#) to define search fields that store data:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2025-09-01
Content-Type: application/json
api-key: [Search service admin key]
{
    "name": "mysearchindex",
    "fields": [{
```

```

        "name": "rid",
        "type": "Edm.String",
        "key": true,
        "searchable": false
    },
    {
        "name": "description",
        "type": "Edm.String",
        "filterable": false,
        "searchable": true,
        "sortable": false,
        "facetable": false,
        "suggestions": true
    }
]
}

```

2. Create a document key field ("key": true). For partitioned collections, the default document key is the Azure Cosmos DB `_rid` property, which Azure AI Search automatically renames to `rid` because field names can't start with an underscore character. Also, Azure Cosmos DB `_rid` values contain characters that are invalid in Azure AI Search keys. For this reason, the `_rid` values are Base64 encoded.
3. Create more fields for more searchable content. See [Create an index](#) for details.

Mapping data types

[] Expand table

JSON data types	Azure AI Search field types
Bool	Edm.Boolean, Edm.String
Numbers that look like integers	Edm.Int32, Edm.Int64, Edm.String
Numbers that look like floating-points	Edm.Double, Edm.String
String	Edm.String
Arrays of primitive types such as ["a", "b", "c"]	Collection(Edm.String)
Strings that look like dates	Edm.DateTimeOffset, Edm.String
GeoJSON objects such as { "type": "Point", "coordinates": [long, lat] }	Edm.GeographyPoint
Other JSON objects	N/A

Configure and run the Azure Cosmos DB for NoSQL indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2025-09-01
Content-Type: application/json
api-key: [search service admin key]
{
    "name" : "[my-cosmosdb-indexer]",
    "dataSourceName" : "[my-cosmosdb-ds]",
    "targetIndexName" : "[my-search-index]",
    "disabled": null,
    "schedule": null,
    "parameters": {
        "batchSize": null,
        "maxFailedItems": 0,
        "maxFailedItemsPerBatch": 0,
        "base64EncodeKeys": false,
        "configuration": {}
    },
    "fieldMappings": [],
    "encryptionKey": null
}
```

2. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.
3. See [Create an indexer](#) for more information about other properties.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, check the indexer execution history in the Azure portal, or send a [Get Indexer Status](#) REST API request

Portal

1. On the search service page, open **Search management > Indexers**.

2. Select an indexer to access configuration and execution history.
3. Select a specific indexer job to view details, warnings, and errors.

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Indexing new and changed documents

Once an indexer has fully populated a search index, you might want subsequent indexer runs to incrementally index just the new and changed documents in your database.

To enable incremental indexing, set the "dataChangeDetectionPolicy" property in your data source definition. This property tells the indexer which change tracking mechanism is used on your data.

For Azure Cosmos DB indexers, the only supported policy is the [HighWaterMarkChangeDetectionPolicy](#) using the `_ts` (timestamp) property provided by Azure Cosmos DB.

The following example shows a [data source definition](#) with a change detection policy:

HTTP

```
"dataChangeDetectionPolicy": {  
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",  
    "highWaterMarkColumnName": "_ts"  
},
```

ⓘ Note

When you assign a `null` value to a field in your Azure Cosmos DB, the AI Search indexer is unable to distinguish between `null` and a missing field value. Therefore, if a field in the index is empty, it will not be substituted with a `null` value, even if that modification was made in your database.

Incremental indexing and custom queries

If you're using a [custom query to retrieve documents](#), make sure the query orders the results by the `_ts` column. This enables periodic check-pointing that Azure AI Search uses to provide incremental progress in the presence of failures.

In some cases, even if your query contains an `ORDER BY [collection alias]._ts` clause, Azure AI Search might not infer that the query is ordered by the `_ts`. You can tell Azure AI Search that results are ordered by setting the `assumeOrderByHighWaterMarkColumn` configuration property.

To specify this hint, [create or update your indexer definition](#) as follows:

```
HTTP

{
    ... other indexer definition properties
    "parameters" : {
        "configuration" : { "assumeOrderByHighWaterMarkColumn" : true } }
}
```

Indexing deleted documents

When rows are deleted from the collection, you normally want to delete those rows from the search index as well. The purpose of a data deletion detection policy is to efficiently identify deleted data items. Currently, the only supported policy is the `Soft Delete` policy (deletion is marked with a flag of some sort), which is specified in the data source definition as follows:

```
HTTP

"dataDeletionDetectionPolicy": {
    "@odata.type" :
    "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",
    "softDeleteColumnName" : "the property that specifies whether a document was
    deleted",
    "softDeleteMarkerValue" : "the value that identifies a document as deleted"
}
```

If you're using a custom query, make sure that the property referenced by `softDeleteColumnName` is projected by the query.

The `softDeleteColumnName` must be a top-level field in the index. Using nested fields within complex data types as the `softDeleteColumnName` isn't supported.

The following example creates a data source with a soft-deletion policy:

```
HTTP

POST https://[service name].search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: [Search service admin key]
```

```
{
  "name": "[my-cosmosdb-ds]",
  "type": "cosmosdb",
  "credentials": {
    "connectionString": "AccountEndpoint=https://[cosmos-account-name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-database-name]"
  },
  "container": { "name": "[my-cosmos-collection]" },
  "dataChangeDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
    "highWaterMarkColumnName": "_ts"
  },
  "dataDeletionDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",
    "softDeleteColumnName": "isDeleted",
    "softDeleteMarkerValue": "true"
  }
}
```

Use .NET

For data accessed through the SQL API protocol, you can use the .NET SDK to automate with indexers. We recommend that you review the previous REST API sections to learn concepts, workflow, and requirements. You can then refer to following .NET API reference documentation to implement a JSON indexer in managed code:

- [azure.search.documents.indexes.models.searchindexerdatasourceconnection](#)
- [azure.search.documents.indexes.models.searchindexerdatasourcetype](#)
- [azure.search.documents.indexes.models.searchindex](#)
- [azure.search.documents.indexes.models.searchindexer](#)

Next steps

You can now control how you [run the indexer](#), [monitor status](#), or [schedule indexer execution](#). The following articles apply to indexers that pull content from Azure Cosmos DB:

- [Set up an indexer connection to an Azure Cosmos DB database using a managed identity](#)
- [Index large data sets](#)
- [Indexer access to content protected by Azure network security features](#)

Index data from Azure Cosmos DB for MongoDB for queries in Azure AI Search

10/09/2025

Important

MongoDB API support is currently in public preview under [supplemental Terms of Use](#). Currently, there is no SDK support.

In this article, learn how to configure an [indexer](#) that imports content from [Azure Cosmos DB for MongoDB](#) and makes it searchable in Azure AI Search.

This article supplements [Create an indexer](#) with information that's specific to Cosmos DB. It uses the REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

Because terminology can be confusing, it's worth noting that [Azure Cosmos DB indexing](#) and [Azure AI Search indexing](#) are different operations. Indexing in Azure AI Search creates and loads a search index on your search service.

Prerequisites

- Register for the preview [to provide scenario feedback](#). You can access the feature automatically after form submission.
- An [Azure Cosmos DB account, database, collection, and documents](#). Use the same region for both Azure AI Search and Azure Cosmos DB for lower latency and to avoid bandwidth charges.
- An [automatic indexing policy](#) on the Azure Cosmos DB collection, set to [Consistent](#). This is the default configuration. Lazy indexing isn't recommended and may result in missing data.
- Read permissions. A "full access" connection string includes a key that grants access to the content, but if you're using Azure roles, make sure the [search service managed identity](#) has [Cosmos DB Account Reader Role](#) permissions.
- A [REST client](#) to create the data source, index, and indexer.

Limitations

These are the limitations of this feature:

- Custom queries aren't supported for specifying the data set.
- The column name `_ts` is a reserved word. If you need this field, consider alternative solutions for populating an index.
- The MongoDB attribute `$ref` is a reserved word. If you need this in your MongoDB collection, consider alternative solutions for populating an index.

As an alternative to this connector, if your scenario has any of those requirements, you could use the [Push API/SDK](#) or consider [Azure Data Factory](#) with an [Azure AI Search index](#) as the sink.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is defined as an independent resource so that it can be used by multiple indexers.

For this call, specify a [preview REST API version](#). You can use 2020-06-30-preview or later to create a data source that connects via the MongoDB API. We recommend the latest preview REST API.

1. [Create or update a data source](#) to set its definition:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [Search service admin key]
{
  "name": "[my-cosmosdb-mongodb-ds]",
  "type": "cosmosdb",
  "credentials": {
    "connectionString": "AccountEndpoint=https://[cosmos-account-name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-database-name];ApiKind=MongoDb;"
  },
  "container": {
    "name": "[cosmos-db-collection]",
    "query": null
  },
  "dataChangeDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
    "highWaterMark": {
      "start": "2024-01-01T00:00:00Z",
      "end": "2024-01-01T23:59:59Z"
    }
  }
}
```

```
        "highWaterMarkColumnName": "_ts"  
    },  
    "dataDeletionDetectionPolicy": null,  
    "encryptionKey": null,  
    "identity": null  
}
```

2. Set "type" to "cosmosdb" (required).
3. Set "credentials" to a connection string. The next section describes the supported formats.
4. Set "container" to the collection. The "name" property is required and it specifies the ID of the database collection to be indexed. For Azure Cosmos DB for MongoDB, "query" isn't supported.
5. [Set "dataChangeDetectionPolicy"](#) if data is volatile and you want the indexer to pick up just the new and updated items on subsequent runs.
6. [Set "dataDeletionDetectionPolicy"](#) if you want to remove search documents from a search index when the source item is deleted.

Supported credentials and connection strings

Indexers can connect to a collection using the following connections. For connections that target the [MongoDB API](#), be sure to include "ApiKind" in the connection string.

Avoid port numbers in the endpoint URL. If you include the port number, the connection will fail.

 [Expand table](#)

Full access connection string

```
{ "connectionString" : "AccountEndpoint=https://<Cosmos DB account  
name>.documents.azure.com;AccountKey=<Cosmos DB auth key>;Database=<Cosmos DB database  
id>;ApiKind=MongoDb" }
```

You can get the *Cosmos DB auth key* from the Azure Cosmos DB account page in the Azure portal by selecting **Connection String** in the left pane. Make sure to copy **Primary Password** and replace *Cosmos DB auth key* value with it.

 [Expand table](#)

Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.DocumentDB/databaseAccounts/<your cosmos db account name>/;(ApiKind=[api-kind]);;" }
```

This connection string doesn't require an account key, but you must have previously configured a search service to [connect using a managed identity](#) and created a role assignment that grants **Cosmos DB Account Reader Role** permissions. See [Setting up an indexer connection to an Azure Cosmos DB database using a managed identity](#) for more information.

Add search fields to an index

In a [search index](#), add fields to accept the source JSON documents or the output of your custom query projection. Ensure that the search index schema is compatible with source data. For content in Azure Cosmos DB, your search index schema should correspond to the [Azure Cosmos DB items](#) in your data source.

1. [Create or update an index](#) to define search fields that will store data:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [Search service admin key]

{
    "name": "mysearchindex",
    "fields": [
        {
            "name": "doc_id",
            "type": "Edm.String",
            "key": true,
            "retrievable": true,
            "searchable": false
        },
        {
            "name": "description",
            "type": "Edm.String",
            "filterable": false,
            "searchable": true,
            "sortable": false,
            "facetable": false,
            "suggestions": true
        }
    ]
}
```

2. Create a document key field ("key": true). For a search index based on a MongoDB collection, the document key can be "doc_id", "rid", or some other string field that

contains unique values. As long as field names and data types are the same on both sides, no field mappings are required.

- "doc_id" represents "_id" for the object identifier. If you specify a field of "doc_id" in the index, the indexer populates it with the values of the object identifier.
- "rid" is a system property in Azure Cosmos DB. If you specify a field of "rid" in the index, the indexer populates it with the base64-encoded value of the "rid" property.
- For any other field, your search field should have the same name as defined in the collection.

3. Create additional fields for more searchable content. See [Create an index](#) for details.

Mapping data types

[] [Expand table](#)

JSON data type	Azure AI Search field types
Bool	Edm.Boolean, Edm.String
Numbers that look like integers	Edm.Int32, Edm.Int64, Edm.String
Numbers that look like floating-points	Edm.Double, Edm.String
String	Edm.String
Arrays of primitive types such as ["a", "b", "c"]	Collection(Edm.String)
Strings that look like dates	Edm.DateTimeOffset, Edm.String
GeoJSON objects such as { "type": "Point", "coordinates": [long, lat] }	Edm.GeographyPoint
Other JSON objects	N/A

Configure and run the Azure Cosmos DB for MongoDB indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [search service admin key]
{
    "name" : "[my-cosmosdb-indexer]",
    "dataSourceName" : "[my-cosmosdb-mongodb-ds]",
    "targetIndexName" : "[my-search-index]",
    "disabled": null,
    "schedule": null,
    "parameters": {
        "batchSize": null,
        "maxFailedItems": 0,
        "maxFailedItemsPerBatch": 0,
        "base64EncodeKeys": false,
        "configuration": {}
    },
    "fieldMappings": [],
    "encryptionKey": null
}
```

2. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.
3. See [Create an indexer](#) for more information about other properties.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, send a [Get Indexer Status](#) request:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
    "status": "running",
```

```

    "lastResult": {
        "status": "success",
        "errorMessage": null,
        "startTime": "2022-02-21T00:23:24.957Z",
        "endTime": "2022-02-21T00:36:47.752Z",
        "errors": [],
        "itemsProcessed": 1599501,
        "itemsFailed": 0,
        "initialTrackingState": null,
        "finalTrackingState": null
    },
    "executionHistory": [
        {
            "status": "success",
            "errorMessage": null,
            "startTime": "2022-02-21T00:23:24.957Z",
            "endTime": "2022-02-21T00:36:47.752Z",
            "errors": [],
            "itemsProcessed": 1599501,
            "itemsFailed": 0,
            "initialTrackingState": null,
            "finalTrackingState": null
        },
        ...
        ... earlier history items
    ]
}

```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Indexing new and changed documents

Once an indexer has fully populated a search index, you might want subsequent indexer runs to incrementally index just the new and changed documents in your database.

To enable incremental indexing, set the "dataChangeDetectionPolicy" property in your data source definition. This property tells the indexer which change tracking mechanism is used on your data.

For Azure Cosmos DB indexers, the only supported policy is the [HighWaterMarkChangeDetectionPolicy](#) using the `_ts` (timestamp) property provided by Azure Cosmos DB.

The following example shows a [data source definition](#) with a change detection policy:

HTTP

```
"dataChangeDetectionPolicy": {  
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",  
    "highWaterMarkColumnName": "_ts"  
},
```

Indexing deleted documents

When rows are deleted from the collection, you normally want to delete those rows from the search index as well. The purpose of a data deletion detection policy is to efficiently identify deleted data items. Currently, the only supported policy is the `Soft Delete` policy (deletion is marked with a flag of some sort), which is specified in the data source definition as follows:

HTTP

```
"dataDeletionDetectionPolicy": {  
    "@odata.type" :  
    "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",  
    "softDeleteColumnName" : "the property that specifies whether a document was  
deleted",  
    "softDeleteMarkerValue" : "the value that identifies a document as deleted"  
}
```

If you're using a custom query, make sure that the property referenced by `softDeleteColumnName` is projected by the query.

The following example creates a data source with a soft-deletion policy:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2024-05-01-  
preview  
Content-Type: application/json  
api-key: [Search service admin key]  
  
{  
    "name": ["my-cosmosdb-mongodb-ds"],  
    "type": "cosmosdb",  
    "credentials": {  
        "connectionString": "AccountEndpoint=https://[cosmos-account-  
name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-  
database-name];ApiKind=MongoDB"  
    },  
    "container": { "name": "[my-cosmos-collection]" },  
    "dataChangeDetectionPolicy": {  
        "@odata.type":  
        "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",  
        "highWaterMarkColumnName": "_ts"
```

```
 },
  "dataDeletionDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.SoftDeleteColumnDeletionPolicy",
    "softDeleteColumnName": "isDeleted",
    "softDeleteMarkerValue": "true"
  }
}
```

Next steps

You can now control how you [run the indexer](#), [monitor status](#), or [schedule indexer execution](#).

The following articles apply to indexers that pull content from Azure Cosmos DB:

- [Set up an indexer connection to an Azure Cosmos DB database using a managed identity](#)
- [Index large data sets](#)
- [Indexer access to content protected by Azure network security features](#)

Index data from Azure Cosmos DB for Apache Gremlin for queries in Azure AI Search

10/09/2025

Important

The Azure Cosmos DB for Apache Gremlin indexer is currently in public preview under [Supplemental Terms of Use](#). Currently, there is no SDK support.

In this article, learn how to configure an [indexer](#) that imports content from [Azure Cosmos DB for Apache Gremlin](#) and makes it searchable in Azure AI Search.

This article supplements [Create an indexer](#) with information that's specific to Cosmos DB. It uses the REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

Because terminology can be confusing, it's worth noting that [Azure Cosmos DB indexing](#) and [Azure AI Search indexing](#) are different operations. Indexing in Azure AI Search creates and loads a search index on your search service.

Prerequisites

- Register for the preview [to provide scenario feedback](#). You can access the feature automatically after form submission.
- An [Azure Cosmos DB account, database, container, and items](#). Use the same region for both Azure AI Search and Azure Cosmos DB for lower latency and to avoid bandwidth charges.
- An [automatic indexing policy](#) on the Azure Cosmos DB collection, set to [Consistent](#). This is the default configuration. Lazy indexing isn't recommended and may result in missing data.
- Read permissions. A "full access" connection string includes a key that grants access to the content, but if you're using Azure roles, make sure the [search service managed identity](#) has [Cosmos DB Account Reader Role](#) permissions.
- A [REST client](#) to create the data source, index, and indexer.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. A data source is defined as an independent resource so that it can be used by multiple indexers.

For this call, specify a [preview REST API version](#) to create a data source that connects via an Azure Cosmos DB for Apache Gremlin. You can use 2021-04-01-preview or later. We recommend the latest preview API.

1. [Create or update a data source](#) to set its definition:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [Search service admin key]
{
  "name": "[my-cosmosdb-gremlin-ds]",
  "type": "cosmosdb",
  "credentials": {
    "connectionString": "AccountEndpoint=https://[cosmos-account-name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-database-name];ApiKind=Gremlin;"
  },
  "container": {
    "name": "[cosmos-db-collection]",
    "query": "g.V()"
  },
  "dataChangeDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
    "highWaterMarkColumnName": "_ts"
  },
  "dataDeletionDetectionPolicy": null,
  "encryptionKey": null,
  "identity": null
}
```

2. Set "type" to `"cosmosdb"` (required).
3. Set "credentials" to a connection string. The next section describes the supported formats.
4. Set "container" to the collection. The "name" property is required and it specifies the ID of the graph.

The "query" property is optional. By default the Azure AI Search indexer for Azure Cosmos DB for Apache Gremlin makes every vertex in your graph a document in the index. Edges will be ignored. The query default is `g.V()`. Alternatively, you could set the query to only index the edges. To index the edges, set the query to `g.E()`.

5. Set "`dataChangeDetectionPolicy`" if data is volatile and you want the indexer to pick up just the new and updated items on subsequent runs. Incremental progress will be enabled by default using `_ts` as the high water mark column.
6. Set "`dataDeletionDetectionPolicy`" if you want to remove search documents from a search index when the source item is deleted.

Supported credentials and connection strings

Indexers can connect to a collection using the following connections. For connections that target [Azure Cosmos DB for Apache Gremlin](#), be sure to include "ApiKind" in the connection string.

Avoid port numbers in the endpoint URL. If you include the port number, the connection will fail.

 Expand table

Full access connection string

```
{ "connectionString" : "AccountEndpoint=https://<Cosmos DB account name>.documents.azure.com;AccountKey=<Cosmos DB auth key>;Database=<Cosmos DB database id>;ApiKind=MongoDb" }
```

You can get the connection string from the Azure Cosmos DB account page in Azure portal by selecting **Keys** in the left pane. Make sure to select a full connection string and not just a key.

 Expand table

Managed identity connection string

```
{ "connectionString" : "ResourceId=/subscriptions/<your subscription ID>/resourceGroups/<your resource group name>/providers/Microsoft.DocumentDB/databaseAccounts/<your cosmos db account name>/;(ApiKind=[api-kind]);;" }
```

This connection string doesn't require an account key, but you must have previously configured a search service to [connect using a managed identity](#) and created a role assignment that grants **Cosmos DB Account Reader Role** permissions. See [Setting up an indexer connection to an Azure Cosmos DB database using a managed identity](#) for more information.

Add search fields to an index

In a [search index](#), add fields to accept the source JSON documents or the output of your custom query projection. Ensure that the search index schema is compatible with your graph. For content in Azure Cosmos DB, your search index schema should correspond to the [Azure Cosmos DB items](#) in your data source.

1. [Create or update an index](#) to define search fields that will store data:

HTTP

```
POST https://[service name].search.windows.net/indexes?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [Search service admin key]
{
  "name": "mysearchindex",
  "fields": [
    {
      "name": "rid",
      "type": "Edm.String",
      "facetable": false,
      "filterable": false,
      "key": true,
      " retrievable": true,
      "searchable": true,
      "sortable": false,
      "analyzer": "standard.lucene",
      "indexAnalyzer": null,
      "searchAnalyzer": null,
      "synonymMaps": [],
      "fields": []
    },
    {
      "name": "label",
      "type": "Edm.String",
      "searchable": true,
      "filterable": false,
      " retrievable": true,
      "sortable": false,
      "facetable": false,
      "key": false,
      "indexAnalyzer": null,
      "searchAnalyzer": null,
      "analyzer": "standard.lucene",
      "synonymMaps": []
    }
  ]
}
```

2. Create a document key field ("key": true). For partitioned collections, the default document key is the Azure Cosmos DB `_rid` property, which Azure AI Search automatically renames to `rid` because field names can't start with an underscore character. Also, Azure Cosmos DB `_rid` values contain characters that are invalid in Azure AI Search keys. For this reason, the `_rid` values are Base64 encoded.

3. Create additional fields for more searchable content. See [Create an index](#) for details.

Mapping data types

 [Expand table](#)

JSON data type	Azure AI Search field types
Bool	Edm.Boolean, Edm.String
Numbers that look like integers	Edm.Int32, Edm.Int64, Edm.String
Numbers that look like floating-points	Edm.Double, Edm.String
String	Edm.String
Arrays of primitive types such as ["a", "b", "c"]	Collection(Edm.String)
Strings that look like dates	Edm.DateTimeOffset, Edm.String
GeoJSON objects such as { "type": "Point", "coordinates": [long, lat] }	Edm.GeographyPoint
Other JSON objects	N/A

Configure and run the Azure Cosmos DB indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
POST https://[service name].search.windows.net/indexers?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [search service admin key]
{
    "name" : "[my-cosmosdb-indexer]",
    "dataSourceName" : "[my-cosmosdb-gremlin-ds]".
```

```
    "targetIndexName" : "[my-search-index]",
    "disabled": null,
    "schedule": null,
    "parameters": {
        "batchSize": null,
        "maxFailedItems": 0,
        "maxFailedItemsPerBatch": 0,
        "base64EncodeKeys": false,
        "configuration": {}
    },
    "fieldMappings": [],
    "encryptionKey": null
}
```

2. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.
3. See [Create an indexer](#) for more information about other properties.

An indexer runs automatically when it's created. You can prevent this by setting "disabled" to true. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

To monitor the indexer status and execution history, send a [Get Indexer Status](#) request:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
    "status": "running",
    "lastResult": {
        "status": "success",
        "errorMessage": null,
        "startTime": "2022-02-21T00:23:24.957Z",
        "endTime": "2022-02-21T00:36:47.752Z",
        "errors": [],
        "itemsProcessed": 1599501,
        "itemsFailed": 0,
```

```

        "initialTrackingState":null,
        "finalTrackingState":null
    },
    "executionHistory":
    [
        {
            "status":"success",
            "errorMessage":null,
            "startTime":"2022-02-21T00:23:24.957Z",
            "endTime":"2022-02-21T00:36:47.752Z",
            "errors":[],
            "itemsProcessed":1599501,
            "itemsFailed":0,
            "initialTrackingState":null,
            "finalTrackingState":null
        },
        ...
        ... earlier history items
    ]
}

```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Indexing new and changed documents

Once an indexer has fully populated a search index, you might want subsequent indexer runs to incrementally index just the new and changed documents in your database.

To enable incremental indexing, set the "dataChangeDetectionPolicy" property in your data source definition. This property tells the indexer which change tracking mechanism is used on your data.

For Azure Cosmos DB indexers, the only supported policy is the [HighWaterMarkChangeDetectionPolicy](#) using the `_ts` (timestamp) property provided by Azure Cosmos DB.

The following example shows a [data source definition](#) with a change detection policy:

HTTP

```

"dataChangeDetectionPolicy": {
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
    "highWaterMarkColumnName": "_ts"
},

```

Indexing deleted documents

When graph data is deleted, you might want to delete its corresponding document from the search index as well. The purpose of a data deletion detection policy is to efficiently identify deleted data items and delete the full document from the index. The data deletion detection policy isn't meant to delete partial document information. Currently, the only supported policy is the `Soft Delete` policy (deletion is marked with a flag of some sort), which is specified in the data source definition as follows:

HTTP

```
"dataDeletionDetectionPolicy": {
    "@odata.type" : "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",
    "softDeleteColumnName" : "the property that specifies whether a document was deleted",
    "softDeleteMarkerValue" : "the value that identifies a document as deleted"
}
```

The following example creates a data source with a soft-deletion policy:

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2024-05-01-preview
Content-Type: application/json
api-key: [Search service admin key]

{
    "name": "[my-cosmosdb-gremlin-ds]",
    "type": "cosmosdb",
    "credentials": {
        "connectionString": "AccountEndpoint=https://[cosmos-account-name].documents.azure.com;AccountKey=[cosmos-account-key];Database=[cosmos-database-name];ApiKind=Gremlin"
    },
    "container": { "name": "[my-cosmos-collection]" },
    "dataChangeDetectionPolicy": {
        "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
        "highWaterMarkColumnName": "`_ts`"
    },
    "dataDeletionDetectionPolicy": {
        "@odata.type": "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",
        "softDeleteColumnName": "isDeleted",
        "softDeleteMarkerValue": "true"
    }
}
```

Even if you enable deletion detection policy, deleting complex (`Edm.ComplexType`) fields from the index is not supported. This policy requires that the 'active' column in the Gremlin database to be of type integer, string or boolean.

Mapping graph data to fields in a search index

The Azure Cosmos DB for Apache Gremlin indexer will automatically map a couple pieces of graph data:

1. The indexer will map `_rid` to an `rid` field in the index if it exists, and Base64 encode it.
2. The indexer will map `_id` to an `id` field in the index if it exists.
3. When querying your Azure Cosmos DB database using the Azure Cosmos DB for Apache Gremlin you may notice that the JSON output for each property has an `id` and a `value`. The indexer will automatically map the properties `value` into a field in your search index that has the same name as the property if it exists. In the following example, 450 would be mapped to a `pages` field in the search index.

HTTP

```
{  
    "id": "Cookbook",  
    "label": "book",  
    "type": "vertex",  
    "properties": {  
        "pages": [  
            {  
                "id": "48cf6285-a145-42c8-a0aa-d39079277b71",  
                "value": "450"  
            }  
        ]  
    }  
}
```

You may find that you need to use [Output Field Mappings](#) in order to map your query output to the fields in your index. You'll likely want to use Output Field Mappings instead of [Field Mappings](#) since the custom query will likely have complex data.

For example, let's say that your query produces this output:

JSON

```
[  
    {  
        "vertex": {  
            "label": "book",  
            "type": "vertex",  
            "properties": {  
                "name": "Cookbook",  
                "pages": "450"  
            }  
        }  
    }  
]
```

```
"id": "Cookbook",
"label": "book",
"type": "vertex",
"properties": {
    "pages": [
        {
            "id": "48cf6085-a211-42d8-a8ea-d38642987a71",
            "value": "450"
        }
    ],
    "written_by": [
        {
            "yearStarted": "2017"
        }
    ]
}
```

If you would like to map the value of `pages` in the JSON above to a `totalpages` field in your index, you can add the following [Output Field Mapping](#) to your indexer definition:

JSON

```
... // rest of indexer definition
"outputFieldMappings": [
    {
        "sourceFieldName": "/document/vertex/pages",
        "targetFieldName": "totalpages"
    }
]
```

Notice how the Output Field Mapping starts with `/document` and does not include a reference to the properties key in the JSON. This is because the indexer puts each document under the `/document` node when ingesting the graph data and the indexer also automatically allows you to reference the value of `pages` by simple referencing `pages` instead of having to reference the first object in the array of `pages`.

Next steps

- To learn more about Azure Cosmos DB for Apache Gremlin, see the [Introduction to Azure Cosmos DB: Azure Cosmos DB for Apache Gremlin](#).
- For more information about Azure AI Search scenarios and pricing, see the [Search service page on azure.microsoft.com](#).

- To learn about network configuration for indexers, see the [Indexer access to content protected by Azure network security features](#).

Index data from Azure Database for MySQL Flexible Server

Important

MySQL support is currently in public preview under [Supplemental Terms of Use](#). We recommend the latest preview API. There is currently no portal support.

In this article, learn how to configure an [indexer](#) that imports content from Azure Database for MySQL and makes it searchable in Azure AI Search. Inputs to the indexer are rows from a single table or view. Output is a search index with searchable content in individual fields.

This article supplements [Create an indexer](#) with information that's specific to indexing from Azure Database for MySQL Flexible Server. It uses the REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

When configured to include a high water mark and soft deletion, the indexer takes all changes, uploads, and deletes for your MySQL database. It reflects these changes in your search index. Data extraction occurs when you submit the Create Indexer request.

Prerequisites

- [Register for the preview](#) to provide scenario feedback. You can access the feature automatically after form submission.
- [Azure Database for MySQL Flexible Server](#) and sample data. Data must reside in a table or view. A primary key is required. If you're using a view, it must have a [high water mark column](#).
- Read permissions. A *full access* connection string includes a key that grants access to the content, but if you're using Azure roles, make sure the [search service managed identity](#) has **Reader** permissions on MySQL.
- A [REST client](#) to create the data source, index, and indexer.

You can also use the [Azure SDK for .NET](#). You can't use the Azure portal for indexer creation, but you can manage indexers and data sources once they're created.

Preview limitations

Currently, change tracking and deletion detection aren't working if the date or timestamp is uniform for all rows. This limitation is a known issue to be addressed in an update to the preview. Until this issue is addressed, don't add a skillset to the MySQL indexer.

The preview doesn't support geometry types and blobs.

As noted, there's no portal support for indexer creation, but a MySQL indexer and data source can be managed in the Azure portal once they exist. For example, you can edit the definitions, and reset, run, or schedule the indexer.

Define the data source

The data source definition specifies the data to index, credentials, and policies for identifying changes in the data. The data source is defined as an independent resource so that it can be used by multiple indexers.

[Create or Update Data Source](#) specifies the definition. Be sure to use a preview REST API when creating the data source.

HTTP

```
{  
  "name" : "hotel-mysql-ds",  
  "description" : "[Description of MySQL data source]",  
  "type" : "mysql",  
  "credentials" : {  
    "connectionString" :  
      "Server=[MySQLServerName].MySQL.database.azure.com; Port=3306; Database=  
      [DatabaseName]; Uid=[UserName]; Pwd=[Password]; SslMode=Preferred;"  
  },  
  "container" : {  
    "name" : "[TableName]"  
  },  
  "dataChangeDetectionPolicy" : {  
    "@odata.type": "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",  
    "highWaterMarkColumnName": "[HighWaterMarkColumn]"  
  }  
}
```

Key points:

- Set `type` to `"mysql"` (required).
- Set `credentials` to an ADO.NET connection string. You can find connection strings in Azure portal, on the [Connection strings](#) page for MySQL.
- Set `container` to the name of the table.

- Set [dataChangeDetectionPolicy](#) if data is volatile and you want the indexer to pick up just the new and updated items on subsequent runs.
- Set [dataDeletionDetectionPolicy](#) if you want to remove search documents from a search index when the source item is deleted.

! Note

For the container name property, the value is restricted to only allow letters, numbers, underscores (_), dots (.), single dashes (-), and square brackets ([])

Create an index

[Create or Update Index](#) specifies the index schema:

HTTP

```
{  
  "name" : "hotels-mysql-ix",  
  "fields": [  
    { "name": "ID", "type": "Edm.String", "key": true, "searchable": false },  
    { "name": "HotelName", "type": "Edm.String", "searchable": true,  
    "filterable": false },  
    { "name": "Category", "type": "Edm.String", "searchable": false,  
    "filterable": true, "sortable": true },  
    { "name": "City", "type": "Edm.String", "searchable": false, "filterable":  
true, "sortable": true },  
    { "name": "Description", "type": "Edm.String", "searchable": false,  
    "filterable": false, "sortable": false }  
  ]  
}
```

If the primary key in the source table matches the document key (in this case, "ID"), the indexer imports the primary key as the document key.

Mapping data types

The following table maps the MySQL database to Azure AI Search equivalents. For more information, see [Supported data types \(Azure AI Search\)](#).

! Note

The preview does not support geometry types and blobs.

MySQL data types	Azure AI Search field types
<code>bool, boolean</code>	Edm.Boolean, Edm.String
<code>tinyint, smallint, mediumint, int, integer, year</code>	Edm.Int32, Edm.Int64, Edm.String
<code>bigint</code>	Edm.Int64, Edm.String
<code>float, double, real</code>	Edm.Double, Edm.String
<code>date, datetime, timestamp</code>	Edm.DateTimeOffset, Edm.String
<code>char, varchar, tinytext, mediumtext, text, longtext, enum, set, time</code>	Edm.String
unsigned numerical data, serial, decimal, dec, bit, blob, binary, geometry	N/A

Configure and run the MySQL indexer

Once the index and data source have been created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors.

[Create or update an indexer](#) by giving it a name and referencing the data source and target index:

HTTP

```
{
  "name" : "hotels-mysql-idxr",
  "dataSourceName" : "hotels-mysql-ds",
  "targetIndexName" : "hotels-mysql-ix",
  "disabled": null,
  "schedule": null,
  "parameters": {
    "batchSize": null,
    "maxFailedItems": null,
    "maxFailedItemsPerBatch": null,
    "base64EncodeKeys": null,
    "configuration": { }
  },
  "fieldMappings" : [ ],
  "encryptionKey": null
}
```

Key points:

- Specify field mappings if there are differences in field name or type, or if you need multiple versions of a source field in the search index.
- An indexer runs automatically when it's created. You can prevent it from running by setting `disabled` to `true`. To control indexer execution, [run an indexer on demand](#) or [put it on a schedule](#).

Check indexer status

Send a [Get Indexer Status](#) request to monitor indexer execution:

HTTP

```
GET https://myservice.search.windows.net/indexers/myindexer/status?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]
```

The response includes status and the number of items processed. It should look similar to the following example:

JSON

```
{
    "status": "running",
    "lastResult": {
        "status": "success",
        "errorMessage": null,
        "startTime": "2024-02-21T00:23:24.957Z",
        "endTime": "2024-02-21T00:36:47.752Z",
        "errors": [],
        "itemsProcessed": 1599501,
        "itemsFailed": 0,
        "initialTrackingState": null,
        "finalTrackingState": null
    },
    "executionHistory": [
        {
            "status": "success",
            "errorMessage": null,
            "startTime": "2024-02-21T00:23:24.957Z",
            "endTime": "2024-02-21T00:36:47.752Z",
            "errors": [],
            "itemsProcessed": 1599501,
            "itemsFailed": 0,
            "initialTrackingState": null,
            "finalTrackingState": null
        },
        ...
    ]
}
```

```
    ... earlier history items  
]  
}
```

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Indexing new and changed rows

Once an indexer has fully populated a search index, you might want subsequent indexer runs to incrementally index just the new and changed rows in your database.

To enable incremental indexing, set the `dataChangeDetectionPolicy` property in your data source definition. This property tells the indexer which change tracking mechanism is used on your data.

For Azure Database for MySQL indexers, the only supported policy is the [HighWaterMarkChangeDetectionPolicy](#).

An indexer's change detection policy relies on having a *high water mark* column that captures the row version, or the date and time when a row was last updated. It's often a `DATE`, `DATETIME`, or `TIMESTAMP` column at a granularity sufficient for meeting the requirements of a high water mark column.

In your MySQL database, the high water mark column must meet the following requirements:

- All data inserts must specify a value for the column.
- All updates to an item also change the value of the column.
- The value of this column increases with each insert or update.
- Queries with the following `WHERE` and `ORDER BY` clauses can be executed efficiently: `WHERE [High Water Mark Column] > [Current High Water Mark Value] ORDER BY [High Water Mark Column]`

The following example shows a [data source definition](#) with a change detection policy:

HTTP

```
{  
  "name" : "[Data source name]",  
  "type" : "mysql",  
  "credentials" : { "connectionString" : "[connection string]" },  
  "container" : { "name" : "[table or view name]" },  
  "dataChangeDetectionPolicy" : {  
    "@odata.type" :  
      "#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",  
    "highWaterMarkColumn" : "[High Water Mark Column Name]" }  
}
```

```
        "highWaterMarkColumnName" : "[last_updated column name]"
    }
}
```

Important

If you're using a view, you must set a high water mark policy in your indexer data source.

If the source table does not have an index on the high water mark column, queries used by the MySQL indexer might time out. In particular, the `ORDER BY [High Water Mark Column]` clause requires an index to run efficiently when the table contains many rows.

Indexing deleted rows

When rows are deleted from the table or view, you normally want to delete those rows from the search index as well. However, if the rows are physically removed from the table, an indexer has no way to infer the presence of records that no longer exist. The solution is to use a *soft-delete* technique to logically delete rows without removing them from the table. Add a column to your table or view and mark rows as deleted using that column.

Given a column that provides deletion state, an indexer can be configured to remove any search documents for which deletion state is set to `true`. The configuration property that supports this behavior is a data deletion detection policy, which is specified in the [data source definition](#) as follows:

HTTP

```
{  
    ...,  
    "dataDeletionDetectionPolicy" : {  
        "@odata.type" : "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",  
        "softDeleteColumnName" : "[a column name]",  
        "softDeleteMarkerValue" : "[the value that indicates that a row is deleted]"  
    }  
}
```

The `softDeleteMarkerValue` must be a string. For example, if you have an integer column where deleted rows are marked with the value 1, use `"1"`. If you have a `BIT` column where deleted rows are marked with the Boolean true value, use the string literal `True` or `true` (the case doesn't matter).

Next steps

You can now [run the indexer](#), [monitor status](#), or [schedule indexer execution](#). The following articles apply to indexers that pull content from Azure MySQL:

- [Index large data sets](#)
- [Indexer access to content protected by Azure network security features](#)

Last updated on 10/09/2025

Index data from Azure SQL Database

In this article, learn how to configure an [indexer](#) that imports content from Azure SQL Database or an Azure SQL managed instance and makes it searchable in Azure AI Search.

This article supplements [Create an indexer](#) with information that's specific to Azure SQL. It uses the Azure portal and REST APIs to demonstrate a three-part workflow common to all indexers: create a data source, create an index, create an indexer. Data extraction occurs when you submit the Create Indexer request.

This article also provides:

- A description of the [change detection policies](#) supported by the Azure SQL indexer so that you can set up incremental indexing.
- A [frequently-asked-questions \(FAQ\) section](#) for answers to questions about feature compatibility.

! Note

Real-time data synchronization isn't possible with an indexer. An indexer can reindex your table at most every five minutes. If data updates need to be reflected in the index sooner, we recommend [pushing updated rows directly](#).

Prerequisites

- An [Azure SQL database](#) or a [SQL Managed Instance with a public endpoint](#).
- A single table or view.

Use a table if your data is large or if you need incremental indexing using SQL's native change detection capabilities ([SQL integrated change tracking](#)) to reflect new, changed, and deleted rows in the search index.

Use a view if you need to consolidate data from multiple tables. Large views aren't ideal for SQL indexer. A workaround is to create a new table just for ingestion into your Azure AI Search index. If you choose to go with a view, you can use [High Water Mark](#) for change detection, but must use a workaround for deletion detection.

- Primary key must be single-valued. On a table, it must also be non-clustered for full SQL integrated change tracking.

- Read permissions. Azure AI Search supports SQL Server authentication, where the user name and password are provided on the connection string. Alternatively, you can [set up a managed identity and use Azure roles](#) with membership in **SQL Server Contributor** or **SQL DB Contributor** roles.

To work through the examples in this article, you need the Azure portal or a [REST client](#). If you're using Azure portal, make sure that access to all public networks is enabled in the Azure SQL firewall and that the client has access via an inbound rule. For a REST client that runs locally, configure the SQL Server firewall to allow inbound access from your device IP address. Other approaches for creating an Azure SQL indexer include Azure SDKs.

Try with sample data

Use these instructions to create and load a table in Azure SQL Database for testing purposes.

1. [Download hotels-azure-sql.sql](#) ↗ from GitHub to create a table on Azure SQL Database that contains a subset of the sample hotels data set.
2. Sign in to the Azure portal and [create an Azure SQL database and database server](#). Consider configuring both SQL Server authentication and Microsoft Entra ID authentication. If you don't have permissions to configure roles on Azure, you can use SQL authentication as a workaround.
3. Configure the server firewall to all inbound requests from your local device.
4. On your Azure SQL database, select **Query editor (preview)** and then select **New Query**.
5. Paste in and then run the T-SQL script that creates the hotels table. A non-clustered primary key is a requirement for SQL integrated change tracking.

Transact-SQL

```
CREATE TABLE tbl_hotels
(
    Id TINYINT PRIMARY KEY NONCLUSTERED,
    Modified DateTime NULL DEFAULT '0000-00-00 00:00:00',
    IsDeleted TINYINT,
    HotelName VARCHAR(40),
    Category VARCHAR(20),
    City VARCHAR(30),
    State VARCHAR(4),
    Description VARCHAR(500)
);
```

6. Paste in and then run the T-SQL script that inserts records.

Transact-SQL

```
-- Insert rows
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (1, CURRENT_TIMESTAMP, 0, 'Stay-Kay City Hotel', 'Boutique', 'New York', 'NY', 'This classic hotel is fully-refurbished and ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Times Square and the historic centre of the city, as well as other places of interest that make New York one of Americas most attractive and cosmopolitan cities.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (10, CURRENT_TIMESTAMP, 0, 'Countryside Hotel', 'Extended-Stay', 'Durham', 'NC', 'Save up to 50% off traditional hotels. Free WiFi, great location near downtown, full kitchen, washer & dryer, 24\7 support, bowling alley, fitness center and more.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (11, CURRENT_TIMESTAMP, 0, 'Royal Cottage Resort', 'Extended-Stay', 'Bothell', 'WA', 'Your home away from home. Brand new fully equipped premium rooms, fast WiFi, full kitchen, washer & dryer, fitness center. Inner courtyard includes water features and outdoor seating. All units include fireplaces and small outdoor balconies. Pets accepted.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (12, CURRENT_TIMESTAMP, 0, 'Winter Panorama Resort', 'Resort and Spa', 'Wilsonville', 'OR', 'Plenty of great skiing, outdoor ice skating, sleigh rides, tubing and snow biking. Yoga, group exercise classes and outdoor hockey are available year-round, plus numerous options for shopping as well as great spa services. Newly-renovated with large rooms, free 24-hr airport shuttle & a new restaurant. Rooms\suites offer mini-fridges & 49-inch HDTVs.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (13, CURRENT_TIMESTAMP, 0, 'Luxury Lion Resort', 'Luxury', 'St. Louis', 'MO', 'Unmatched Luxury. Visit our downtown hotel to indulge in luxury accommodations. Moments from the stadium and transportation hubs, we feature the best in convenience and comfort.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (14, CURRENT_TIMESTAMP, 0, 'Twin Vortex Hotel', 'Luxury', 'Dallas', 'TX', 'New experience in the making. Be the first to experience the luxury of the Twin Vortex. Reserve one of our newly-renovated guest rooms today.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (15, CURRENT_TIMESTAMP, 0, 'By the Market Hotel', 'Budget', 'New York', 'NY', 'Book now and Save up to 30%. Central location. Walking distance from the Empire State Building & Times Square, in the Chelsea neighborhood. Brand new rooms. Impeccable service.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (16, CURRENT_TIMESTAMP, 0, 'Double Sanctuary Resort', 'Resort and Spa', 'Seattle', 'WA', '5 Star Luxury Hotel - Biggest Rooms in the city. #1 Hotel in the area listed by Traveler magazine. Free WiFi, Flexible check in\out, Fitness Center & espresso in room.');
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (17, CURRENT_TIMESTAMP, 0, 'City Skyline Antiquity Hotel', 'Boutique', 'New York', 'NY', 'In vogue since 1888, the Antiquity Hotel takes you back to bygone era. From the crystal chandeliers that adorn the Green Room, to the arched ceilings of the Grand Hall, the elegance of old New York beckons. Elevate Your Experience. Upgrade to a premiere city skyline view for
```

```
less, where old world charm combines with dramatic views of the city, local cathedral and midtown.'');
```

```
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (18, CURRENT_TIMESTAMP, 0, 'Ocean Water Resort & Spa', 'Luxury', 'Tampa', 'FL', 'New Luxury Hotel for the vacation of a lifetime. ```

```
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (19, CURRENT_TIMESTAMP, 0, 'Economy Universe Motel', 'Budget', 'Redmond', 'WA', 'Local, family-run hotel in bustling downtown Redmond. We are a pet-friendly establishment, near expansive Marymoor park, haven to pet owners, joggers, and sports enthusiasts. Close to the highway and just a short drive away from major cities.');
```

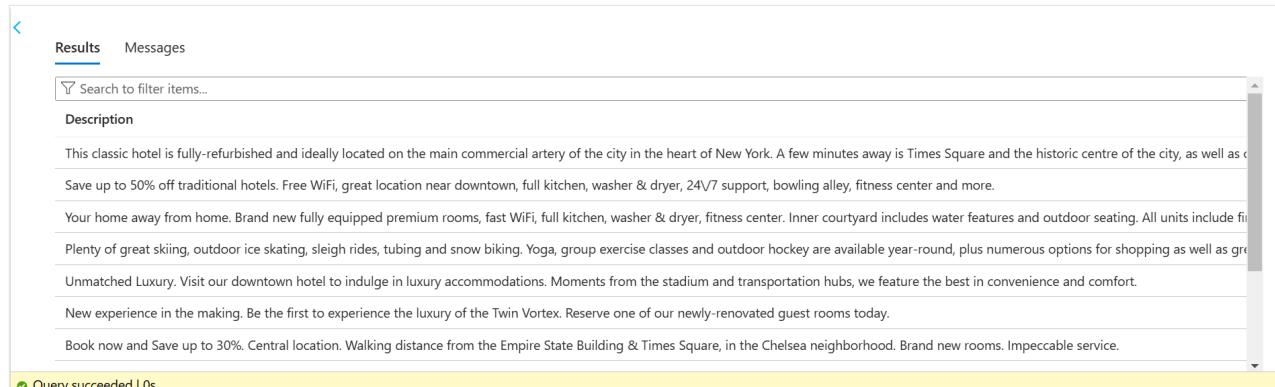

```
INSERT INTO tbl_hotels (Id, Modified, IsDeleted, HotelName, Category, City, State, Description) VALUES (20, CURRENT_TIMESTAMP, 0, 'Delete Me Hotel', 'Unknown', 'Nowhere', 'XX', 'Test-case row for change detection and delete detection . For change detection, modify any value, and then re-run the indexer. For soft-delete, change IsDelete from zero to a one, and then re-run the indexer.');
```

7. Run a query to confirm the upload.

Transact-SQL

```
SELECT Description FROM tbl_hotels;
```

You should see results similar to the following screenshot.

The screenshot shows a SQL query results window. The 'Results' tab is selected. A search bar at the top says 'Search to filter items...'. Below it is a table with a single row. The table has two columns: 'Description'. The content of the 'Description' column is:

```
This classic hotel is fully-refurbished and ideally located on the main commercial artery of the city in the heart of New York. A few minutes away is Times Square and the historic centre of the city, as well as central business district. Save up to 50% off traditional hotels. Free WiFi, great location near downtown, full kitchen, washer & dryer, 24/7 support, bowling alley, fitness center and more. Your home away from home. Brand new fully equipped premium rooms, fast WiFi, full kitchen, washer & dryer, fitness center. Inner courtyard includes water features and outdoor seating. All units include free WiFi. Plenty of great skiing, outdoor ice skating, sleigh rides, tubing and snow biking. Yoga, group exercise classes and outdoor hockey are available year-round, plus numerous options for shopping as well as great restaurants. Unmatched Luxury. Visit our downtown hotel to indulge in luxury accommodations. Moments from the stadium and transportation hubs, we feature the best in convenience and comfort. New experience in the making. Be the first to experience the luxury of the Twin Vortex. Reserve one of our newly-renovated guest rooms today. Book now and Save up to 30%. Central location. Walking distance from the Empire State Building & Times Square, in the Chelsea neighborhood. Brand new rooms. Impeccable service.
```

At the bottom of the results pane, there is a yellow status bar that says 'Query succeeded | 0s'.

The Description field provides the most verbose content. You should target this field for full text search and optional vectorization.

Now that you have a database table, you can use the Azure portal, REST client, or an Azure SDK to index your data.

Tip

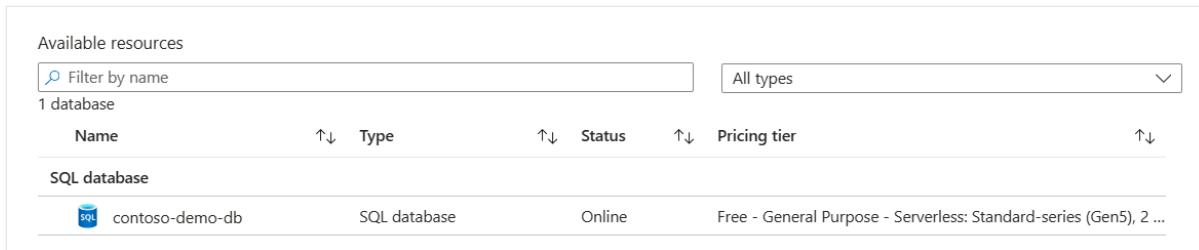

Another resource that provides sample content and code can be found on [Azure-Samples/SQL-AI-samples](#).

Set up the indexer pipeline

In this step, specify the data source, index, and indexer.

Azure portal

1. Make sure your SQL database is active and not paused due to inactivity. In the Azure portal, navigate to the database server page and verify the database status is *online*. You can run a query on any table to activate the database.

The screenshot shows the 'Available resources' blade in the Azure portal. It includes a search bar labeled 'Filter by name' and a dropdown menu set to 'All types'. Below this, there is a table with the following data:

Name	Type	Status	Pricing tier
contoso-demo-db	SQL database	Online	Free - General Purpose - Serverless: Standard-series (Gen5), 2 ...

2. Make sure you have a table or view that meets the requirements for indexers and change detection.

First, you can only pull from a single table or view. We recommend tables because they support SQL integrated change tracking policy, which detects new, updated, and deleted rows. A high water mark policy doesn't support row deletion and is harder to implement.

Second, the primary key must be a single value (compound keys aren't supported) and non-clustered.

3. Switch to your search service and create a data source. Under **Search management > Data sources**, select **Add data source**:
 - a. For data source type, choose *Azure SQL Database*.
 - b. Provide a name for the data source object on Azure AI Search.
 - c. Use the dropdowns to select the subscription, account type, server, database, table or view, schema, and table name.
 - d. For change tracking we recommend **SQL Integrated Change Tracking Policy**.
 - e. For authentication, we recommend connecting with a **managed identity**. Your search service must have **SQL Server Contributor** or **SQL DB Contributor** role membership on the database.
 - f. Select **Create** to create the data source.

Home >

Add data source

Data Source

Data Source	Azure SQL Database
Name *	hotels-ds
Subscription *	my-demo-azure-subscription
Azure SQL account type	SQL databases
Server *	my-demo-sql-server
Database *	hotels-db
Table or View	Table
Schema *	dbo
Table name *	tbl_hotels

Select an authentication option

 SQL server authentication Authenticate using managed identity. [Learn more](#)Managed identity type (1)

System-assigned

Advanced options

Encryption

[Microsoft-managed keys](#)

4. Use an [import wizard](#) to create the index and indexer.

- a. On the [Overview](#) page, select **Import data** or **Import data (new)**.
- b. Select the data source you just created.
- c. Skip the step for adding AI enrichments.
- d. Name the index, set the key to your primary key in the table, attribute all fields as **Retrievable** and **Searchable**, and optionally add **Filterable** and **Sortable** for short strings or numeric values.
- e. Name the indexer and finish the wizard to create the necessary objects.

Check indexer status

To monitor the indexer status and execution history, check the indexer execution history in the Azure portal, or send a [Get Indexer Status](#) REST API request

Portal

1. On the search service page, open **Search management > Indexers**.
2. Select an indexer to access configuration and execution history.
3. Select a specific indexer job to view details, warnings, and errors.

Execution history contains up to 50 of the most recently completed executions, which are sorted in the reverse chronological order so that the latest execution comes first.

Indexing new, changed, and deleted rows

If your SQL database supports [change tracking](#), a search indexer can pick up just the new and updated content on subsequent indexer runs.

To enable incremental indexing, set the "dataChangeDetectionPolicy" property in your data source definition. This property tells the indexer which change tracking mechanism is used on your table or view.

For Azure SQL indexers, there are two change detection policies:

- "SqlIntegratedChangeTrackingPolicy" (applies to tables only)
- "HighWaterMarkChangeDetectionPolicy" (works for views)

SQL integrated change tracking policy

We recommend using "SqlIntegratedChangeTrackingPolicy" for its efficiency and its ability to identify deleted rows.

Database requirements:

- Azure SQL Database or SQL Managed Instance. SQL Server 2016 or later if you're using an Azure VM.
- Database must have [change tracking enabled](#)
- Tables only (no views).

- Tables can't be clustered. To meet this requirement, drop the clustered index and recreate it as non-clustered index. This workaround often degrades performance. Duplicating content in a second table that's dedicated to indexer processing can be a helpful mitigation.
- Tables can't be empty. If you use TRUNCATE TABLE to clear rows, a reset and rerun of the indexer won't remove the corresponding search documents. To remove orphaned search documents, you must [index them with a delete action](#).
- Primary key can't be a compound key (containing more than one column).
- Primary key must be non-clustered if you want deletion detection.

Change detection policies are added to data source definitions. To use this policy, edit the data source definition in the Azure portal, or use REST to update your data source like this:

HTTP

```
POST https://myservice.search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: admin-key
{
  "name" : "myazuresqldatasource",
  "type" : "azuresql",
  "credentials" : { "connectionString" : "connection string" },
  "container" : { "name" : "table name" },
  "dataChangeDetectionPolicy" : {
    "@odata.type" :
    "#Microsoft.Azure.Search.SqlIntegratedChangeTrackingPolicy"
  }
}
```

When using SQL integrated change tracking policy, don't specify a separate data deletion detection policy. The SQL integrated change tracking policy has built-in support for identifying deleted rows. However, for the deleted rows to be detected automatically, the document key in your search index must be the same as the primary key in the SQL table, and the primary key must be non-clustered.

High water mark change detection policy

This change detection policy relies on a "high water mark" column in your table or view that captures the version or time when a row was last updated. If you're using a view, you must use a high water mark policy.

The high water mark column must meet the following requirements:

- All inserts specify a value for the column.
- All updates to an item also change the value of the column.

- The value of this column increases with each insert or update.
- Queries with the following WHERE and ORDER BY clauses can be executed efficiently:

```
WHERE [High Water Mark Column] > [Current High Water Mark Value] ORDER BY [High  
Water Mark Column]
```

!*Note*

We strongly recommend using the `rowversion` data type for the high water mark column. If any other data type is used, change tracking isn't guaranteed to capture all changes in the presence of transactions executing concurrently with an indexer query. When using `rowversion` in a configuration with read-only replicas, you must point the indexer at the primary replica. Only a primary replica can be used for data sync scenarios.

Change detection policies are added to data source definitions. To use this policy, create or update your data source like this:

HTTP

```
POST https://myservice.search.windows.net/datasources?api-version=2025-09-01
Content-Type: application/json
api-key: admin-key
{
    "name" : "myazuresqldatasource",
    "type" : "azuresql",
    "credentials" : { "connectionString" : "connection string" },
    "container" : { "name" : "table or view name" },
    "dataChangeDetectionPolicy" : {
        "@odata.type" :
"#Microsoft.Azure.Search.HighWaterMarkChangeDetectionPolicy",
        "highWaterMarkColumnName" : "[a rowversion or last_updated column name]"
    }
}
```

!*Note*

If the source table doesn't have an index on the high water mark column, queries used by the SQL indexer may time out. In particular, the `ORDER BY [High Water Mark Column]` clause requires an index to run efficiently when the table contains many rows.

convertHighWaterMarkToRowVersion

If you're using a `rowversion` data type for the high water mark column, consider setting the `convertHighWaterMarkToRowVersion` property in indexer configuration. Setting this property to

true results in the following behaviors:

- Uses the rowversion data type for the high water mark column in the indexer SQL query. Using the correct data type improves indexer query performance.
- Subtracts one from the rowversion value before the indexer query runs. Views with one-to-many joins might have rows with duplicate rowversion values. Subtracting one ensures the indexer query doesn't miss these rows.

To enable this property, create or update the indexer with the following configuration:

HTTP

```
{  
    ... other indexer definition properties  
    "parameters" : {  
        "configuration" : { "convertHighWaterMarkToRowVersion" : true } }  
}
```

queryTimeout

If you encounter timeout errors, set the `queryTimeout` indexer configuration setting to a value higher than the default 5-minute timeout. For example, to set the timeout to 10 minutes, create or update the indexer with the following configuration:

HTTP

```
{  
    ... other indexer definition properties  
    "parameters" : {  
        "configuration" : { "queryTimeout" : "00:10:00" } }  
}
```

disableOrderByHighWaterMarkColumn

You can also disable the `ORDER BY [High Water Mark Column]` clause. However, this isn't recommended because if the indexer execution is interrupted by an error, the indexer has to reprocess all rows if it runs later, even if the indexer has already processed almost all the rows at the time it was interrupted. To disable the `ORDER BY` clause, use the `disableOrderByHighWaterMarkColumn` setting in the indexer definition:

HTTP

```
{  
    ... other indexer definition properties
```

```
"parameters" : {  
    "configuration" : { "disableOrderByHighWaterMarkColumn" : true } }  
}
```

Soft delete column deletion detection policy

When rows are deleted from the source table, you probably want to delete those rows from the search index as well. If you use the SQL integrated change tracking policy, this is taken care of for you. However, the high water mark change tracking policy doesn't help you with deleted rows. What to do?

If the rows are physically removed from the table, Azure AI Search has no way to infer the presence of records that no longer exist. However, you can use the "soft-delete" technique to logically delete rows without removing them from the table. Add a column to your table or view and mark rows as deleted using that column.

When using the soft-delete technique, you can specify the soft delete policy as follows when creating or updating the data source:

HTTP

```
{  
    ...,  
    "dataDeletionDetectionPolicy" : {  
        "@odata.type" : "#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",  
        "softDeleteColumnName" : "[a column name]",  
        "softDeleteMarkerValue" : "[the value that indicates that a row is  
deleted]"  
    }  
}
```

The **softDeleteMarkerValue** must be a string in the JSON representation of your data source. Use the string representation of your actual value. For example, if you have an integer column where deleted rows are marked with the value 1, use `"1"`. If you have a BIT column where deleted rows are marked with the Boolean true value, use the string literal `"True"` or `"true"`, the case doesn't matter.

If you're setting up a soft delete policy from the Azure portal, don't add quotes around the soft delete marker value. The field contents are already understood as a string and are translated automatically into a JSON string for you. In the previous examples, simply type `1`, `True` or `true` into the Azure portal's field.

FAQ

Q: Can I index Always Encrypted columns?

No, [Always Encrypted](#) columns aren't currently supported by Azure AI Search indexers.

Q: Can I use Azure SQL indexer with SQL databases running on IaaS VMs in Azure?

Yes. However, you need to allow your search service to connect to your database. For more information, see [Configure a connection from an Azure AI Search indexer to SQL Server on an Azure VM](#).

Q: Can I use Azure SQL indexer with SQL databases running on-premises?

Not directly. We don't recommend or support a direct connection, as doing so would require you to open your databases to Internet traffic. Customers have succeeded with this scenario using bridge technologies like Azure Data Factory. For more information, see [Push data to an Azure AI Search index using Azure Data Factory](#).

Q: Can I use a secondary replica in a [failover cluster](#) as a data source?

It depends. For full indexing of a table or view, you can use a secondary replica.

For incremental indexing, Azure AI Search supports two change detection policies: SQL integrated change tracking and High Water Mark.

On read-only replicas, SQL Database doesn't support integrated change tracking. Therefore, you must use High Water Mark policy.

Our standard recommendation is to use the rowversion data type for the high water mark column. However, using rowversion relies on the `MIN_ACTIVE_ROWVERSION` function, which isn't supported on read-only replicas. Therefore, you must point the indexer to a primary replica if you're using rowversion.

If you attempt to use rowversion on a read-only replica, you get the following error:

"Using a rowversion column for change tracking isn't supported on secondary (read-only) availability replicas. Update the datasource and specify a connection to the primary availability replica. Current database 'Updateability' property is 'READ_ONLY'".

Q: Can I use an alternative, non-rowversion column for high water mark change tracking?

It's not recommended. Only **rowversion** allows for reliable data synchronization. However, depending on your application logic, it can be safe if:

- You can ensure that when the indexer runs, there are no outstanding transactions on the table that's being indexed (for example, all table updates happen as a batch on a

schedule, and the Azure AI Search indexer schedule is set to avoid overlapping with the table update schedule).

- You periodically do a full reindex to pick up any missed rows.

Indexer connections to Azure SQL Managed Instance through a public endpoint

07/11/2025

Indexers in Azure AI Search connect to external data sources over a public endpoint. If you're setting up an [Azure SQL indexer](#) for a connection to a SQL managed instance, follow the steps in this article to ensure the public endpoint is set up correctly.

Alternatively, for private connections, [create a shared private link](#) instead.

 Note

Always Encrypted columns are not currently supported by Azure AI Search indexers.

Enable a public endpoint

This article highlights just the steps for an indexer connection in Azure AI Search. If you want more background, see [Configure public endpoint in Azure SQL Managed Instance](#) instead.

1. For a new SQL Managed Instance, create the resource with the [Enable public endpoint](#) option selected.

Microsoft Azure Search resources, services, and docs (G+) Copilot ...

Public endpoint (data) [i](#)

[Enable](#) [Disable](#)

This option requires port 3342 to be open for inbound traffic. You will need to configure NSG rule for this port separately. [Learn more](#)

Get public endpoint connection string

1. To get a connection string, go to **Settings > Connection strings**.
2. Copy the connection string to use in the search indexer's data source connection. Be sure to copy the connection string for the **public endpoint** (port 3342, not port 1433).

Next steps

With configuration out of the way, you can now specify a SQL managed instance as an indexer data source using the basic instructions for [setting up an Azure SQL indexer](#).

Configure an indexer connection to a SQL Server instance on an Azure virtual machine

05/29/2025

When configuring an [Azure SQL indexer](#) to extract content from a database on an Azure virtual machine, extra steps are required for secure connections.

A connection from Azure AI Search to SQL Server instance on a virtual machine is a public internet connection. In order for secure connections to succeed, perform the following steps:

- Obtain a certificate from a [Certificate Authority provider](#) for the fully qualified domain name of the SQL Server instance on the virtual machine.
- Install the certificate on the virtual machine.

After you install the certificate on your VM, you're ready to complete the following steps in this article.

(!) Note

Always Encrypted columns are not currently supported by Azure AI Search indexers.

Enable encrypted connections

Azure AI Search requires an encrypted channel for all indexer requests over a public internet connection. This section lists the steps to make this work.

1. Check the properties of the certificate to verify the subject name is the fully qualified domain name (FQDN) of the Azure VM.

You can use a tool like CertUtils or the Certificates snap-in to view the properties. You can get the FQDN from the VM service page Essentials section, in the **Public IP address/DNS name label** field, in the [Azure portal](#).

The FQDN is typically formatted as `<your-VM-name>.<region>.cloudapp.azure.com`

2. Configure SQL Server to use the certificate using the Registry Editor (regedit).

Although SQL Server Configuration Manager is often used for this task, you can't use it for this scenario. It won't find the imported certificate because the FQDN of the VM on

Azure doesn't match the FQDN as determined by the VM (it identifies the domain as either the local computer or the network domain to which it's joined). When names don't match, use regedit to specify the certificate.

- a. In regedit, browse to this registry key:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Microsoft SQL Server\  
[MSSQL13.MSSQLSERVER]\MSSQLServer\SuperSocketNetLib\Certificate.
```

The `[MSSQL13.MSSQLSERVER]` part varies based on version and instance name.

- b. Set the value of the **Certificate** key to the **thumbprint** (without spaces) of the TLS/SSL certificate you imported to the VM.

For example, copy the hexadecimal characters to text editor, such as Notepad. Delete all spaces from the thumbprint string. If the thumbprint is `c0 d0 f2 70 95 b0 3d 43 17
e2 19 84 10 24 32 8c ef 24 87 79`, then change it to
`c0d0f27095b03d4317e219841024328cef248779`.

There are several ways to get the thumbprint, some better than others. If you copy it from the **Certificates** snap-in in MMC, you might pick up an invisible leading character, which results in an error when you attempt a connection. Several workarounds exist for correcting this problem. The easiest is to backspace over and then retype the first character of the thumbprint to remove the leading character in the key value field in regedit. Alternatively, you can use a different tool to copy the thumbprint. For more information, see [Certificate thumbprint displayed in MMC certificate snap-in has extra invisible unicode character ↴](#).

3. Grant permissions to the service account.

Make sure the SQL Server service account is granted appropriate permission on the private key of the TLS/SSL certificate. If you overlook this step, SQL Server doesn't start. You can use the **Certificates** snap-in or **CertUtils** for this task.

4. Restart the SQL Server service.

Connect to SQL Server

After you set up the encrypted connection required by Azure AI Search, connect to the instance through its public endpoint. The following article explains the connection requirements and syntax:

- [Connect to SQL Server over the internet](#)

Configure the network security group

It's a best practice to configure the [network security group \(NSG\)](#) and corresponding Azure endpoint or Access Control List (ACL) to make your Azure VM accessible to other parties.

Chances are you've done this before to allow your own application logic to connect to your SQL Azure VM. It's no different for an Azure AI Search connection to your SQL Azure VM.

The following steps and links provide instructions on NSG configuration for VM deployments. Use these instructions to ACL a search service endpoint based on its IP address.

1. Obtain the IP address of your search service. See the [following section](#) for instructions.
2. Add the search IP address to the IP filter list of the security group. Either one of following articles explains the steps:
 - [Tutorial: Filter network traffic with a network security group using the Azure portal](#)
 - [Create, change, or delete a network security group](#)

IP addressing can pose a few challenges that are easily overcome if you're aware of the issue and potential workarounds. The remaining sections provide recommendations for handling issues related to IP addresses in the ACL.

Restrict network access to Azure AI Search

We strongly recommend that you restrict the access to the IP address of your search service and the IP address range of `AzureCognitiveSearch` [service tag](#) in the ACL instead of making your SQL Azure VMs open to all connection requests.

You can find out the IP address by pinging the FQDN (for example, `<your-search-service-name>.search.windows.net`) of your search service. Although it's possible for the search service IP address to change, it's unlikely that it will change. The IP address tends to be static for the lifetime of the service.

You can find out the IP address range of `AzureCognitiveSearch` [service tag](#) by either using [Downloadable JSON files](#) or via the [Service Tag Discovery API](#). The IP address range is updated weekly.

Include the Azure portal IP addresses

If you're using the Azure portal to create an indexer, you must grant the Azure portal inbound access to your SQL Azure virtual machine. An inbound rule in the firewall requires that you provide the IP address of the Azure portal.

To get the Azure portal IP address, ping `stamp2.ext.search.windows.net`, which is the domain of the traffic manager. The request times out, but the IP address is visible in the status message. For example, in the message "Pinging azsyrie.northcentralus.cloudapp.azure.com [52.252.175.48]", the IP address is "52.252.175.48".

Clusters in different regions connect to different traffic managers. Regardless of the domain name, the IP address returned from the ping is the correct one to use when defining an inbound firewall rule for the Azure portal in your region.

Supplement network security with token authentication

Firewalls and network security are a first step in preventing unauthorized access to data and operations. Authorization should be your next step.

We recommend role-based access, where Microsoft Entra ID users and groups are assigned to roles that determine read and write access to your service. See [Connect to Azure AI Search using role-based access controls](#) for a description of built-in roles and instructions for creating custom roles.

If you don't need key-based authentication, we recommend that you disable API keys and use role assignments exclusively.

Next steps

With configuration out of the way, you can now specify a SQL Server on Azure VM as the data source for an Azure AI Search indexer. For more information, see [Index data from Azure SQL](#).

Index data from OneLake files and shortcuts

In this article, learn how to configure a OneLake files indexer for extracting searchable data and metadata data from a [lakehouse](#) on top of [Microsoft OneLake](#).

To configure and run the indexer, you can use:

- [Data Source REST API](#) with an [Indexer REST API](#)
- An Azure SDK package that provides the feature
- [Import data wizard](#) in the Azure portal
- [Import data \(new\) wizard](#) in the Azure portal.

This article uses the REST APIs to illustrate each step.

Prerequisites

- A Fabric workspace. Follow this tutorial to [create a Fabric workspace](#).
- A lakehouse in a Fabric workspace. Follow this tutorial to [create a lakehouse](#).
- Textual data. If you have binary data, you can use [AI enrichment](#) image analysis to extract text or generate descriptions of images. File content can't exceed the [indexer limits](#) for your search service tier.
- Unstructured content in the **Files** location of your lakehouse. You can add data by:
 - [Upload into a lakehouse directly](#)
 - [Use data pipelines from Microsoft Fabric](#)
 - [Add shortcuts](#) from external data sources like [Amazon S3](#) or [Google Cloud Storage](#).
- An AI Search service, basic pricing tier or higher, configured for either a [system managed identity](#) or [user-assigned assigned managed identity](#). The AI Search service must reside within the same tenant as the Microsoft Fabric workspace.
- A Contributor role assignment in the Microsoft Fabric workspace where the lakehouse is located. Steps are outlined in the [Grant permissions](#) section of this article.
- A [REST client](#) to formulate REST calls similar to the ones shown in this article.

Limitations

- Parquet (including delta parquet) file types aren't currently supported.

- File deletion isn't supported for Amazon S3 and Google Cloud Storage shortcuts.
- This indexer doesn't support OneLake workspace Table location content.
- This indexer doesn't support SQL queries, but the query used in the data source configuration is exclusively to add optionally the folder or shortcut to access.
- There's no support to ingest files from **My Workspace** workspace in OneLake since this is a personal repository per user.
- Microsoft Purview sensitivity labels [applied to Fabric items](#) (such as lakehouses) will cause the indexer to fail if the search service doesn't have the required access. To prevent this behavior, you must either:
 - Add the AI Search service's Service Principal Name (SPN) to an existing organization group that grants access under the sensitivity label policy, or
 - Request an exception from your organization's IT team responsible for Purview sensitivity label policy configurations, and have them add the SPN directly to the policy.
- Workspace role-based permissions in Microsoft OneLake may affect indexer access to files. Ensure that the Azure AI Search service principal (managed identity) has sufficient permissions over the files you intend to access in the target [Microsoft Fabric workspace](#).

Supported tasks

You can use this indexer for the following tasks:

- **Data indexing and incremental indexing:** The indexer can index files and associated metadata from data paths within a lakehouse. It detects new and updated files and metadata through built-in change detection. You can configure data refresh on a schedule or on demand.
- **Deletion detection:** The indexer can [detect deletions via custom metadata](#) for most files and shortcuts. This requires adding metadata to files to signify that they have been "soft deleted", enabling their removal from the search index. Currently, it's not possible to detect deletions in Google Cloud Storage or Amazon S3 shortcut files because custom metadata isn't supported for those data sources.
- **Applied AI enrichment through skillsets:** [Skillsets](#) are fully supported by the OneLake files indexer. This includes key features like [integrated vectorization](#) that adds data chunking and embedding steps.
- **Parsing modes:** The indexer supports [JSON parsing modes](#) if you want to parse JSON arrays or lines into individual search documents. It also supports [Markdown parsing mode](#).

- **Compatibility with other features:** The OneLake indexer is designed to work seamlessly with other indexer features, such as [debug sessions](#), [indexer cache for incremental enrichments](#), and [knowledge store](#).

Supported document formats

The OneLake files indexer can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Supported shortcuts

The following OneLake shortcuts are supported by the OneLake files indexer:

- [ADLS Gen2 shortcut](#)
- [OneLake shortcut](#) (a shortcut to another OneLake instance)
- [Amazon S3 shortcut](#)
- [Google Cloud Storage shortcut](#)

Prepare data for indexing

Before you set up indexing, review your source data to determine whether any changes should be made to your data in the lakehouse. An indexer can index content from one container at a

time. By default, all files in the container are processed. You have several options for more selective processing:

- Place files in a virtual folder. An indexer [data source definition](#) includes a "query" parameter that can be either a lakehouse subfolder or shortcut. If this value is specified, only those files in the subfolder or shortcut within the lakehouse are indexed.
- Include or exclude files by file type. The [supported document formats list](#) can help you determine which files to exclude. For example, you might want to exclude image or audio files that don't provide searchable text. This capability is controlled through [configuration settings](#) in the indexer.
- Include or exclude arbitrary files. If you want to skip a specific file for whatever reason, you can add metadata properties and values to files in your lakehouse. When an indexer encounters this property, it skips the file or its content in the indexing run.

File inclusion and exclusion are covered in the [indexer configuration](#) step. If you don't set criteria, the indexer reports an ineligible file as an error and moves on. If enough errors occur, processing might stop. You can specify error tolerance in the indexer [configuration settings](#).

An indexer typically creates one search document per file, where the text content and metadata are captured as searchable fields in an index. If files are whole files, you can potentially parse them into [multiple search documents](#). For example, you can parse rows in a [CSV file](#) to create one search document per row. If you need to chunk a single document into smaller passages to vectorize data, consider using [integrated vectorization](#).

Indexing file metadata

File metadata can also be indexed, and that's helpful if you think any of the standard or custom metadata properties are useful in filters and queries.

User-specified metadata properties are extracted verbatim. To receive the values, you must define field in the search index of type `Edm.String`, with same name as the metadata key of the blob. For example, if a blob has a metadata key of `Priority` with value `High`, you should define a field named `Priority` in your search index and it will be populated with the value `High`.

Standard file metadata properties can be extracted into similarly named and typed fields, as listed below. The OneLake files indexer automatically creates internal field mappings for these metadata properties, converting the original hyphenated name ("metadata-storage-name") to an underscored equivalent name ("metadata_storage_name").

You still have to add the underscored fields to the index definition, but you can omit [indexer field mappings](#) because the indexer makes the association automatically.

- **metadata_storage_name** (`Edm.String`) - the file name. For example, if you have a file `/mydatalake/my-folder/subfolder/resume.pdf`, the value of this field is `resume.pdf`.
- **metadata_storage_path** (`Edm.String`) - the full URI of the blob, including the storage account. For example, `https://myaccount.blob.core.windows.net/my-container/my-folder/subfolder/resume.pdf`
- **metadata_storage_content_type** (`Edm.String`) - content type as specified by the code you used to upload the blob. For example, `application/octet-stream`.
- **metadata_storage_last_modified** (`Edm.DateTimeOffset`) - last modified timestamp for the blob. Azure AI Search uses this timestamp to identify changed blobs, to avoid reindexing everything after the initial indexing.
- **metadata_storage_size** (`Edm.Int64`) - blob size in bytes.
- **metadata_storage_content_md5** (`Edm.String`) - MD5 hash of the blob content, if available.

Lastly, any metadata properties specific to the document format of the files you're indexing can also be represented in the index schema. For more information about content-specific metadata, see [Content metadata properties](#).

It's important to point out that you don't need to define fields for all of the above properties in your search index - just capture the properties you need for your application.

Grant permissions

The OneLake indexer uses token authentication and role-based access for connections to OneLake. Permissions are assigned in OneLake. There are no permission requirements on the physical data stores backing the shortcuts. For example, if you're indexing from AWS, you don't need to grant search service permissions in AWS.

The minimum role assignment for your search service identity is Contributor.

1. [Configure a system or user-managed identity](#) for your AI Search service.

The following screenshot shows a system managed identity for a search service named "onelake-demo".

This screenshot shows the Identity settings for a search service named 'onelake-demo'. The 'System assigned' tab is selected. A red box highlights the 'Status' switch, which is set to 'On'. Another red box highlights the 'User assigned' link in the top navigation bar.

This screenshot shows a user-managed identity for the same search service.

This screenshot shows the Identity settings for the same search service 'onelake-demo'. The 'User assigned' tab is selected. A red box highlights the 'demo-mi' entry in the list of identities.

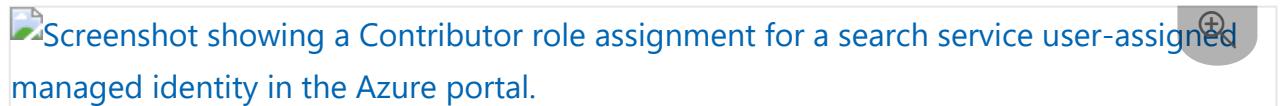

2. Grant permission for search service access to the Fabric workspace. The search service makes the connection on behalf of the indexer.

If you use a system-assigned managed identity, search for the name of the AI Search service. For a user-assigned managed identity, search for the name of the identity resource.

The following screenshot shows a Contributor role assignment using a system managed identity.

This screenshot shows a Contributor role assignment using a user-assigned managed identity:

Configure a shared private link (required if using Fabric workspace-level private link)

If your Fabric workspace is secured with a [private link](#), Azure AI Search won't be able to access your lakehouse data over the public internet, and you won't be able to configure the indexer or its required dependencies, such as the data source. To enable access, you must configure a [shared private link](#) between Azure AI Search and your Fabric workspace.

Define the data source

A data source is defined as an independent resource so that it can be used by multiple indexers.

1. Use the [Create or update a data source REST API](#) to set its definition. These are the most significant steps of the definition.
 2. Set "type" to "onelake" (required).
 3. Get the Microsoft Fabric workspace GUID and the lakehouse GUID:
 - In Power BI, open the lakehouse you'd like to import data from. Notice the lakehouse URL in the browser. It should look similar to this example: "<https://msit.powerbi.com/groups/00000000-0000-0000-0000-000000000000/lakehouses/11111111-1111-1111-1111-111111111111>". The URL contains both the workspace GUID and the lakehouse GUID. If the Fabric workspace is secured with a private link, the URL would start with "<https://{{FabricWorkspaceGuid}}.z{{xy}}.blob.fabric.microsoft.com>".
 - Copy the workspace GUID, which is listed to the right of "groups" in the URL. In this example, it would be 00000000-0000-0000-000000000000. In your REST file, create an environment variable for {{FabricWorkspaceGuid}} and set it to the workspace GUID. If your workspace uses a private link, the workspace GUID will appear in a different location in the URL. Be sure to reference the correct part of the URL based on your setup.

A screenshot of the Microsoft Power BI Groups interface. The URL in the browser's address bar is `https://msit.powerbi.com/groups/00000000-0000-0000-0000-000000000000/lakehouses/11111111-1111-1111-1111-111111111111`. A red arrow points from the text "Copy the lakehouse GUID" in the instructions below to the GUID in the URL.

- Copy the lakehouse GUID, which is listed right after "lakehouses" in the URL. In this example, it would be `11111111-1111-1111-1111-111111111111`. In your REST file, create an environment variable for `{LakehouseGuid}` and set it to the lakehouse GUID.

A screenshot of the Microsoft Power BI Groups interface, similar to the one above but with a different URL. The URL in the browser's address bar is `https://msit.powerbi.com/groups/00000000-0000-0000-0000-000000000000/lakehouses/11111111-1111-1111-1111-111111111111`. A red arrow points from the text "Set 'credentials'" in the instructions below to the GUID in the URL.

- Set "credentials" to the Microsoft Fabric workspace GUID by replacing `{FabricWorkspaceGuid}` with the value you copied in the previous step. This is the OneLake to access with the managed identity you'll set up later in this guide.

JSON

```
"credentials": {  
  "connectionString": "ResourceId={FabricWorkspaceGuid}"  
}
```

For your setup with [shared private link](#), setup the managed identities using the following connection string, that varies from the setup using the internet for communication. Note that not only the URL is different, but also `WorkspaceEndpoint` is used, instead of `ResourceId`. Take this into consideration when configuring either the system-managed identity or user-managed identity setups.

JSON

```
"credentials": {  
  "connectionString":  
    "WorkspaceEndpoint=https://{{FabricWorkspaceGuid}}.z{{xy}}.blob.fabric.microsoft.com"  
}
```

1. Set `"container.name"` to the lakehouse GUID, replacing `{LakehouseGuid}` with the value you copied in the previous step. Use `"query"` to optionally specify a lakehouse subfolder or shortcut.

JSON

```
"container": {  
  "name": "{LakehouseGuid}",  
  "query": "{optionalLakehouseFolderOrShortcut}"  
}
```

2. Set the authentication method using the user-assigned managed identity, or skip to the next step for system-managed identity.

JSON

```
{  
  "name": "{dataSourceName}",  
  "description": "description",  
  "type": "onelake",  
  "credentials": {  
    "connectionString": "ResourceId={{FabricWorkspaceGuid}}"  
  },  
  "container": {  
    "name": "{LakehouseGuid}",  
    "query": "{optionalLakehouseFolderOrShortcut}"  
  },  
  "identity": {  
    "@odata.type": "Microsoft.Azure.Search.DataUserAssignedIdentity",  
    "userAssignedIdentity": "{userAssignedManagedIdentity}"  
  }  
}
```

The `userAssignedIdentity` value can be found by accessing the `{userAssignedManagedIdentity}` resource, under Properties and it's called `Id`.

Example:

JSON

```
{  
  "name": "mydatasource",  
  "description": "description",  
  "type": "onelake",  
  "credentials": {  
    "connectionString": "ResourceId=a0a0a0a0-bbbb-cccc-dddd-e1e1e1e1e1"  
  },  
  "container": {  
    "name": "11111111-1111-1111-1111-111111111111",  
    "query": "folder_name"  
  },  
  "identity": {  
    "@odata.type": "Microsoft.Azure.Search.DataUserAssignedIdentity",  
    "userAssignedIdentity": "/subscriptions/333333-3333-3333-  
33333333/resourcegroups/myresourcegroup/providers/Microsoft.ManagedIdentity/use  
rAssignedIdentities/demo-mi"  
  }  
}
```

3. Optionally, use a system-assigned managed identity instead. The "identity" is removed from the definition if using system-assigned managed identity.

JSON

```
{
  "name": "{dataSourceName}",
  "description": "description",
  "type": "onelake",
  "credentials": {
    "connectionString": "ResourceId={FabricWorkspaceGuid}"
  },
  "container": {
    "name": "{LakehouseGuid}",
    "query": "{optionalLakehouseFolderOrShortcut}"
  }
}
```

Example:

JSON

```
{
  "name": "mydatasource",
  "description": "description",
  "type": "onelake",
  "credentials": {
    "connectionString": "ResourceId=a0a0a0a0-bbbb-cccc-dddd-e1e1e1e1e1"
  },
  "container": {
    "name": "1111111-1111-1111-1111-111111111111",
    "query": "folder_name"
  }
}
```

Detect deletions via custom metadata

The OneLake files indexer data source definition can include a [soft deletion policy](#) if you want the indexer to delete a search document when the source document is flagged for deletion.

To enable automatic file deletion, use custom metadata to indicate whether a search document should be removed from the index.

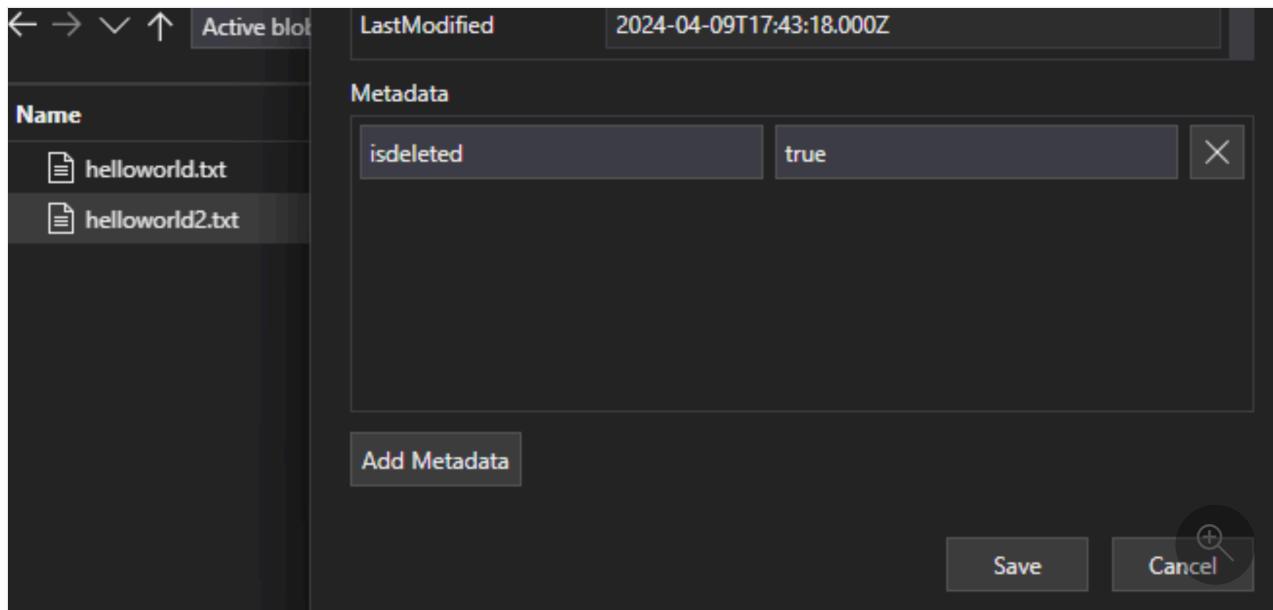

Workflow requires three separate actions:

- "Soft-delete" the file in OneLake
- Indexer deletes the search document in the index
- "Hard delete" the file in OneLake

"Soft-deleting" tells the indexer what to do (delete the search document). If you delete the physical file in OneLake first, there's nothing for the indexer to read and the corresponding search document in the index is orphaned.

There are steps to follow in both OneLake and Azure AI Search, but there are no other feature dependencies.

1. In the lakehouse file, add a custom metadata key-value pair to the file to indicate the file is flagged for deletion. For example, you could name the property "IsDeleted", set to false. When you want to delete the file, change it to true.

2. In Azure AI Search, edit the data source definition to include a "dataDeletionDetectionPolicy" property. For example, the following policy considers a file to be deleted if it has a metadata property "IsDeleted" with the value true:

https

```
PUT https://[service name].search.windows.net/datasources/file-datasource?api-version=2025-09-01
{
    "name" : "onelake-datasource",
    "type" : "onelake",
    "credentials": {
        "connectionString": "ResourceId={FabricWorkspaceGuid}"
    },
    "container": {
        "name": "{LakehouseGuid}",
        "query": "{optionalLakehouseFolderOrShortcut}"
    },
    "dataDeletionDetectionPolicy" : {
        "@odata.type"
        :"#Microsoft.Azure.Search.SoftDeleteColumnDeletionDetectionPolicy",
        "softDeleteColumnName" : "IsDeleted",
        "softDeleteMarkerValue" : "true"
    }
}
```

After the indexer runs and deletes the document from the search index, you can then delete the physical file in the data lake.

Some key points include:

- [Scheduling an indexer run](#) helps automate this process. We recommend schedules for all incremental indexing scenarios.
- If the deletion detection policy wasn't set on the first indexer run, you must [reset the indexer](#) so that it reads the updated configuration.
- Recall that deletion detection isn't supported for Amazon S3 and Google Cloud Storage shortcuts due to the dependency on custom metadata.

Add search fields to an index

In a [search index](#), add fields to accept the content and metadata of your OneLake data lake files.

1. [Create or update an index](#) to define search fields that store file content and metadata:

HTTP

```
{  
    "name" : "my-search-index",  
    "fields": [  
        { "name": "ID", "type": "Edm.String", "key": true, "searchable": false  
    },  
        { "name": "content", "type": "Edm.String", "searchable": true,  
        "filterable": false },  
        { "name": "metadata_storage_name", "type": "Edm.String", "searchable":  
        false, "filterable": true, "sortable": true },  
        { "name": "metadata_storage_size", "type": "Edm.Int64", "searchable":  
        false, "filterable": true, "sortable": true },  
        { "name": "metadata_storage_content_type", "type": "Edm.String",  
        "searchable": false, "filterable": true, "sortable": true }  
    ]  
}
```

2. Create a document key field ("key": true). For file content, the best candidates are metadata properties.

- `metadata_storage_path` (default) full path to the object or file. The key field ("ID" in this example) is populated with values from `metadata_storage_path` because it's the default.

- `metadata_storage_name`, usable only if names are unique. If you want this field as the key, move `"key": true` to this field definition.
- A custom metadata property that you add to your files. This option requires that your file upload process adds that metadata property to all blobs. Since the key is a required property, any files that are missing a value fail to be indexed. If you use a custom metadata property as a key, avoid making changes to that property. Indexers add duplicate documents for the same file if the key property changes.

Metadata properties often include characters, such as `/` and `-`, that are invalid for document keys. Because the indexer has a `"base64EncodeKeys"` property (true by default), it automatically encodes the metadata property, with no configuration or field mapping required.

3. Add a "content" field to store extracted text from each file through the file's "content" property. You aren't required to use this name, but doing so lets you take advantage of implicit field mappings.
4. Add fields for standard metadata properties. The indexer can read custom metadata properties, [standard metadata](#) properties, and [content-specific metadata](#) properties.

Configure and run the OneLake files indexer

Once the index and data source are created, you're ready to create the indexer. Indexer configuration specifies the inputs, parameters, and properties controlling run time behaviors. You can also specify which parts of a blob to index.

1. [Create or update an indexer](#) by giving it a name and referencing the data source and target index:

JSON

```
{
  "name" : "my-onelake-indexer",
  "dataSourceName" : "my-onelake-datasource",
  "targetIndexName" : "my-search-index",
  "parameters": {
    "batchSize": null,
    "maxFailedItems": null,
    "maxFailedItemsPerBatch": null,
    "base64EncodeKeys": null,
    "configuration": {
      "indexedFileNameExtensions" : ".pdf,.docx",
      "excludedFileNameExtensions" : ".png,.jpeg",
      "dataToExtract": "contentAndMetadata",
      "parsingMode": "default"
    }
  }
}
```

```
        }
    },
    "schedule" : { },
    "fieldMappings" : [ ]
}
```

2. Set "batchSize" if the default (10 documents) is either under utilizing or overwhelming available resources. Default batch sizes are data source specific. File indexing sets batch size at 10 documents in recognition of the larger average document size.
3. Under "configuration", control which files are indexed based on file type, or leave unspecified to retrieve all files.

For "indexedFileNameExtensions", provide a comma-separated list of file extensions (with a leading dot). Do the same for "excludedFileNameExtensions" to indicate which extensions should be skipped. If the same extension is in both lists, it's excluded from indexing.

4. Under "configuration", set "dataToExtract" to control which parts of the files are indexed:
 - "contentAndMetadata" is the default. It specifies that all metadata and textual content extracted from the file are indexed.
 - "storageMetadata" specifies that only the [standard file properties and user-specified metadata](#) are indexed. Although the properties are documented for Azure blobs, the file properties are the same for OneLake, except for the SAS related metadata.
 - "allMetadata" specifies that standard file properties and any [metadata for found content types](#) are extracted from the file content and indexed.
5. Under "configuration", set "parsingMode" if files should be mapped to [multiple search documents](#), or if they consist of [plain text](#), [JSON documents](#), or [CSV files](#).
6. [Specify field mappings](#) if there are differences in field name or type, or if you need multiple versions of a source field in the search index.

In file indexing, you can often omit field mappings because the indexer has built-in support for mapping the "content" and metadata properties to similarly named and typed fields in an index. For metadata properties, the indexer automatically replaces hyphens - with underscores in the search index.

For more information about other properties, [Create an indexer](#). For the full list of parameter descriptions, see [Create Indexer \(REST\)](#) in the REST API. The parameters are the same for Microsoft OneLake.

By default, an indexer runs automatically when you create it. You can change this behavior by setting "disabled" to true. If you create an indexer in a disabled state, [run an indexer on demand](#) when you're ready to use it, or [put it on a schedule](#).

Check indexer status

Learn multiple approaches to [monitor the indexer status and execution history here](#).

Handle errors

Errors that commonly occur during indexing include unsupported content types, missing content, or oversized files. By default, the OneLake files indexer stops as soon as it encounters a file with an unsupported content type. However, you might want indexing to proceed even if errors occur, and then debug individual documents later.

Transient errors are common for solutions involving multiple platforms and products. However, if you keep the [indexer on a schedule](#) (for example every 5 minutes), the indexer should be able to recover from those errors in the following run.

There are five indexer properties that control the indexer's response when errors occur.

JSON

```
{  
  "parameters" : {  
    "maxFailedItems" : 10,  
    "maxFailedItemsPerBatch" : 10,  
    "configuration" : {  
      "failOnUnsupportedContentType" : false,  
      "failOnUnprocessableDocument" : false,  
      "indexStorageMetadataOnlyForOversizedDocuments": false  
    }  
  }  
}
```

[] [Expand table](#)

Parameter	Valid values	Description
"maxFailedItems"	-1, null or 0, positive integer	Continue indexing if errors happen at any point of processing, either while parsing blobs or while adding documents to an index. Set these properties to the number of

Parameter	Valid values	Description
		acceptable failures. A value of <code>-1</code> allows processing no matter how many errors occur. Otherwise, the value is a positive integer.
<code>"maxFailedItemsPerBatch"</code>	<code>-1</code> , null or 0, positive integer	Same as above, but used for batch indexing.
<code>"failOnUnsupportedContentType"</code>	true or false	If the indexer is unable to determine the content type, specify whether to continue or fail the job.
<code>"failOnUnprocessableDocument"</code>	true or false	If the indexer is unable to process a document of an otherwise supported content type, specify whether to continue or fail the job.
<code>"indexStorageMetadataOnlyForOversizedDocuments"</code>	true or false	Oversized blobs are treated as errors by default. If you set this parameter to true, the indexer tries to index its metadata even if the content can't be indexed. For limits on blob size, see service Limits .

Next steps

Review how the [Import data \(new\) wizard](#) works and try it out for this indexer. You can use [integrated vectorization](#) to chunk and create embeddings for vector or hybrid search using a default schema.

Index data from SharePoint document libraries

ⓘ Important

SharePoint in Microsoft 365 indexer support is in public preview. It's offered "as-is", under [Supplemental Terms of Use](#) and supported on best effort only. Preview features aren't recommended for production workloads and aren't guaranteed to become generally available.

See [known limitations](#) section before you start.

[Fill out this form](#) to register for the preview. All requests are approved automatically. After you fill out the form, use a [preview REST API](#) to index your content.

This article explains how to configure a [search indexer](#) to index documents stored in SharePoint document libraries for full text search in Azure AI Search. Configuration steps are first, followed by behaviors and scenarios.

In Azure AI Search, an indexer extracts searchable data and metadata from a data source. The SharePoint in Microsoft 365 indexer provides the following functionality:

- Indexes files and metadata from one or more document libraries.
- Indexes incrementally, picking up just the new and changed files and metadata.
- Detects deleted content automatically. Document deletion in the library is picked up on the next indexer run, and the corresponding search document is removed from the index.
- Extracts text and normalized images from indexed documents automatically. Optionally, you can add a [skillset](#) for deeper [AI enrichment](#), such as optical character recognition (OCR) or entity recognition.
- Supports document [basic Access Control Lists \(ACL\) ingestion](#) in public preview during initial document sync. It also supports full data set incremental data sync.
- Supports [Microsoft Purview sensitivity label ingestion and honoring at query time](#). This functionality is in public preview.

Prerequisites

- [Azure AI Search](#), Basic pricing tier or higher.
- [SharePoint in Microsoft 365](#) cloud service (OneDrive isn't a supported data source).
- Files in a [document library](#).
- [Visual Studio Code](#) with the [REST Client extension](#) for setting up and running the indexer pipeline.

Supported document formats

The SharePoint in Microsoft 365 indexer can extract text from the following document formats:

- CSV (see [Indexing CSV blobs](#))
- EML
- EPUB
- GZ
- HTML
- JSON (see [Indexing JSON blobs](#))
- KML (XML for geographic representations)
- Microsoft Office formats: DOCX/DOC/DOCM, XLSX/XLS/XLSM, PPTX/PPT/PPTM, MSG (Outlook emails), XML (both 2003 and 2006 WORD XML)
- Open Document formats: ODT, ODS, ODP
- PDF
- Plain text files (see also [Indexing plain text](#))
- RTF
- XML
- ZIP

Limitations and considerations

Here are the limitations of this feature:

- The indexer can index content from supported document formats in a document library. There's no indexer support for [SharePoint Lists](#), .ASX site content, or OneNote notebook files. Furthermore, indexing sub-sites recursively from a specific site isn't supported.
- Incremental indexing limitations:
 - Renaming a SharePoint folder breaks incremental indexing. A renamed folder is treated as new content.
 - Microsoft 365 processes that update SharePoint file system metadata can trigger incremental indexing, even if there are no other changes to content. Test your setup and check your document processing behaviors in Microsoft 365 platform before using the indexer or any AI enrichment.
- Security limitations:
 - No support for [Private endpoint](#). Secure network configuration must be enabled [via a firewall](#).
 - No support for tenants with [Microsoft Entra ID Conditional Access](#) enabled.
 - User-encrypted files and password-protected ZIP files aren't supported. However, encrypted content is allowed if it's protected by [Purview sensitivity labels](#) and if the [configuration to preserve and honor those labels \(preview\)](#) is enabled.
 - Limited support for document-level access permissions. A basic level of Access Control Lists (ACL) sync is currently in public preview. Review the [SharePoint ACL configuration documentation](#) for details and setup.

① Important

Don't test or enable both [SharePoint ACL ingestion \(preview\)](#) and [preserving and honoring sensitivity labels \(preview\)](#) in the same indexer or index during preview. Use separate indexers / indexes for each feature. Coexistence of both features is not currently supported at this time.

Here are some considerations when using this feature:

- To build a custom Copilot or Retrieval-Augmented Generation (RAG) app that interacts with SharePoint data using Azure AI Search, Microsoft recommends using the [SharePoint \(Remote\) Knowledge Source](#). This knowledge source uses the [Copilot Retrieval API](#) to query textual content directly from SharePoint in Microsoft 365, returning results to the agentic retrieval engine for merging, ranking, and response formulation. There's no search index used by this knowledge source, and only textual content is queried. Azure AI Search doesn't replicate data. It enforces the SharePoint permission model by returning only the results that each user is authorized to see.
- If you need to create a custom Copilot / RAG (Retrieval Augmented Generation) application or AI agent to chat with SharePoint data in production environments, consider first building it directly via [Microsoft Copilot Studio](#).
- If you still need a custom copilot / RAG application or agent indexing data from SharePoint in Azure AI Search in a production environment, despite the recommendation to use Copilot Studio, consider:
 - Creating a custom connector with [SharePoint Webhooks](#), calling [Microsoft Graph API](#) to export the data to an Azure Blob container, and then use the [Azure blob indexer](#) for incremental indexing.
 - Creating your own [Azure Logic Apps workflow](#) using [Azure Logic Apps SharePoint connector](#) and [Azure AI Search connector](#) when reaching General Availability. You can use the workflow generated by the [Azure portal wizard](#) as a starting point and then customize it in the [Azure Logic Apps designer](#) to include the transformation steps you need. The Azure Logic App workflow created when using the [Azure AI Search wizard](#) to index SharePoint in Microsoft 365 data is a [consumption workflow](#). When setting up production workloads, switch to a [standard logic app workflow](#) to use its extra enterprise features.

Regardless of the approach you choose, whether building a custom connector with SharePoint hooks or creating an Azure Logic Apps workflow, be sure to implement robust security measures. These measures include configuring shared private links, setting up firewalls, preserving user permissions from the source and honor those permissions at query time, among others. You should also regularly audit and monitor your pipeline.

Configure the SharePoint in Microsoft 365 indexer

To set up the SharePoint in Microsoft 365 indexer, use a preview REST API. This section provides the steps.

Step 1 (Optional): Enable system assigned managed identity

Enable a [system-assigned managed identity](#) to automatically detect the tenant in which the search service is provisioned.

Perform this step if the SharePoint site is in the same tenant as the search service. Skip this step if the SharePoint site is in a different tenant. The identity is used for tenant detection. You can also skip this step if you want to put the tenant ID in the [connection string](#). If you would like to use

the system-managed identity or configure a user-assigned managed identity for secretless indexing, configure the [application permissions with secretless authentication](#)

After selecting **Save**, you receive an Object ID assigned to your search service.

Step 2: Decide which permissions the indexer requires

The SharePoint in Microsoft 365 indexer supports both [delegated and application](#) permissions. Choose which permissions you want to use based on your scenario.

We recommend app-based permissions. See [limitations](#) for known issues related to delegated permissions.

- Application permissions (recommended), where the indexer runs under the [identity of the SharePoint tenant](#) with access to all sites and files. The indexer requires a [client secret](#). The indexer also requires [tenant admin approval](#) before it can index content. This permission type is the only one that supports basic [ACL preservation \(preview\)](#) configuration. Delegated permissions can't be used for ACL sync.
- Delegated permissions, where the indexer runs under the identity of the user or app sending the request. Data access is limited to the sites and files to which the caller has access. To support delegated permissions, the indexer requires a [device code prompt](#) to sign in on behalf of the user. User-delegated permissions enforce token expiration every 75 minutes, per the most recent security libraries used to implement this authentication type. This isn't a behavior that can be adjusted. An expired token requires manual indexing using [Run Indexer \(preview\)](#). For this reason, you should use app-based permissions instead. This configuration is only recommended for small testing operations, due to token expiration period and since this permission type doesn't support any level of [ACL preservation](#) configuration.

Step 3: Create a Microsoft Entra application registration

The SharePoint in Microsoft 365 indexer uses a Microsoft Entra application for authentication. Create the application registration in the same tenant as Azure AI Search.

- Sign in to the [Azure portal](#).
- Search for or navigate to **Microsoft Entra ID**, then select **Add > App registrations**.
- Select + New registration:
 - Provide a name for your app.
 - Select **Single tenant**.
 - Skip the URI designation step. No redirect URI required.
 - Select **Register**.
- On the navigation pane under **Manage**, select **API permissions**, then **Add a permission**, then **Microsoft Graph**.
 - If your indexer uses application API permissions, choose **Application** permissions.
 - For standard indexing, select: `Files.Read.All` `Sites.Read.All`
 - If you're enabling content indexing and [basic ACL sync \(preview\)](#), select: `Files.Read.All` `Sites.FullControl.All` (instead of `Sites.Read.All`)
 - If you need to enable content indexing and limit [ACL sync \(preview\)](#) to specific sites, select: `Files.Read.All` `Sites.Selected` Then grant the application full control only for those selected sites.

Using application permissions means that the indexer accesses the SharePoint site in a service context. So when you run the indexer, it has access to all content in the SharePoint tenant, which requires tenant admin approval. A client secret or secretless configuration is also required for authentication. Setting up the authentication mechanism is described later in this article under [authentication modes for application API permissions only](#).

- If the indexer is using delegated API permissions, select **Delegated permissions** and then select `Delegated - Files.Read.All`, `Delegated - Sites.Read.All`, and `Delegated - User.Read`.

Add a permission				
API / Permissions name	Type	Description	Admin consent req...	Status
Microsoft Graph (3)				
Files.Read.All	Delegated	Read all files that user can access	-	...
Sites.Read.All	Delegated	Read items in all site collections	-	...
User.Read	Delegated	Sign in and read user profile	-	...

Delegated permissions allow the search client to connect to SharePoint under the security identity of the current user.

5. Give admin consent.

Tenant admin consent is required when using application API permissions. Some tenants are locked down in such a way that tenant admin consent is required for delegated API permissions as well. If either of these conditions apply, you'll need to have a tenant admin grant consent for this Microsoft Entra application before creating the indexer.

6. Select the Authentication tab.

7. Set Allow public client flows to Yes then select Save.

8. Select + Add a platform, then Mobile and desktop applications, then check

<https://login.microsoftonline.com/common/oauth2/nativeclient>, then **Configure**.

9. Configure the indexer **authentication method** according to your solution needs.

Available authentication methods for application API permissions only

To authenticate the Microsoft Entra application with application permissions, the indexer uses either a client secret or a secretless configuration.

Using client secret

These are the instructions to configure the application to use a client secret to authenticate the indexer, so it can ingest data from SharePoint.

- Select Certificates & Secrets from the menu on the left, then Client secrets, then New client secret.

- In the menu that pops up, enter a description for the new client secret. Adjust the expiration date if necessary. If the secret expires, it needs to be recreated and the indexer needs to be updated with the new secret.

Add a client secret

Description	SharePoint Online Indexer
Expires	Recommended: 6 months
<input type="button" value="Add"/> <input type="button" value="Cancel"/>	

- The new client secret appears in the secret list. Once you navigate away from the page, the secret is no longer be visible, so copy the value using the copy button and save it in a secure location.

Using secretless authentication to obtain application tokens

These are the instructions to configure the application so Microsoft Entra trusts a managed identity to obtain an application token to authenticate without a client secret, so the indexer can ingest data from SharePoint.

Configuring the registered application with a managed identity

1. Create (or select) a [user-assigned managed identity](#) and assign to your search service or a [system-assigned managed identity](#), depending on your scenario requirements.
2. Capture the **object (principal)** ID. This will be used as part of the credentials configuration when creating the data source.
3. Select **Certificates & Secrets** from the menu on the left.
4. Under **Federated credentials** select + **Add a credential**.
5. Under **Federated credential scenario** select **Managed Identity**.
6. Select managed identity: Choose the created managed identity created as part of step 1.
7. Add a name for your credential and click on **Save**.

Step 4: Create data source

Starting in this section, use the latest preview REST API and a REST client or the latest supported beta SDK of your preference for the remaining steps.

A data source specifies which data to index, credentials, and policies to efficiently identify changes in the data (new, modified, or deleted rows). Multiple indexers in the same search service can use the same data source.

For SharePoint indexing, the data source must have the following required properties:

- **name** is the unique name of the data source within your search service.
- **type** must be "sharepoint". This value is case-sensitive.
- **credentials** provide the SharePoint endpoint and the authentication method allowed for the application to request the Microsoft Entra tokens. An example SharePoint endpoint is <https://microsoft.sharepoint.com/teams/MySharePointSite>. You can get the endpoint by navigating to the home page of your SharePoint site and copying the URL from the browser. Review the [connection string format](#) for the supported syntax.
- **container** specifies which document library to index. Properties [control which documents are indexed](#).

To create a data source, call [Create Data Source \(preview\)](#).

Here's a data source definition sample for credentials with application secret or service-assigned managed identity.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sharepoint-datasource",
    "type" : "sharepoint",
    "credentials" : { "connectionString" : "[connection-string]" },
    "container" : { "name" : "defaultSiteLibrary", "query" : null }
}
```

Here's a data source definition sample for credentials with user-assigned managed identity.

HTTP

```
POST https://[service name].search.windows.net/datasources?api-version=2025-11-01-preview
Content-Type: application/json
api-key: [admin key]

{
    "name" : "sharepoint-datasource",
    "type" : "sharepoint",
    "credentials" : { "connectionString" : "[connection-string]" },
    "container" : { "name" : "defaultSiteLibrary", "query" : null },
    "identity": {
        "@odata.type": "#Microsoft.Azure.Search.DataUserAssignedIdentity",
        "userAssignedIdentity": "/subscriptions/[Azure Subscription ID]/resourceGroups/[resource-group]/providers/Microsoft.ManagedIdentity/userAssignedIdentities/[user-assigned managed identity]"
    }
}
```

Connection string format

The format of the connection string changes based on whether the indexer is using delegated API permissions or application API permissions.

- Delegated API permissions connection string format

```
SharePointOnlineEndpoint=[SharePoint site url];ApplicationId=[Azure AD App ID];TenantId=[SharePoint site tenant id]
```

- Application API permissions with application secret connection string format

```
SharePointOnlineEndpoint=[SharePoint site url];ApplicationId=[Azure AD App ID];ApplicationSecret=[Azure AD App client secret];TenantId=[SharePoint site tenant id]
```

- Application API permissions with secretless (system-assigned managed identity) connection string format

```
SharePointOnlineEndpoint=[SharePoint site url];ApplicationId=[Azure AD App ID];FederatedCredentialObjectId=[selected managed identity object (principal) ID];TenantId=[SharePoint site tenant id]
```

You can get `TenantId` from the overview page in the Microsoft Entra admin center in your Microsoft 365 subscription. You can get the managed identity `object (principal) ID` from the section [Configuring the registered application with a managed identity](#)

① Note

If the SharePoint site is in the same tenant as the search service and system-assigned managed identity is enabled, `TenantId` doesn't have to be included in the connection string. If the SharePoint site is in a different tenant from the search service, `TenantId` must be included.

If your indexer uses [SharePoint ACL configuration \(preview\)](#) or [preserves and honors Microsoft Purview sensitivity labels \(preview\)](#), review the related articles for data source setup before creating the indexer. Each feature has specific configuration steps.

Step 5: Create an index

The index specifies the fields in a document, attributes, and other constructs that shape the search experience.
